Voles in a healthy state have a shiny coat and are vigorous. Ill animals are often hunched with fluffed-up, dull fur. It is essential that any animals showing signs of illness be examined and either treated or euthanased promptly. The abdomen of adult voles may occasionally become greatly enlarged without any matching increase in body weight, so that the females in such cases are clearly not pregnant. Such animals should be culled. *Post-mortem* examination will reveal that the small intestine is grossly distended with gas, or that the caecum is greatly engorged with digesta.

Wild voles can carry a number of ectoparasites, including fleas, ticks and mites, the human ringworm fungus, endoparasitic protozoa (including *Toxoplasma*), trematodes, cestodes and nematodes, as well as *Mycobacterium tuberculosis* and the spirochaete *Leptospira*. Tuberculosis can be endemic in wild populations of voles, and infected animals may have extensive caseous areas in subcutaneous tissue, lungs and elsewhere in the body. Antibody reacting with orthopoxvirus (cowpox virus) has been detected in both field and bank voles from the wild and both species are susceptible to a number of other viruses, including spontaneous mouse encephalomyelitis and encephalomyocarditis and various

hantaviruses (Kaplan *et al.* 1980; Flowerdew *et al.* 1985; Bennett *et al.* 1997; Barnard *et al.* 2002; Harris & Yalden 2008). The latter group is responsible for important rural and sometimes urban public health problems throughout some parts of Europe and Asia (for example, Korean haemorrhagic fever, nephropathia epidemica). The infective agent(s) can occur in urban and laboratory rodents from which people have apparently become infected. The mite *Laelaps hilaris* Koch is often found in small numbers in the perineal region of field voles, feeding on host body secretion, and apparently causing little harm. Bank voles are hosts for the sheep tick (*Ixodes ricinus*) which transmits the spirochaete *Borrelia burgdorferi* responsible for Lyme disease (Randolph & Craine 1995). Infection can have arthritic, cardiac and neurological consequences for people. Bank voles are also competent hosts for the protozoan *Babesia microti* which can cause illness in people. This protozoan is transmitted by the ectoparasitic tick *Ixodes trianguliceps* (Randolph 1995).

When wild voles are brought into the laboratory for outcrossing of the breeding stock or for experimental purposes, a protocol for quarantine, screening and, where appropriate, treatment, for any parasitic or other infectious agents should be carefully devised and implemented. In order to guard against infection of laboratory workers, colonies of wild voles should be kept well separated from breeding colonies of the same or other laboratory rodent species.

## Behaviour and welfare

### Aggressive Interactions

Sexually mature male voles from laboratory stock are often very aggressive towards each other. This has been seen in groups of male voles housed in laboratory cages (Sorensen & Randrup 1986) as well as larger more naturalistic enclosures with high stocking densities (Clarke 1955, 1956). Sexually mature males may fight viciously if they are put together and fighting can also occur amongst sexually mature males which have cohabited since weaning (whether from the same or different litters). In cages with high levels of aggressive encounters the problem can be moderated by identifying and removing the principle aggressor(s). It may be possible to identify such individuals from size and muscle tone and also from bite marks. They will tend to be larger animals with a muscular feel when handled due to little subcutaneous or abdominal fat. They may have small wounds on the nose inflicted by the defensive actions of subordinate voles. The latter, in contrast tend to have wounds anywhere on the body but especially on the hind-quarters, incurred as they flee from the aggressor. Alternatively, given the risk of aggressive encounters in group-housed males and the potential for harm, avoid group housing males in stock cages. Females do not tend to have serious aggressive interactions, except perhaps when they are pregnant or lactating, so group housing is less problematic with female voles.

### Social isolation and distress

The prairie vole has been used to investigate the effects of social isolation on stress physiology (Kim & Kirkpatrick

1996). Under laboratory conditions, pairs of prairie voles develop close relationships, spending much of their time sitting side by side (Insel & Shapiro 1992; Insel 1997). This contrasts markedly with the closely related, but polygamous, montane vole (*Microtus montanus*), as well as the meadow, field and bank voles described earlier, which generally avoid contact with conspecifics in both laboratory and natural conditions except when mating. Housing adult female prairie voles in isolation causes chronic distress and has been described as leading to anxiety and depression, and consequently has been used as a model for these responses in man. Isolation leads to elevated serum corticosteroid and reduced body weight, whilst behavioural consequences of isolation include anhedonia as measured by decreased sucrose intake, a decline in swimming in a forced swimming task, which are used as measures of depression, and also reduced time in open arms of raised plus maze (Grippio 2009) which has been developed as a measure of anxiety. This extreme response to social isolation indicates the importance of maintaining prairie voles in stable pairs in breeding colonies both in terms of their welfare and in terms of successful breeding programmes.

### Stereotypic behaviour

Stereotypic behaviour can be reliably induced in voles and consequently they have been used as a model species to investigate the causes and effects of repetitive, invariant apparently functionless activities. These behaviours, especially the sustained gnawing of the wire mesh of cages, as well as some weaving, jumping and somersaulting (Sorensen & Randrup 1986), have been found in field voles, but are more commonly observed in bank voles (Ödberg 1987), where they can lead to injuries such as broken tails and facial lesions due to repeated collision with cage features.

Voles readily develop stereotypies in standard laboratory conditions without the use of drug treatments. In addition, vole stereotypy can be varied by manipulation of dopamine activity, in a similar way to rat and mouse stereotypy, with dopamine antagonists blocking the performance of stereotypies, and agonists increasing their occurrence (Randrup *et al.* 1988). Stereotypic behaviour can be manipulated in bank voles by simple changes to cage conditions, for example by increasing cage size or more effectively by providing cover in the form of hay or straw (Ödberg 1987; Cooper *et al.* 1996). For example, rearing voles in 33 cm × 15 cm × 13 cm cages with sawdust litter and no bedding leads to an incidence of locomotor stereotypic behaviour approaching 100%; whereas providing a handful of bedding (eg, hay) results in only 50% of the population exhibiting the behaviour. The use of larger cages (eg, 45 cm × 28 cm × 13 cm) with ample bedding, nesting and/or sheltering substrates results in a very low incidence of stereotypic behaviour (Cooper *et al.* 1996).

The motivation underlying the performance of stereotypies in voles appears to be persistence of locomotor behaviour, possibly related to motivation to escape from the cage. Stereotypies can be initiated by an alarming stimulus (for example running a pen along the cage bars), and providing extensive shelter appears to be the most effective means of reducing the behaviour. Fine detailed observation of

responses and the development of the behaviour, suggests those voles which show the highest amount of locomotor behaviour following disturbance in the absence of cover are most likely to develop stereotypies, suggesting a development from this active response. Finally, whilst environmental enrichment such as housing voles in larger cages with more shelter can prevent the performance of stereotypies, this is less effective for older voles (Cooper *et al.* 1996). It is therefore recommended that to minimise stereotypic activities, voles should be housed from weaning in large cages provided with both shelter and nesting material.

## The guinea pig

Sylvia Kaiser, Christine Krüger and Norbert Sachser

### Biological overview

The guinea pig (*Cavia aperea* f. *porcellus*) was domesticated about 3000–6000 years ago in the highlands of South America (Hückinghaus 1961; Gade 1967; Hyams 1972; Wing 1977; Herre & Röhrs 1990; Benecke 1994). The main aim of domestication was to provide the Indians with meat (Herre & Röhrs 1990) and guinea pigs are still one of the main sources of meat in some rural populations of South America. They have also, occasionally, been used for ritual healing (Gade 1967; Hyams 1972; Weir 1974; Wing 1977; Clutton-Brock 1989; Herre & Röhrs 1990; Benecke 1994). Guinea pigs in South America today are left to scavenge in and around the huts of the Indians, and it may be assumed that a similar husbandry has always existed (Weir 1974; Stahnke & Hendrichs 1988). In the middle of the 16th century the Spaniards discovered guinea pigs and introduced them into Europe. Within the European population, the animals rapidly became a popular pet (Gade 1967; Hyams 1972; Clutton-Brock 1989; Benecke 1994). Nowadays, guinea pigs are one of the most popular pets throughout the world, raised for fancy and companion uses.

### The wild ancestor *Cavia aperea*

According to anatomical and morphological studies the domestic guinea pig derives from the subspecies *tschudii* of the wild cavy (*Cavia aperea*), which is among the most common and widespread rodents of South America (Nehring 1889; Hückinghaus 1961; Gade 1967; Rood 1972; Weir 1972; Nachtsheim & Stengel 1977; Herre & Röhrs 1990; Benecke 1994; Künzl & Sachser 1999). The wild cavy and the domestic guinea pig belong to the order Rodentia and to the family Caviidae (Figure 27.1). All cavy-like members of this family (about 14 species; Wilson & Reeder 2005) are medium-sized, tailless rodents that have four digits on the front feet and three digits on the hindfeet. All digits have claws. All forms – except the domestic guinea pig – have agouti dorsal pelage and a lighter underside (Rood 1972; Wagner 1976). The cavy-like members of the Caviidae are divided into four genera (*Cavia*, *Galea*, *Kerodon* and *Microcavia*), which are widely distributed throughout South America and inhabit a wide range of ecological niches (Mares & Ojeda 1982; Redford & Eisenberg 1992; Eisenberg & Redford 1999).

The wild cavy is a herbivorous, neotropical rodent that occurs in humid grassland habitats from Colombia through Brazil into Argentina (Mares & Ojeda 1982; Stahnke & Hendrichs 1988; Redford & Eisenberg 1992).

They live in small harem groups consisting of one adult male and one or a few females and their unweaned offspring (Rood 1972; Sachser *et al.* 1999; Asher *et al.* 2004, 2008). *C. aperea* is a crepuscular, non-climbing species, which does not dig burrows, but hides and moves through tunnels made in dense vegetation (Rood 1972; Stahnke & Hendrichs 1988; Guichón & Cassini 1998). The typical habitat of *C. aperea* contains a cover zone with high and dense vegetation, which the animals use as protection from predator attacks (Rood 1972), and an adjacent, more open zone of short vegetation where cavy forage (Cassini 1991; Cassini & Galante 1992; Guichón & Cassini 1998; Asher *et al.* 2008). *C. aperea* is a species difficult to study in the field as most social activities occur in tall vegetation (Rood 1972; Asher *et al.* 2004, 2008).

Under semi-natural and laboratory conditions adult male *C. aperea* are highly incompatible in the presence of females, whereas female *C. aperea* organise themselves into linear dominance hierarchies. The males' body mass is 11% higher than the body mass of non-pregnant females. The male–male competition brings about a polygynous mating system (Sachser *et al.* 1999). Whenever a female comes into oestrus, only one male is present. This male thus mates with several females, whereas every female mates with a single male (Sachser 1998). Females play an active role in bringing about this species' social and mating system by displaying clear preferences for single males (Adrian *et al.* 2008). Moreover, the low relative testis weights and the small epididymis size of *Cavia aperea* are within the typical range of species with a single-male mating system (Kenagy & Trombulak 1986; Sachser 1998; Sachser *et al.* 1999; Cooper *et al.* 2000).

### Behavioural and physiological consequences of domestication

As described above, the domestic guinea pigs derived from the wild cavy at least 3000 years ago. The process of domestication is always accompanied by distinct changes in morphology, physiology and behaviour (Darwin 1859, 1868; Hale 1969; Fox 1978; Haase & Donham 1980; Price 1984; Clutton-Brock 1989; Herre & Röhrs 1990; Künzl & Sachser 1999). As a consequence, wild and domestic animals require

**Figure 27.1** The wild cavy (*Cavia aperea*; left) and the domestic guinea pig (*Cavia aperea f. porcellus*, right). (Photo: M. Aulbur.)

somewhat different conditions and resources to achieve good welfare although, in a biological sense, they still belong to the same species (Sachser 2001).

Behavioural studies indicate that the repertoire of behavioural patterns is similar in domesticated and wild guinea pigs. Thus, domestication has not resulted in the loss or addition of behavioural elements (Rood 1972; Stahnke 1987; Künzl & Sachser 1999). Distinct differences have, however, developed in behavioural frequencies and thresholds (Künzl & Sachser 1999) (Table 27.1). Domestic guinea pigs display lower levels of intraspecific aggressive behaviour and higher levels of sociopositive behaviour (eg, social grooming) than the wild ancestors. They also show more frequent overt courtship behaviour and have a lower threshold for vocalisation. Finally, guinea pigs are less attentive to their physical environment and show much less exploration behaviour than their ancestors (Künzl & Sachser 1999; Künzl *et al.* 2003).

These behavioural differences are associated with marked changes in social structure compared with the wild form. When domestic guinea pigs are kept in breeding groups of one adult male and several adult females, the mature sons and daughters will integrate rather peacefully into the social system of the groups and all animals will cohabitate in a non-aggressive and non-stressful way (Sachser 1998). When adult wild cavies are kept in breeding groups of one male and several females, a completely different picture emerges: the daughters integrate into the linear dominance hierarchy of the females. In contrast, the father and his sons often become incompatible when the sons attain sexual maturity. In most cases, the sons must then be taken out of the groups, otherwise the father will injure or kill them (Sachser 1998).

Artificial selection and breeding in guinea pigs has not, however, led to degenerated animals with impaired cognitive abilities. Male and female domestic guinea pigs perform better in the Morris Water Maze (a frequently used test for the assessment of spatial learning in rodents) than their wild relatives (unpublished data of SK).

A series of experiments has been conducted to compare endocrine stress responses between wild and domestic guinea pigs (Table 27.1). Wild cavies respond with a significantly stronger increase of their serum cortisol concentra-

**Table 27.1** Physiological and behavioural consequences of domestication: comparison between domestic (*Cavia aperea f. porcellus*) and wild guinea pigs (*Cavia aperea*) (– rare/low; + frequent/high). For references and original data see Künzl and Sachser (1999), Künzl *et al.* (2003) and Sachser (2001).

		Domestic	Wild

tions to environmental challenge than domestic guinea pigs. Furthermore, immediately after removing animals from their home cages catecholamine concentrations are distinctly higher in the wild than in the domesticated form. In addition, significantly lower cortisol levels in response to an adrenocorticotrophic hormone (ACTH) challenge indicate that there is a generalised reduction in the stress response of the domestic guinea pig (Künzl & Sachser 1999; Künzl *et al.* 2003), and this is the physiological correlate of the reduced alertness, nervousness and sensitivity of the domesticated animals. While the reduced stress response obviously helps domestic animals to live in artificial housing conditions, it would be counter-selected for by natural selection in wild animals in their natural habitats (Künzl & Sachser 1999).

## General biology

Newborn guinea pigs (body mass of about 60–100 g) are precocial, looking like small-sized adults (Table 27.2). They are fully furred, their eyes are open and the secondary teeth have already replaced the primary teeth during foetal development. On the day of birth young guinea pigs start to eat solid food and drink water, although lactation lasts for 2–3 weeks. Young males reach their sexual maturity within 2–3 months of age (body mass about 500 g), while young females may reach sexual maturity at less than 1 month of age (with a body mass of around 300 g) (Table 27.3).

Guinea pigs are fully grown at the age of 8–12 months. They live up to an age of 8 years and reach a body mass of about 800 to more than 1000 g, which is distinctly higher than in the wild form. Adult guinea pigs measure up to 30 cm in length (Sutherland & Festing 1987).

All teeth are open rooted and grow continuously throughout life. The dental formula of the guinea pig is as follows:  $I_1^1C_0^0Pm_1^1M_3^3$ .

Wild cavies have an agouti dorsal pelage and a lighter underside (see above), but in the domestic guinea pig there is a wide variety of colours. The coat can be unicoloured or multicoloured. The most popular breed of guinea pigs in scientific research is the short-haired English, and the most common strain is the Dunkin–Hartley (albino outbred guinea pig of the English breed). Several inbred guinea pig strains have been produced, of which strains 2 and 13 are

Parameter	Normal value
Lifespan (years)	2–8
Birth weight (g)	60–100
Adult weight (g)	700–1300
Food consumption (g/100g body weight per day)	6
Water consumption (ml/100g body weight per day)	10–14.5
Rectal temperature (°C)	37.2–39.8
Heart rate (beats/minute)	150–400
Blood pressure (mmHg)	
Systolic	77–94
Diastolic	47–58
Respiratory rate (breaths/minute)	42–150
Tidal volume (ml)	1.0–5.3
Total blood volume (ml/kg)	69–75
Dental formula	$I^1_1C^0_0Pm^1_1M^3_3$

**Table 27.3** Reproductive data for the guinea pig.

Reproductive parameter	Normal value
Sexual maturity	
Female	~1 month of age
Male	2–3 months of age
Oestrous cycle	Polyoestrus, ~16 days
Gestation period	63–72 days
Lactation	~21 days
Litter size	1–7

the most widely used (North 1999). If not bred on-site in the facility, animals are obtained from commercial breeders.

Female guinea pigs exhibit a post-partum oestrus which means they become receptive immediately after giving birth. If they do not become pregnant at this time, females show periodic oestrous cycles of about 16 days (Shi *et al.* 1999). It is well known that female guinea pigs have some behavioural changes during their oestrous cycle (Birke 1981). The young are born after a gestation period of around 67 days. Usually one to four (up to a maximum of seven) young are born in one litter (Table 27.3) (Sutherland & Festing 1987; Sachser 1994a).

Guinea pigs do not show a day–night cycle of activity. Rather, they are characterised by an ultradian rhythm, that is, alternating phases of activity and rest last for about 2–3 h. Thus, the activity is not dependent on the light–dark regime (Sachser *et al.* 1992).

Guinea pigs have dichromatic colour vision with a spectral neutral point centred at about 480 nm (Jacobs & Deegan 1994). However, guinea pigs may have poor depth perception. Guinea pigs possess two different classes of retinal cones with peak sensitivities of about 429 nm and 529 nm.

The maximum auditory sensitivity is around 500 and 8000 Hz. However, guinea pigs are responsive to frequen-

cies of 125–32 000 Hertz (Harper 1976). The upper limit of their hearing is probably 40 000–50 000 Hz.

The olfactory sense is most important in social behaviour (Beauchamp *et al.* 1979, 1980, 1982; Martin & Beauchamp 1982). Male guinea pigs mark individual females with their anal glands. Guinea pigs also mark the environment with their anal glands. Urine has a high communicative value for this species. Young guinea pigs, for example, discriminate between maternal urine and urine of an unknown lactating female (Jäckel & Trillmich 2003).

## Uses in the laboratory

The guinea pig is commonly used in scientific research, in areas such as toxicology, product development and medical quality control.

## Laboratory management and breeding

### Social life and welfare: basic research

There is a long tradition of basic research concerning the social structure and sociophysiology of guinea pigs (Kunkel & Kunkel 1964; Rood 1972; Beauchamp 1973; Berryman & Fullerton 1976; Jacobs 1976; Sachser 1986; Sachser 1994a, 1994b; Kaiser *et al.* 2003a; Hennessy & Morris 2005; Hennessy *et al.* 2006; Wallner *et al.* 2006; Bauer *et al.* 2008; Fey & Trillmich 2008). From this research, conclusions can be drawn regarding which social housing conditions can be recommended and which conditions should be avoided.

### Social organisation

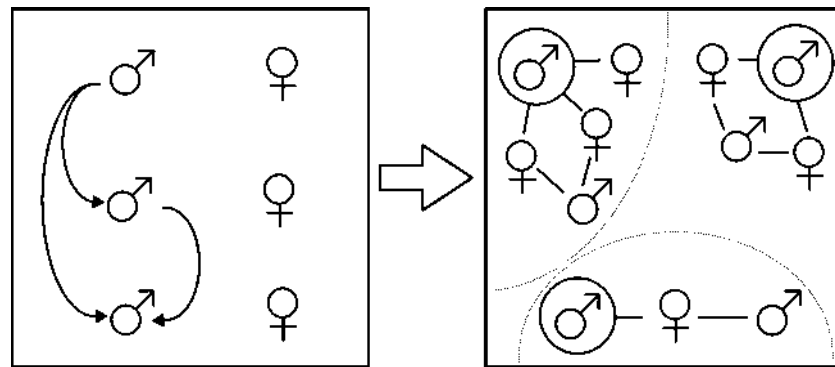

As for other species, the social interactions of guinea pigs are composed of agonistic behaviours and the development of dominance hierarchies, together with positive or sexual interactions, which may result in the establishment of social bonds. The overall structure of dominance relationships and social bonds constitute the animals' social organisation.

#### Low and high population density

The effects of increasing population density on the patterns of social interactions and reproductive success have been studied by Sachser (1986; 1994b). Four males and two females were placed in a 16 m<sup>2</sup> enclosure and allowed to reproduce freely, so that after 20 months there were about 50 individuals in the colony. Even at this high population density the reproductive success of females (that is, the number of surviving offspring/time) did not decline, and the number of fights between individuals did not increase distinctly. So what mechanisms allow guinea pigs to cope so effectively with high population numbers? The answer is shown in Figure 27.2. As population density increases, guinea pigs change their patterns of social interactions and their social relationships, that is, their social organisation (Sachser 1986).

At low population densities (for example, three males and three females) the social organisation is characterised mainly by a linear dominance hierarchy among the adult males.

**Figure 27.2** Social organisation in guinea pigs at high and low densities. Low density at the left side: arrows among males indicate direction of aggressive behaviours. High density at the right side: lines between males and females indicate individual social bonds. Alpha-males (circled males) dominate non-alpha males (non-circled males). Dotted lines represent the borders of 'territories' (Sachser 1986). Reproduced from Sachser N (1998): *Of domestic and wild guinea pigs: studies in sociophysiology, domestication and social evolution*, Naturwissenschaft, copyright 1998 with kind permission of Springer Science and Business Media.

Subordinate males retreat whenever a higher-ranking conspecific approaches; this largely precludes threat displays and fights. Individuals of identical rank are never found. The highest-ranking male shows much more courtship behaviour towards each of the females than any other male, and he is probably the father of the offspring. Social bonds do not exist between males and females. Among the females there is also a linear rank order (Thyen & Hendrichs 1990). However, their agonistic interactions are less pronounced than those among males. Between the sexes fighting and threat displays do not occur.

When individual numbers increase, guinea pigs change their social organisation. Groups of 10–15 or more split into subunits, each consisting of one to four males and one to seven females. The highest-ranking male of each subunit, the alpha-male, establishes long-lasting social bonds toward all females of his subunit. The alphas guard and defend their females around oestrus, and they sire more than 85% of offspring, as shown by DNA fingerprinting (Sachser 1998). The lower-ranking males also have bonds with the females of their subunits, ie, they interact predominantly with these animals. Alphas of different subunits respect each other's bonds, that is, they do not court other alphas' females even if these are receptive. In general, individuals belonging to a given subunit live in an area that does not overlap with the area of other subunits. It is in these areas that most of the social interactions are displayed, and where the individuals have their resting and sleeping places. The alphas defend the borders of these areas around the time of their females' oestrus (Sachser 1986, 1994b).

Social organisation at high population densities is therefore characterised by the following: (1) the splitting of the whole group into subunits provides all individuals with social and spatial orientation; (2) escalated fighting is rare because alphas respect the male–female bonds of other alphas; (3) the individuals' different social positions are stable over months, and the basic patterns of social organisation are independent of individual animals. Thus the change in social organisation from a strictly dominance-structured system to a system in which long-lasting bonds are predominant seems to be a mechanism for adjusting to increasing population density.

#### *Physiological consequences of social stratification*

When male guinea pigs living at different population densities are compared, those at high densities show increased

activity of the sympathetic–adrenomedullary system at high densities. In contrast, the activity of the pituitary–adrenocortical system is not affected by population density. That is, a male living in a large colony does not have higher cortisol concentrations than a male living in a small group or with only one female. These endocrinological data support the behavioural findings that a change in density does not necessarily result in increased social stress for the individuals as long as a stable social environment is maintained by social mechanisms (Sachser 1990, 1994a).

At high and low population densities, males take different social positions, which are stable over months. Alphas, for example, always clearly dominate non-alphas of the same subunit. These dominance relationships are independent of place and time. Alphas bite more often and are bitten less often than non-alphas, and display far more courtship and sexual behaviour than the lower-ranking males (Sachser 1990). Surprisingly, despite these clear differences in behaviour and status, alphas and non-alphas do not differ significantly in their activity of their pituitary–adrenocortical and sympathetic–adrenomedullary systems (Sachser 1987, 1994b; Sachser *et al.* 1998); that is, having low social status does not necessarily entail a higher degree of social stress than having high social status. This is probably because of the stable social relationships which result in predictable behaviour.

#### **Social support**

In a variety of animals, the presence of specific social partners can often inhibit or ameliorate the individual's neuroendocrine responses in stressful situations; ie, the increase of the pituitary–adrenocortical and the sympathetic–adrenomedullary activities is reduced (Sachser *et al.* 1998; Kawachi & Berkman 2001). This class of effects, often referred to as social buffering of the stress response, is clearly seen in the context of the mother–infant relationship. The domestic guinea pig is one of the few animals in which social buffering effects on HPA activity have been found in both infants and adults.

Prior to weaning, guinea pig pups show evidence of a specific attachment to their mother, and the presence of the mother reduces or eliminates HPA responses in a novel environment (Hennessy & Ritchey 1987; Hennessy 1997, 1999; Hennessy *et al.* 2006). During the pre-weaning period the presence of other animals, particularly adult females,

has also been found to reduce HPA activity in pups, but not as consistently as the presence of the mother (Hennessy & Ritchey 1987; Ritchey & Hennessy 1987; Sachser *et al.* 1998; Graves & Hennessy 2000; Hennessy *et al.* 2002a, 2002b). The spatial environment also seems to influence the neuroendocrine and behavioural responses of guinea pig pups to a threatening situation. For example, the pups express more distress calls in an unfamiliar than in a familiar environment irrespective of whether their mothers are present or absent (Pettijohn 1979). Furthermore, cortisol concentrations in infant guinea pigs do not increase after separation from their mother when they stay in their familiar enclosure together with familiar group members (Wewers *et al.* 2003).

Among adults, males and females form attachment-like bonds with opposite-sex partners (see earlier in this chapter) (Jacobs 1976; Sachser 1986). As regards interactions with an individual colony-living male, females can be placed in three categories: (1) his bonded females with whom most amicable interactions take place; (2) females which live in the same colony, and with whom he is familiar but has no social ties; and (3) unfamiliar females which live in a different colony, and which he has never encountered before. Interestingly, the male's endocrine stress response – ie, increase in activity of his pituitary–adrenocortical system – when placed in an unfamiliar cage is sharply reduced when a female with which he is bonded is present. In contrast, the presence of an unfamiliar female or of one with whom he is merely acquainted has little effect. Thus, the effect of various types of relationships differs remarkably, and substantial social support is given only by the bonded partner (Sachser *et al.* 1998; Hennessy *et al.* 2006).

The presence of the bonded partner also leads to a sharp reduction in the acute stress response in female guinea pigs living in large mixed-sex colonies. Thus, in guinea pigs, there is a two-way provision of social support between male and female bonded pairs. However, female guinea pigs show a different reaction to males in the presence of a familiar conspecific, who is not the bonded partner. In this case their stress response is lower than in the absence of a familiar conspecific. Thus, a familiar social partner can provide social support for females but not for males (Kaiser *et al.* 2003a).

#### Effects of social experiences on physiology and behaviour

Guinea pigs can co-exist in a non-stressful and non-aggressive way even at high densities. This can be attributed to three factors: (1) a greater tolerance toward conspecifics, which has been acquired during the process of domestication (see earlier in this chapter); (2) the ability to establish and to respect dominance relationships; (3) the ability to establish and to respect social bonds. However, whether these features are expressed depends on the social conditions under which the individuals were reared.

When two adult males reared in different large colonies are placed into an unfamiliar enclosure in the presence of an unfamiliar female they quickly establish stable dominance relationships without displaying overt aggression. No significant changes in pituitary–adrenocortical system or sympathetic–adrenomedullary system activities are found, either in the dominant or in the subdominant male (Sachser

& Lick 1991). However, this 'peaceful' stratification into different social positions requires that the opponents, around puberty, have previously had agonistic interactions with older dominant males, which is the case in individuals reared in colonies. In these encounters as a subdominant individual, they acquire the social skills needed to adapt to conspecifics in a non-aggressive and non-stressful way (Sachser & Lick 1991; Sachser 1993; Sachser *et al.* 1994).

In contrast, a male that has grown up singly or with a female does not experience agonistic interactions around puberty (since in this species no fighting and threat displays are found between the sexes) and thus does not learn these social skills. If two of these males confront one another in the presence of an unfamiliar female in an unfamiliar enclosure, high levels of aggressive behaviour occur, and escalated fighting is frequent which, if not stopped, may lead to severe injuries or deaths. During the first days of the confrontation no stable dominance relationships are established but once this has occurred marked and persistent increases in pituitary–adrenocortical system activities occur in the subdominant males (Sachser & Lick 1991; Sachser *et al.* 1994). The evidence is that it is not fighting ability that determines the outcome of such contests, but that the winners are the males that succeed in establishing a bond toward the female.

The crucial role of social experiences has also been shown in a study taking a different approach (Sachser & Renninger 1993). Colony-reared males introduced singly into unfamiliar colonies of conspecifics easily adjust to this new social situation. They explore the new environment, but do not court any female, thereby avoiding attacks from the male residents, which have established bonds with the females. The colony-reared males gradually integrate into the social network of the established colonies and may even gain a higher social rank than they had in their native colonies. In contrast, individually reared males placed into a colony of conspecifics are frequently involved in threat displays and fights (Sachser & Lick 1991; Sachser & Renninger 1993) and may lose body weight and die, even when not injured or attacked by the residents.

In contrast, female guinea pigs reared in colonies or in pairs can adapt to introduction into a group of unfamiliar conspecifics without the occurrence of overt aggression and high degrees of social stress. Thus female guinea pigs are able to adapt to unfamiliar conspecifics independent of their social rearing conditions (Kaiser *et al.* 2003c).

#### Effects of the prenatal social environment on physiology and behaviour

Instability of the social environment during pregnancy and lactation (through exchange of females between groups) alters the development of guinea pig offspring. Behaviour, endocrine systems and brain development of daughters and sons, whose mothers have lived in a stable social environment during pregnancy and lactation, differ in a sex-specific fashion from those whose mothers lived in an unstable social environment during this period of life (Sachser & Kaiser 1996; Kaiser & Sachser 1998, 2005; Kaiser *et al.* 2003b, 2003d). Daughters whose mothers have lived in an unstable social environment show conspicuous behavioural masculin-

linisation (Sachser & Kaiser 1996) displaying significantly more behaviours which are essential parts of the male courtship behaviour, such as intensive nasoinal sniffing and rumba (a swinging movement of the posterior part of the body), than daughters whose mothers have lived in a stable social environment. The behavioural masculinisation is accompanied by increased testosterone concentrations and an elevated activity of the sympathetic–adrenomedullary system as indicated by greater adrenal tyrosine hydroxylase activity (Kaiser & Sachser 1998). Daughters whose mothers have lived in an unstable social environment show an up-regulation of androgen receptors and oestrogen receptor- $\alpha$  in specific areas in the limbic system of the brain compared to daughters whose mothers have lived in a stable social environment (Kaiser *et al.* 2003b).

Sons of mothers from unstable social environments show a behavioural infantilisation that is accompanied by significantly decreased adrenal tyrosine hydroxylase activities and a delayed development of the adrenocortical system (Kaiser & Sachser 2001). Furthermore, these males show a down-regulation of androgen receptors and oestrogen receptor- $\alpha$  in specific parts of the limbic system such as the medial preoptic area of the hypothalamus and the hippocampus compared to males whose mothers have lived in a stable social environment (Kaiser *et al.* 2003d). Thus, early social stress induces changes in endocrine, autonomic and limbic brain function, which are mirrored by changes in male and female adult social behaviour.

## Social housing of guinea pigs

This section provides recommendations on the social housing of guinea pigs that are based on findings from basic research into their social life and welfare. Table 27.4 summarises the housing conditions which can be recommended and those which should be avoided (see Sachser *et al.* 2004).

**Table 27.4** Beneficial and detrimental housing conditions for guinea pigs. Reproduced from Sachser *et al.* (2004) *The welfare of laboratory guinea pigs*, In: *The welfare of laboratory animals*, E. Kaliste (ed.), copyright with kind permission of Springer.

Housing condition	Recommended	To be avoided
Solitary		X
Pair: 1 male, 1 female	X	
Harems (1 male, several females)	X	
Female groups: 2 females	X	
>2 females	X	
Male groups: 2 males	X	
>2 males		X
Small mixed-sex groups	X	
Large mixed-sex groups	X	

## Single housing

Domestic guinea pigs still bear the heritage of their wild ancestors the cavy (*Cavia aperea*). Thus, we should not expect that they are able to adjust to any artificial housing but instead require at least some essential features of the environment in which their wild ancestors evolved (Sachser 2001). Since the ancestor of the guinea pig is a socially living wild species, it seems likely that single housing is not appropriate for its domesticated counterpart. Single-housed male guinea pigs cope with stress situations in a less effective way than guinea pigs living in social groups (Sachser 1994a).

## Housing in pairs (one male, one female)

This housing condition is appropriate for guinea pigs. In this species, no fighting or threat displays are found between the sexes. Moreover, pair-reared males can cope with adversity in a much more effective way than solitary housed conspecifics.

## Housing in harems

This housing system is also appropriate for guinea pigs. Agonistic interactions do occur between females, but such aggression is rare and of low intensity: escalated fights and bites almost never occur.

## Female groups

Guinea pigs can be satisfactorily housed in all-female groups. The number is limited only by the enclosure size (with a maximum of about 0.25 m<sup>2</sup>/animal), since females can be housed without problems in large groups. It is true that in all-female groups levels of aggression are slightly higher than in groups with one male and several females (Thyen & Hendrichs 1990) but aggression is rare and of low intensity. As in groups of one male and several females, escalated fights and bites almost never occur. Females living in large all-female groups do not experience high levels of stress.

## Male groups

In groups consisting of two males, agonistic behaviour is rarely or never found. In contrast, in groups of more than two males, escalated agonistic interactions frequently occur beginning when the animals reach about 3–4 months. Additionally, animals that live in groups of two or four individuals show lower concentrations of the stress hormone cortisol than animals living in groups of six or twelve (Beer & Sachser 1992). Thus there seems to be good welfare when guinea pigs are housed in groups of two males, while indicators of social stress regularly occur in larger groups. So where mixed-sex housing is not possible we recommend keeping male guinea pigs in groups of two.

Males show courtship and sexual behaviour towards each other in the same way as males usually court females: pseudo-copulations occur including mounts and ejaculations. Specific males also display female-typical behaviour. These individuals, termed ‘pseudofemales’, not only toler-

ate the courtship and mounting by others, but also actively display defence urine-spraying, a behavioural pattern which is typical for females and usually serves to keep off courting males. The other males of the group behave towards these pseudofemales as towards real females and compete with each other for them. The pseudofemales do not take part in the aggressive conflicts. They rarely receive aggressive behaviour. Physiological stress indicators show that pseudofemales are subjected to lowest stress in the group (Beer & Sachser 1992).

#### Mixed-sex groups of a few males and females

Housing guinea pigs in small mixed-sex groups can also be acceptable. However, the formation of such a group with animals of unknown social rearing experience should be avoided since it frequently leads to intensive threat and fighting behaviour, extreme stress responses and injuries (see paragraph on effects of social experiences on physiology and behaviour).

#### Mixed-sex groups of many males and females

The housing condition, which we most favour for guinea pigs, is the large mixed-sex colony. In this, dominant as well as subordinate animals live a good life and are not subjected to high degrees of stress. All animals are able to learn the social skills which are necessary for interactions with conspecifics (see earlier). However, such a large mixed-sex group should have a varied age structure. The best system is to allow a small mixed-sex group to increase to the desired size. The assembly of a large group, using animals coming from pairs or solitary housing as well as with animals of unknown origin, should be avoided since it frequently leads to intensive threat and fighting behaviour, extreme stress responses and health problems.

### Physical housing and care of guinea pigs

#### Housing

Guinea pigs from commercial breeders are frequently used as specific pathogen free (SPF) animals. Such guinea pigs have to be housed under barrier conditions (eg, separated positive-pressure rooms) to prevent introduction of pathogens. It is also possible to house guinea pigs in individually ventilated cages (IVCs) such as 1500 cm<sup>2</sup> or 2000 cm<sup>2</sup> cages for rats, but the space of the smaller ones does not comply with the revised Council of Europe recommendations (Appendix A, ETS 123) or the revised Annex II to the European Directive. Moreover, the 2000 cm<sup>2</sup> cages are very difficult to handle, and are therefore not in common use.

Guinea pigs can be kept in pens or cages (Figure 27.3). The authors also have experience with keeping guinea pigs in pens on the floor, and recommend this type of housing. In this case bedding (eg, wood shavings) is necessary. However, certain floor covering materials such as flagstones can become contaminated with uroliths because adequate cleaning at regular intervals is difficult. For this reason, rooms should be emptied periodically for cleaning, descaling and disinfection.

It is important to provide enough space. High stocking densities can lead to endocrine stress reactions and high frequencies of aggression. The recently revised Council of Europe Appendix A and the European Directive Annex II give guidelines for the accommodation and care of guinea pigs (Council of Europe 2006; European Commission 2007). These recommend a minimum enclosure size of 2500 cm<sup>2</sup> and a floor area per adult animal (>700 g body weight) of 900 cm<sup>2</sup>. Sachser *et al.* (2004), however, suggest providing a floor area of about 2500 cm<sup>2</sup> per adult animal if possible. According to the European documents a minimum enclosure size of 1800 cm<sup>2</sup> for smaller animals (≤450 g body weight) is possible. However, the usual height of 20 cm in Makrolon cages type III is not sufficient, since this impairs playing behaviour ('frisky hops') of juveniles and prevents adult individuals from fully standing on their hindlegs. A minimum height of 23 cm is recommended by Appendix A, whereas Sachser *et al.* (2004) recommend 30 cm.

Specific forms of grid floors (eg, in metabolic cages) can cause problems and therefore should be used only for short periods during experiments. Grid floors are often the cause of diseases (eg, pododermatitis). Young animals' extremities are especially vulnerable if the mesh is too wide. On the other hand, openings have to be big enough to ensure the passage of faeces. If solid floors are not possible for experimental reasons, so that grids or wire mesh have to be used, then at least a solid or bedded area should be provided on which the animals can rest. Furthermore, it is important to check the grid floors closely to ensure that there is no risk of injury from loose or sharp projections. Pregnant and lactating females should always be kept on solid floors with bedding.

The most important environmental enrichment for the guinea pig is the social group. However, some physical enrichment should also be provided, eg, structural division of the environment by, for example, refuges or plastic piping into which all animals can retreat. It is important, however, to provide sufficient ventilation holes. Piping should be short enough to prevent more than two animals using it simultaneously. If more animals can enter it, a number of animals may press into the piping and there is a risk that animals in the middle will be asphyxiated. Branches for gnawing are a very easy kind of enrichment but should be autoclaved before use. Hay provides a substrate and is a useful enrichment (see section on feeding). Where hay is not used reproductive performance may be reduced.

#### Environmental provisions

Accommodation must provide draught-free ventilation. Relative humidity should be around 50–60%. The optimal temperature is around 18–22 °C (according to the European convention, Appendix A, 20–24 °C (Council of Europe 2006)). Guinea pigs are better able to withstand cold than heat. There are some indications that reproduction will decrease if temperature exceeds 30 °C.

Guinea pigs should be kept neither in constant light nor in constant darkness. A light-dark rhythm of about 12 h light and 12 h dark and also the natural light-dark rhythm are suitable (eg, if the animals are living in outdoor pens).

**Figure 27.3** Different types of cages suitable for housing of guinea pigs as well as floor housing.

Guinea pigs should be protected against loud noise, which can cause panic reactions, leading to injuries.

### Feeding

Guinea pigs are herbivores. Their wild ancestors live on grass, roots and seeds. In the laboratory, guinea pigs are usually fed with commercial plant-based pellets. The food has to be stored in cool, dry conditions and be protected against contamination. It should be available *ad libitum*. It is essential that food is provided in such a way to ensure access

by all animals. Pellets have to be small (with a diameter of about 3 mm), enabling the guinea pigs to take them directly by mouth. It is important to ensure the availability of vitamins, especially of vitamin C, since guinea pigs are susceptible to vitamin C deficiency. Signs of deficiency include: poor skin, poor haircoat, weight loss, stiffness, difficulties in walking, and even paralysis and poor bone and tooth development. If the vitamin C content in the food is insufficient (it remains active in pellets for only 90 days), ascorbic acid can be added to the drinking water (0.5 g/l). This should be freshly made as dissolved vitamin C decomposes within 24 h.

Good-quality hay should always be available. Besides diet-related benefits (eg, it may protect against digestive disturbances), hay is used for play as well as a material in which to burrow and hide. Due to the high proportion of fibre, hay also seems to prevent alopecia and teeth overgrowth (Wolf & Kamphues 2004; Wasel 2007). Since hay can represent an infection risk, heat treatment at 70°C is recommended (autoclaving at higher temperatures may lead to injury due to hardening of the halms).

Feeding dishes or food hoppers should be designed and positioned so as to prevent animals being able to defecate or urinate into them. Guinea pigs often spill food, and on grid floors (which should be avoided, see Housing section), the food will be wasted. There are available some suitable hoppers that reduce wastage. The water supply should be spatially separated from the feeding dish because guinea pigs tend to dribble water into the feeding dish, resulting in agglutinated pellets. Guinea pigs will rapidly learn to use drinking nipples attached to bottles or automatic systems. Stainless steel sipper tubes and nipples should be used because the animals like to gnaw at them.

### Bedding

The bedding material, eg wood fibres or granulate, has to be dry and absorbent. It should be free of toxic residue (eg, timber preservative), parasites and infectious agents. Dust should be kept to a minimum. The interval between cleaning depends on the kind of cage or pen used. Normally, once a week is reasonable.

### Housing and change

Guinea pigs react highly sensitively to changes of environment. Thus it is important to habituate them slowly to new conditions. The combination of several factors – each of which individually would have no negative effects – may result in strong stress responses and severe health problems. For example, the simultaneous provision of a new cage and a new drinking bottle should be avoided. New drinking bottles should be offered together with the old one until the animals begin to drink from the new one. Also unfamiliar food should be mixed with the familiar food, and the portion of the old food should be reduced step-by-step. When transferring animals to a new cage, no other modifications, such as providing new food or removing a social partner, should be made simultaneously. Whether or not an animal can adjust to a new situation can be assessed reliably from its drinking and feeding behaviour. If the animals are feeding and, particularly, drinking, then they can adapt to the new situation. In contrast, refusing water and food, scrubby fur and apathy point to extremely poor welfare.

### Identification and sexing

Coloured animals can be identified individually by natural markings without problems. Albino animals can be coloured, eg with food colouring on the fur. The dyes have to be renewed at regular intervals (3–4 weeks).

A frequently used method for permanent marking is ear tattooing. Another method is to implant microchips. Radio frequency identification (RFID) is a rapidly evolving tech-

nique and it is becoming an increasingly important tool in animal sciences. Even very small animals can be individually marked using small encapsulated RFID transponders. The animals can be identified with suitable readers, but only at short distances.

Guinea pigs are very easy to sex (Figure 27.4). Male and female guinea pigs can be differentiated by gentle pressing around the genital area. The penis is easily extruded. In older animals, the testes are also apparent, but can be lifted through the open inguinal ring into the abdominal cavity. In females, this technique will expose the vaginal membrane which closes the vagina (except during oestrus and parturition).

### Health monitoring

Guinea pigs should undergo regular health checks: appearance should be assessed (skin state, teeth, claws, eyes, nose, anal region) and the body weight should be measured regularly. Furthermore, behavioural abnormalities should be recorded and investigated. Incoming animals should be quarantined and screened for potential infections.

When laboratory guinea pigs are kept as SPF animals, care must be taken to maintain this status for microbiological standardisation. Therefore, besides well organised housing, the colony should be involved in health-monitoring programmes. On the one hand, such programmes serve to prevent the facility from introducing pathogens by newly arrived animals; on the other hand, long-term colony health status will be monitored for accidental infections. Monitoring protocols, including the number of animals tested, can vary based upon the number of animals in the colony and the duration of their husbandry. Recommendations for reasonable monitoring design are provided by the Federation of European Laboratory Animal Science Associations (FELASA 2002) (Table 27.5).

### Laboratory procedures

#### Handling

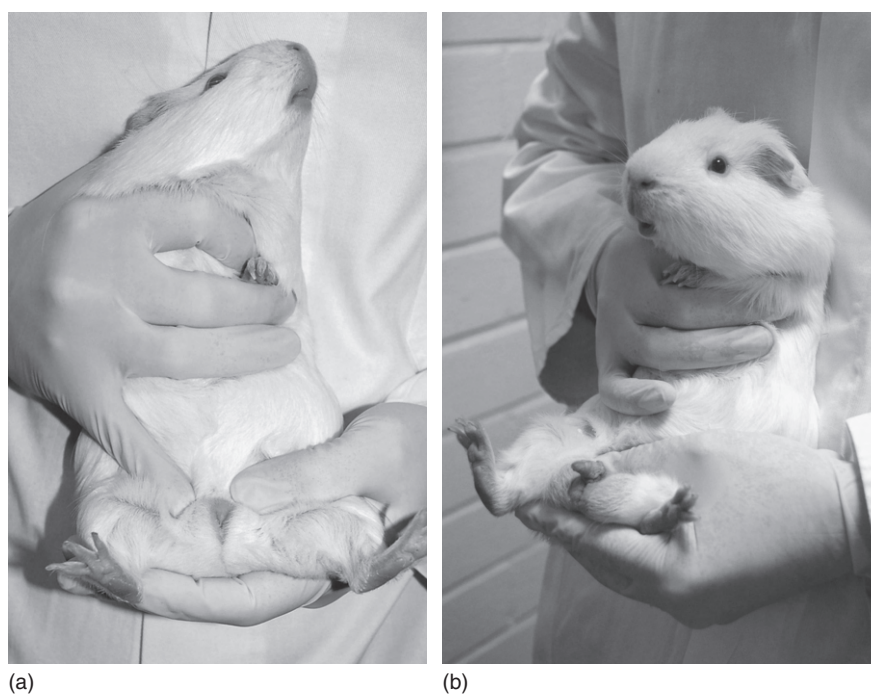

Guinea pigs are normally relatively docile and they bite very rarely. They should be picked up gently with both hands: one hand should hold firmly the shoulder or chest, the other hand has to support the hindquarters. In the case of pregnant guinea pigs, this is particularly important because they can become very heavy. After picking them up, guinea pigs should be held against the handler's body (Figure 27.5).

#### Sampling techniques

##### Blood collection

Choosing the right site for blood sampling depends on the size of the guinea pig and the amount of blood needed. For single blood collection no more than 10% of the total blood volume (approximately 75 ml/kg of the body mass) should be taken. Weekly collected blood volumes should not exceed 7.5% and daily collected volumes should not exceed 1% of the total blood volume (Joint Working Group on Refinement

**Figure 27.4** Sexing a guinea pig. (a) In the female the vaginal membrane will be exposed. (b) In the male the penis is easily extruded from the genital opening using gentle pressure.

**Table 27.5** FELASA recommendations for the health monitoring of guinea pig colonies.

Disease	Test frequency
<b>Viruses</b>	
Guinea pig adenovirus	3 months
Sendai virus	3 months
Guinea pig cytomegalovirus	Annually
<b>Bacteria, mycoplasma and fungi</b>	
<i>Bordetella bronchiseptica</i>	3 months
<i>Chlamydia psittaci</i>	3 months
<i>Corynebacterium kutscheri</i>	3 months
Dermatophytes	3 months
Pasteurellaceae	3 months
<i>Salmonella</i> spp.	3 months
<i>Streptobacillus moniliformis</i>	3 months
Streptococci $\beta$ -haemolytic (not group D)	3 months
<i>Streptococcus pneumoniae</i>	3 months
<i>Yersinia pseudotuberculosis</i>	3 months
<i>Clostridium piliforme</i> (Tyzzer's disease)	Annually
<b>Parasites</b>	
Ectoparasites	3 months
Endoparasites:	3 months
<i>Encephalitozoon cuniculi</i>	3 months
Pathological lesions observed	3 months

(JWGR) 1993). Since rodent blood often coagulates within the needle, short needles are recommended and sometimes it may be useful to remove the cone of the needle from the syringe before puncturing a vessel.

For collecting small amounts of blood, the ear vessels may be punctured (Figure 27.6). In coloured animals a cold point lamp behind the ear increases the visibility of the blood vessels. In albinos this is not necessary. To increase blood flow, the veins can be compressed manually. After disinfect-

ing the skin the ear vessels are punctured with a sterile disposable needle ( $0.6 \times 25$  mm (23G)) and the blood is collected, for example, in heparinised capillaries.

The lateral saphenous vein is another site for blood collection (Figure 27.6). After shaving the fur from the back of the hindlimb and disinfecting the skin, one person restrains the guinea pig with one hindlimb extended backwards. The vein runs laterally to the Achilles tendon, and the insertion site is close to the tendon in the middle third of the lower leg. Even if the vein is not visible, the needle ( $0.7 \times 30$  mm or  $0.6 \times 25$  mm) can be inserted at a  $30$ – $45^\circ$  angle from disto-caudal direction and blood can be collected in a vial.

To collect larger volumes, the jugular vein or the cranial vena cava can be used as a survival method, although there is a risk of haemorrhage or cardiac tamponade. Usually the procedure is done under anaesthesia in dorsal recumbancy. The puncture site is the thoracic inlet left or right of the sternum. A needle with a 2 ml syringe is inserted at a  $45^\circ$  angle while pulling back the plunger until blood appears in the syringe. After removal of the needle, pressure should be applied to the site of puncture. Hillyer *et al.* (1997) described a method to collect blood from the jugular vein without anaesthesia by restraining the animal with the forelegs extended down over a table edge and head and neck extended up. This procedure appears to be very stressful and should be done by trained personnel only, since location of the vein is often difficult.

Cardiac puncture is only recommended as terminal procedure under anaesthetic because of the comparatively high risk of cardiac tamponade. The heart can be punctured laterally in the area where the strongest heartbeat can be felt, or from a caudal direction with the insertion site behind the xiphoid.

The retro-orbital sinus may be used for blood sampling under anaesthesia, but access to the sinus is more difficult than in rats and mice and may result in severe complications (eg, exophthalmus). JWGR (1993) consider that this

technique, which samples a mixture of blood and tissue fluid, is only appropriate under terminal anaesthesia.

### Urine collection

Urine may be collected manually by applying gentle pressure over the caudal abdominal area. This method will provide a cleaner sample than collecting urine in a metabolic cage, where faeces may contaminate the urine sample. Uncontaminated urine samples can be collected via cystocentesis. For this, the guinea pig should be prepared as for surgery. Anaesthesia may be necessary for safe restraint and the bladder should be fixed manually while it is punctured with a fine needle through the abdominal wall.

A method to introduce a fine, flexible catheter into the urethra of male and female guinea pigs has been described, but there are risks of pathogen introduction into the bladder and mucosa injury, particularly in males (Ewringmann & Gloeckner 2005; Wasel 2007).

### Administration of medicines

For general principles of administering substances see JWGR (2001). Oral medications can be administered by adding small quantities of liquids or solids to the feed or drinking water. However, using this method it is not possible to determine or ensure the dose consumed. Furthermore, the intake may be influenced by drug-related changes of appearance or taste of feed or water. Another method is to take a syringe or dosing needle with a rounded end to drop the liquid onto the back of the tongue. A rat dosing needle or a polyethylene catheter with outside diameter 1.0–1.3 mm can also be used. The catheter should be introduced via the interdental space. Care has to be taken that the animals have enough time to swallow during these procedures. For application of exact or larger doses of compounds, oral gavage via a gastric tube can be performed (Figure 27.7). For this, another person has to restrain the animal and a mouth gag with a hole in its middle should be placed behind the incisors to prevent the animals from biting into the tube. Subsequently, the moistened tube can be inserted carefully into the oesophagus. If coughing or dyspnoea occurs during administration of the compound, the procedure must be stopped immediately and the tube has to be reinserted.

Parenteral administration may be done in several ways. Subcutaneous or intramuscular injections (Figure 27.7) are both suitable methods, even though, depending on the agent to be administered, the subcutaneous method may be generally preferred. For administration of small volumes intramuscular injections into the thigh muscles of the hindlimbs can be performed. The needle should not be introduced too far, to avoid damage of the femur or nervus ischiadicus with associated bruising, periostitis or nerve irritation. No more than 0.3 ml should be injected into one site (Terril & Clemons 1998; North 1999) to minimise risks of muscle necrosis. Subcutaneous injections can be used for application of larger volumes (up to 3 ml per site) under the skin of the neck, back, or flanks of the animal. For intradermal injections (maximum 0.1 ml) the usual sites are the flank or the dorsum. Larger volumes of up to 10 ml can be given

(a)

(b)

**Figure 27.7** Administration techniques. (a) Intramuscular injection into the hindlimb of a guinea pig. (b) Oral gavage via gastric tube. A mouth gag prevents the guinea pig from biting into the tube.

by intraperitoneal injection, but care has to be taken to avoid injuries to the internal organs or injecting the substance into the caecum, where it may not be absorbed. If the substance is irritant, peritonitis or adhesions of the caecum can result. Although access to superficial veins is sometimes difficult in guinea pigs, intravascular administration is also possible. The auricular veins are the most suitable. Fine needles are recommended; veins may be dilated by warming before injection; and injection must be performed very slowly by a trained person.

Injection sites should be clipped, shaved and then swabbed with a suitable antiseptic. Depending on the kind and the amount of the substance which is administered, it may be necessary to use multiple injection sites.

### Anaesthesia and analgesia

Anaesthesia should be used for all procedures causing more pain or stress than the anaesthesia itself. Guinea pigs, like other small rodents, have a high metabolic rate and oxygen consumption, so hypoglycaemia, dehydration, hypothermia and hypoxaemia can develop rapidly. For this reason,

animals should not be fasted except for intubation or experimental reasons and oxygen should be administered if possible. If fasting is necessary, fasting time should not exceed 4 h (Abou-Madi 2006). To avoid hypothermia heating pads or lamps may be used, only small areas of fur should be clipped for surgery, and warmed fluids can be given subcutaneously (10–20 ml/kg). Anticholinergics like atropine (0.05 mg/kg sc) and glycopyrrolate (0.01–0.02 mg/kg sc) (Mason 1997) can be recommended to avoid excessive salivation, bronchial secretion and vagally induced bradycardia.

### Inhalation anaesthesia

Because of its potential to induce respiratory depression as well as excessive salivation and secretion, inhalation anaesthesia alone is possible but is not the best method for general anaesthesia of guinea pigs. It is better to use a balanced technique that takes advantage of both sedative and analgesic effects of the injectable compounds. The main advantages of inhalants are their good controllability and rapid recovery of the animals. Currently, isoflurane seems to be the agent of choice for inhalants, because halothane and methoxyflurane may represent a health risk to exposed

people while sevoflurane may lead to asphyxia in guinea pigs (Henke & Erhardt 2004). An anticholinergic medication should be administered before inhalation anaesthesia to decrease secretion. Some authors practise endotracheal intubation of guinea pigs with a tube size of 1.5–3.5 mm (Blouin & Cormier 1987), but long and narrow approaches to the trachea can make this difficult. In addition, food remnants stored in the cheeks may lead to obstruction or aspiration pneumonia. Therefore, intubating guinea pigs is an uncommon method and face masks are used instead. For induction 4–5% isoflurane is adequate and anaesthesia can be maintained with 2–4%.

### Injectable anaesthesia

Various combinations of anaesthetics are widely used for injectable anaesthesia. Compared to inhalation anaesthesia the precise control of depth of anaesthesia and attainment of a surgical stage is more difficult when using injectable agents. Exact dosing may be difficult due to variable gastrointestinal content and its effect on body weight. Sedative and analgesic agents may be used for premedication or in combinations to induce general anaesthesia. Various anaesthetics and their dosages are summarised in Table 27.6.

**Table 27.6** Sedative and anaesthetic agents for guinea pigs.

Anaesthetics	Dosage	Route	Comments	Reference
Diazepam/midazolam	2.5–5 mg/kg	im	Only sedation	Henke & Erhardt 2004, Terril & Clemons 1998
Xylazine	3–5 mg/kg	im/ip	Pre-anaesthetic, sedation	Terril & Clemons 1998
Medetomidine	0.15–0.5 mg/kg	im	Pre-anaesthetic, sedation	Henke & Erhardt 2004, North 1999
Ketamine + Xylazine	25–80 mg/kg 0.15–13 mg/kg	im/ip	Variable effect and duration, surgical anaesthesia possible	North 1999, Radde <i>et al.</i> 1996, Terril & Clemons 1998
Ketamine + Medetomidine	40–60 mg/kg 0.25–0.5 mg/kg	im/ip	Surgical anaesthesia	North 1999, Pfizer product information
Ketamine + Diazepam	44–125 mg/kg 0.1–5 mg/kg	im/ip		North 1999, Radde <i>et al.</i> 1996
Pentobarbital	15–35 mg/kg	ip	Lasts 2 h, no analgesia	Radde <i>et al.</i> 1996, Terril & Clemons 1998
Fentanyl + Midazolam + Medetomidine	0.025 mg/kg 1 mg/kg 0.2 mg/kg	im	Surgical anaesthesia	Henke & Erhardt 2004
Fentanyl + Midazolam + Xylazine	0.05 mg/kg 2 mg/kg 2 mg/kg	im	Surgical anaesthesia	Henke & Erhardt 2004
<u>Reversal agents:</u>				
Naloxone + Flumazenil + Atipamezole	0.03 mg/kg 0.1 mg/kg 1 mg/kg	sc		Henke & Erhardt 2004
Tiletamine + Zolazepam (Zoletil®)	10–80 mg/kg	im	Minor procedures, more effective when combined with xylazine	Jacobson 2001, Terril & Clemons 1998

Increased dosages often lead to a longer anaesthetic time. In general, anaesthetics should be administered intramuscularly because subcutaneous applications often prove insufficient. Where appropriate, depending on the anaesthetic agents used, antidotes like naloxone and atipamezole should be given to promote rapid recovery.

Local anaesthetics can be used to reduce dose of general anaesthetics or for minor procedures in combination with some premedication. Usually, they are injected subcutaneously. Lidocaine 0.5–2% may be used in small volumes of 0.5–2 ml (5 mg/kg), diluted if necessary. For further advice see Flecknell (2009).

### Analgesia

To control pain during and after surgery, analgesics should be administered pre-emptively, intra- and/or post-operatively, depending on the type of anaesthesia and the severity of the intervention. Different types of analgesics like NSAIDs or opioids may be used as a single treatment or combined as multimodal pain therapy. A list of analgesics and suggested dosages is provided in Table 27.7.

### Euthanasia

Several methods for euthanasia are described in the literature. Currently, the American Veterinary Medical Association (AVMA) *Guidelines on Euthanasia* (2007) are considered the main reference for humane methods to euthanase animals. Furthermore, recommendations for euthanasia of laboratory animals have been published by the European Commission (Close *et al.* 1996, 1997). See also Chapter 17.

For guinea pigs, an overdose of injectable anaesthetic is preferred; the most suitable agent is sodium pentobarbital (200–400 mg/kg ip); this can be given by the intracardiac route only under anaesthesia. T-61<sup>®</sup> (a mixture of three drugs especially produced for euthanasia) should never be

used without anaesthesia, due to induction of respiratory paralysis. It can be dosed intracardially or intrapulmonally. Inhalant agents like carbon dioxide or volatile anaesthetics are also commonly used, but these can be irritant to the animals. However, carbon dioxide is still widely used because it is a practical method for larger numbers of animals (and it can be an advantage in some studies that no chemical residues remain in tissues). Decapitation by guillotine and exsanguination subsequent to stunning are possible methods, but require well trained personnel. Cervical dislocation is not recommended for this species due to its short and strong neck.

### Common welfare problems

#### Assessing welfare in guinea pigs

As for other mammals, the welfare of guinea pigs can be assessed from: (1) the guinea pig's general appearance; (2) body weight; (3) behaviour; and (4) physiological parameters (eg, Broom & Johnson 1993). See Chapter 6 for general aspects of welfare assessment.

1. General appearance of the animals: Experienced animal technicians, who know the normal appearance and behaviour of the animals, are well suited to monitor their health. The fur should be sleek and not scrubby, the claws should be short, the eyes clear and lucent, not clotted and dull, and the nose and anal region should be clean. Abnormal respiratory rate and pattern can point to disease and/or pain.
2. Body weight records: This parameter is a non-specific, but extremely reliable, indicator of welfare. Body weights of infant guinea pigs should increase regularly. In contrast, the body weights of adult animals should remain relatively constant. If there are modifications to their environment, guinea pigs can lose body weight. If an adult guinea pig loses more than 10% of its body

**Table 27.7** Analgesic drug dosages for guinea pigs (NSAIDs: non-steroidal anti-inflammatory drugs).

weight within 3 days, the former housing conditions should be restored immediately (Beer *et al.* 1994; Sachser *et al.* 2004). Weight increase in adults should be investigated as tumour growth may lead to unexpected increase in weight.

3. Behaviour: In general, normal frequencies of courtship, comfort, feeding, drinking and locomotor activity point to good welfare of the individuals. In juveniles, play behaviour ('frisky hops') should be displayed regularly. In contrast, high frequencies of aggression, apathy and absence or reduced frequencies of feeding, drinking and comfort behaviour indicate high degrees of stress. Such behavioural patterns are often paralleled by extreme neuroendocrine stress responses. Moreover, in guinea pigs there are specific vocalisations which signal stress: In juveniles the so-called 'distress call' occurs. It is a high-pitched whistle, which indicates excitement or anxiety. The distress call can be repeated several times in a bout of calls. Distress calls are most frequently encountered upon separation of the juveniles from their mothers. Frequent occurrence of the vocalisation 'chirp' is also a stress indicator. This call is emitted in situations of discomfort (Rood 1972). Chirps are a rapidly repeated series of high-pitched birdlike notes. The animal is in an alert posture and the body twitches at each note. Chirps may be given in a continuous series lasting for 10 or 15 minutes. Vocalisation in response to handling can indicate pain or stress.
4. Physiological parameters: Stress levels can be diagnosed reliably from endocrine parameters. In mammals, two stress axes exist: the pituitary–adrenocortical and the sympathetic–adrenomedullary systems (Henry & Stephens 1977; Sachser 1994a; von Holst 1998). These systems play a major role in adjusting an individual to its physical and social environment. The activation of each of these systems provides the organism with energy and shifts it into a state of heightened reactivity that is a prerequisite for responding to environmental changes in an appropriate way. Although the short-term or moderate activation of both systems represents an adaptive mechanism to cope with conflict situations, the long-term hyperactivation of both the pituitary–adrenocortical and the sympathetic–adrenomedullary systems is related to the aetiology of irreversible injury and even death (Henry & Stephens 1977; von Holst 1998). Serum glucocorticoid concentrations represent a good indication of the activity of the pituitary–adrenocortical system. Good indicators for the activity of the sympathetic–adrenomedullary system are: the serum concentrations of catecholamines (epinephrine, norepinephrine); the heart rate; and the adrenal tyrosine hydroxylase activity (Sachser 1994a; von Holst 1998). However, it should be mentioned that to determine adrenal tyrosine hydroxylase activity the animals have to be killed first. The most common method to assess stress in guinea pigs is to determine concentrations of serum cortisol (in guinea pigs cortisol is the main glucocorticoid (Jones 1974; Fujieda *et al.* 1982). Blood samples for this (about 200 µl blood) can be taken from the ear vessels (Sachser & Pröve 1984). Guinea pigs rarely struggle or vocalise during sampling with this

procedure, and, since it is not necessary to anaesthetise the animals, later samples are not influenced by previous exposure to anaesthesia (Sachser 1994a). This sampling procedure is described in detail earlier in this chapter. Blood samples should be taken within a time span of 5 minutes as glucocorticoid concentrations do not increase until 5 minutes after exposure to a stressor. Recently non-invasive techniques to assess degrees of stress have been developed. For example, glucocorticoids can be determined from saliva. In guinea pigs, saliva can be sampled very easily by putting a piece of cotton wool (eg, cotton bud) into the mouth of the animal for several minutes. Aside from endocrinological stress parameters, other indicators such as immune parameters can contribute to the diagnosis of stress and welfare in guinea pigs. Furthermore, measurements of haematological parameters as well as of blood biochemistry are helpful to indicate abnormal physiological states.

For haematological and biochemical data see Tables 27.8 and 27.9.

## Disease

Details of diseases of guinea pigs are given among others in Seamer and Chesterman (1967), Wagner and Manning (1976), Harkness and Wagner (1989), Owen (1992), Huerkamp *et al.* (1996), North (1999) and Harkness *et al.* (2002). Signs of diseases may be non-specific, including symptoms like weight loss, lethargy or a rough coat. First indications of diseases are described in the section on welfare assessment. Routine checks should include observation of the behaviour, gait, urine and faeces. Animals should be regularly examined with special attention paid to their coat, eyes, nose, ears, mouth and teeth, as well as feet and nails.

Bacterial diseases, like salmonellosis, pneumonia and *Staphylococcus aureus* infections, viral diseases, like adenovirus, parainfluenza virus and herpesvirus infections, as well as parasitic diseases like mite and lice infestations can cause problems in guinea pigs. Non-infectious diseases include behavioural problems, nutritional imbalances and deficiencies (eg, hypovitaminosis C) and reproductive problems. In

Blood biochemistry parameter	Normal value
Serum blood glucose (mg/dl)	60–125
Blood urea nitrogen (mg/dl)	9–31.5
Total plasma protein (g/dl)	4.2–6.5
Albumin (g/dl)	1.8–3.9
Globulin (g/dl)	0.8–2.6
Creatinine (mg/dl)	0.6–2.2
Total bilirubin (mg/dl)	0.3–0.9
Cholesterol (mg/dl)	20–43
Serum calcium (mg/dl)	4.5–12
Serum phosphate (mg/dl)	3.0–7.6

pregnant guinea pigs, especially in obese or anorexic females, toxæmia can occur during the last 2 weeks of gestation or 7–10 days after parturition. Dystocia often occurs in guinea pigs due to the large foetuses, particularly if females are bred either too young or too old for the first time. If they are older than 6–8 months, the pubic symphysis may not separate sufficiently, and obesity may furthermore obstruct the birth canal.

Tumours do not develop frequently and occur mainly in older animals. Lymphosarcoma and mammary gland tumours are the most common tumour diseases in guinea pigs and can occur both in females and males.

Table 27.10 summarises common diseases of guinea pigs. More detailed information can be taken from the cited authors as well as from North (1999).

Treatment of diseases is often difficult. First of all, sick animals have to be separated from the others. Housing conditions should be checked and optimised if necessary. The same papers cited above as well as Smith and Burgmann (1997), Ewringmann and Gloeckner (2005) and Wasel (2007) give information on treatment and drug dosages. Some bacterial diseases may be treated with antibiotics, however, antibiotic sensitivity should be tested first. Unlike most other species, the gastrointestinal flora of guinea pigs is predominated by Gram-positive bacteria. Therefore, certain antibiotics, including penicillin, ampicillin, or lincomycin cause an alteration to Gram-negative bacteria like *Escherichia coli* or *Clostridium difficile*, often resulting in severe enterotoxaemia. Broad-spectrum antibiotics such as enrofloxacin should be used for therapy, but only if really necessary.

It is often more humane and reasonable to sacrifice sick animals and above all pay attention to preventive measures.

## Acknowledgements

Thanks go to Dr. Andreas Haemisch and Dr. Gero Hilken for substantial comments on aspects of care and use of guinea pigs in experimental animal sciences as well as Dr. Oliver Adrian, Dr. Philip Dammann and Dr. Ralph Waldschuetz for critical comments on the manuscript.

**Table 27.10** Common diseases of guinea pigs (Noonan 1994; Schaeffer & Donnelly 1997; Wasel 2007).

Organ system	Diseases
Skin	Dermatophytosis (mainly <i>Trichophyton mentagrophytes</i> )
	Ectoparasites (mites like <i>Trixacarus caviae</i> , <i>Chirodiscoides caviae</i> , lice like <i>Glinicola porcelli</i> , <i>Gyropus ovalis</i> )
	Pododermatitis
	Endocrine alopecia (gestational, ovarian cysts)
	Bite wounds
	Barbering
Gastrointestinal tract	Malocclusion (incisors as well as back teeth)
	Antibiotic-associated enterotoxaemia
	Bacterial enteritis ( <i>Salmonella</i> sp., <i>Clostridium</i> sp., <i>Escherichia coli</i> , <i>Yersinia pseudotuberculosis</i> , <i>Clostridium piliforme</i> etc)
	Parasitic diarrhoea ( <i>Eimeria caviae</i> , <i>Paraspidodera uncinata</i> )
	Viral pneumonia (adenovirus)
Respiratory tract	Bacterial pneumonia ( <i>Bordetella bronchiseptica</i> , <i>Streptococcus pneumoniae</i> , <i>Streptococcus zooepidemicus</i> , <i>Pasteurella multocida</i> , <i>Klebsiella pneumoniae</i> )
	Viral pneumonia (adenovirus)
	Cystitis
	Urolithiasis
Urogenital tract	Chronic interstitial nephritis (found in older animals)
	Ovarian cysts
	Endometritis
	Dystocia
	Pregnancy toxæmia
	Mastitis
	Nervous system
Torticollis (caused by progressive otitis media/interna, <i>Streptococcus pneumoniae</i> , <i>Streptococcus zooepidemicus</i> , <i>Bordetella bronchiseptica</i> , etc)

# 28 The laboratory rabbit

Lena Lidfors and Therese Edström

## Biological overview

### General biology

The laboratory rabbit is descended from the European wild rabbit (*Oryctolagus cuniculus*) (Harcourt-Brown 2002), which appears to have had a widespread distribution across Europe before the last Pleistocene glaciations 1.8 million to 10 000 years ago (Flux 1994). After the last Ice Age (20 000 years ago), it was confined to the Iberian Peninsula and small areas of France and northwest Africa (Parker 1990; Wilson & Reeder 1993). However, the spread of the rabbit over the world has mainly been the result of man's activities (Flux 1994). Due to the adaptability of the species the European rabbit exists in the wild on every continent except Asia and Antarctica (Parker 1990; Wilson & Reeder 1993). In many places where rabbits have been introduced, the lack of predators has led to an explosion in the number of animals, leading them to become pests. In order to find ways to diminish the high population of wild rabbits their behaviour and reproduction have been investigated in a large number of ecological studies.

There are different views on exactly when rabbits were domesticated; from the first century BC (Nachtsheim 1949) to the sixth to the tenth century AD (Zeuner 1963). It has also been reported that rabbits were kept in fenced hunting areas by the Romans as long ago as 2000 years ago (Meredith 2000). Domestication probably occurred in the French monasteries, where several different breeds were developed (Zeuner 1963). These were further developed to create a large number of breeds for different purposes during the past century. In 2001 the British Rabbit Council<sup>1</sup> recognised 57 breeds of fancy fur and Rex rabbits, whereas the American Rabbit Breeders' Association in 2006 recognised 47 rabbit breeds<sup>2</sup>.

When the behaviour of European wild rabbits has been compared with domestic strains of rabbits kept in semi-natural enclosures their behaviour has been found to be very similar in most aspects (reviewed by Bell 1984); however, there are some differences. Domestic rabbits spend more time resting above ground during the day (Stodart & Myers 1964). Bucks chin-mark more often (Kraft 1979) and will do so in unfamiliar territory (Mykytowycz 1968). Stodart and

Myers (1964) found that domestic does had fewer days out of reproduction than wild does, and therefore produced more litters with a larger mean size. When European wild rabbits were brought into the laboratory they failed to breed, and females born into the laboratory as a result of egg transfer from wild to domestic mothers retained their nervous disposition and failed to mature sexually (Adams 1982). European wild rabbits may be used for experimental research, but there are several problems in keeping and breeding them (Bell 1999), and they also may bring in several infectious agents that are normally excluded in barrier housing.

Of the 12.1 million animals used for experimental and other scientific purposes in the member states of the European Union in 2005, 2.6% (314 600) were rabbits (Commission of the European Communities 2003). In general, the number of rabbits used in research has declined. As an example, in Sweden the number of rabbits used has decreased from 7141 in 1993 to 1808 in 2006 (Swedish Board of Agriculture 2007).

The most common breed used for laboratory research is the New Zealand White (NZW), which was originally bred for meat production (Bennett 2001). Other breeds used include the Dutch and the Half Lop (Batchelor 1999). A major breeder in Europe is currently breeding NZW, Chinchilla Bastard and Himalyan rabbits. The Watanabe heritable hyperlipidaemic (WHHL) rabbits have been developed as a model to study hypercholesterolaemia and atherosclerosis *in vivo* (Wetterholm *et al.* 2007), and the myocardial infarction-prone Watanabe heritable hyperlipidaemic (WHHLMI) rabbits have been developed as a model to study human acute coronary syndromes (Shiomi & Jianglin 2008).

### Size range and lifespan

The European wild rabbit has been reported to vary widely in both adult weight range and lifespan both within and between populations. From northern to southern Europe the body weight (Rogers *et al.* 1994) and skull size (Sharples *et al.* 1996) are reduced. It has been suggested that this is due to phenotypic rather than genetic variation (Sharples *et al.* 1996). In a long-term study the body weight of European wild rabbits in East Anglia, UK, was found to be 1.3–2.1 kg in males and 1.3–2.3 kg in females (Bell 1999). In the

<sup>1</sup><http://www.thebrc.org/>

<sup>2</sup><http://www.arba.net>

domesticated rabbit, differences in weight between breeds are large: from around 1 kg (Netherland Dwarfs) to 5 kg (New Zealand White) and up to 10 kg (German Grey Rabbits) (Sawin 1950; Bennett 2001). There is large variation in the size and position of ears, body conformation, fur quality and coat colour between breeds of rabbits (Sawin 1950; Bennett 2001).

The European wild rabbit has no dimorphism in adult body size (Webb 1993). The only difference in appearance between males and females is that bucks have a more rounded, broader appearance to the front of the head, whereas does have a more pointed head (Bell 1999). Domesticated rabbit breeds do not seem to have developed dimorphism in size either. The NZW rabbit should have an ideal weight of 4.5 kg in adult bucks (8 months of age and over) and 5.0 kg in adult does (Sawin 1950). When kept as laboratory rabbits NZWs tend to lay down excessive amounts of body fat in the abdominal cavity and around the chin when they grow older. This occurs irrespective of whether they are kept single housed in a cage or group housed in a pen (Batchelor 1999).

In the European wild rabbit, mortality in the wild is very high during the first year of life and can reach up to 90% (Macdonald 1984; Nowak 1999), mainly due to myxomatosis and predation (Bell & Webb 1991; Rogers *et al.* 1994). In a long-term English study maximum age of bucks was 8 years and of does 9 years (Bell 1999), whereas Gibb (1993) had rabbits living over 10 years in a study in New Zealand. Domestic rabbits have been reported to have an average lifespan of 9 years<sup>3</sup>, and Comfort (1956) stated that lifespan can exceed 15 years and gave examples of bucks reaching 10–14 years old.

### Social organisation

European wild rabbits live in small, stable, territorial breeding groups (Parer 1977; Gibb *et al.* 1978; Cowan 1987; Bell & Webb 1991). This is the social unit and consists of one to four males and one to nine females, but different breeding groups may comprise colonies of up to 70 rabbits (Meredith 2000). The breeding group defends its territory, a core area with a warren within a larger home range, by patrolling the borders and scent-marking (Bell 1999). A warren is an area of soil or sand containing underground tunnels and nests made by the rabbits. Breeding groups can either occupy single warrens (Myers & Schneider 1964; Bell 1977) or multiple warrens (Dunsmore 1974; Parer 1977; Wood 1980; Daly 1981; Cowan 1987). Each warren has several entrances which allow quick escape from predators (Cowan 1987). Neighbouring breeding groups can move out from their territories to forage in communal grazing areas at dawn and dusk (Bell 1980).

Dominance hierarchies are formed within each sex for each breeding group, and they are stable over time (Bell 1983). The hierarchy is maintained by rabbits keeping a fixed distance from one another and exhibiting submissive behav-

our. The rabbit spends a rather large portion of its daily activity in either direct or indirect aggression (Mykytowycz & Rowley 1958; Mykytowycz & Fullager 1973), and this may underlie the social and territorial organisation that influence the numbers of free-living populations (Mykytowycz 1960). It is a general perception that bucks are involved in more fighting, but does have been found to be more aggressive than bucks (Southern 1948; Myers & Poole 1961), or to fight as strongly as bucks (Lockley 1961). The does mainly fight over breeding nests (Cowan & Garson 1985), and are more aggressive towards juvenile does than towards juvenile bucks (Cowan 1987). When the number of rabbits living together increases, fighting increases dramatically (Myers 1966; Myers *et al.* 1971). Young bucks normally move to a new social group before starting their first breeding season, while young does stay on to breed in their natal group (Parer 1982; Webb *et al.* 1995).

In a study of NZW rabbits kept in a semi-natural enclosure, a total of 20 different social behaviours and their changes with age were described (Lehmann 1991). Lehmann grouped the behaviours into indifferent contacts, amicable behaviour, subdominant behaviour, aggressive behaviour and actual fights. When male and female European wild rabbits and NZW rabbits were tested with paired encounters in a home pen it was found that NZW rabbits showed as much agonistic behaviour as the wild rabbits, aggression was equally prevalent in both sexes and inter-sexual fighting occurred just as frequently as fighting between members of the same sex (Mykytowycz & Hesterman 1975).

The rabbit has three specialised scent glands. These are located in the anal region, the groin and under the chin (Mykytowycz 1968). Rabbit territory is scent-marked by placing faeces in dunghills, and by pressing the under-chin against structures in the environment so that droplets from the rabbit's submandibular glands are excreted through pores of the skin (Mykytowycz 1968). Male rabbits scent-mark more intensively than females and dominant individuals more than subdominant animals; this is correlated with larger anal and submandibular glands in dominant males (Mykytowycz 1968) with the heaviest anal glands being found in the most dominant animals. Bucks also scent mark does and young rabbits of their breeding group by spraying urine on them (Mykytowycz 1968). Does scent mark their young, attack other young within the same breeding group, and may chase and even kill young from other breeding groups (Mykytowycz 1968). Does may attack even their own young if they have been smeared with foreign urine (Mykytowycz 1968).

### Biological data

Basic biological data are presented in the different sections of this chapter where they are of specific interest. The data presented here may be of interest for research purposes as well as for checking animal health. Cardiovascular and respiratory functions are of great importance for anaesthesia and normal values are presented in Table 28.1. Haematology and blood chemistry parameters can be used to assess the homeostasis of the animals prior to surgery or dosing as well

<sup>3</sup>[http://animaldiversity.umm.umich.edu/site/accounts/information/Oryctolagus\\_cuniculus.html](http://animaldiversity.umm.umich.edu/site/accounts/information/Oryctolagus_cuniculus.html)

**Table 28.1** Normal values of cardiovascular and respiratory functions in rabbits (Gillett 1994; Flecknell 1996).

Parameter	Values
Respiratory rate (breaths/min)	40–60
Heart rate (beats/min)	200–300
Tidal volume (ml/kg)	4–6
Arterial systolic pressure (mmHg)	90–130
Arterial diastolic pressure (mmHg)	80–90
Arterial blood pO <sub>2</sub> (kPa)	11–12.5
Arterial blood pCO <sub>2</sub> (kPa)	5–6.5
Arterial blood pH	7.35–7.45

**Table 28.2** Normal values of haematology in rabbits (Jenkins 2008).

Parameter	Values
Erythrocytes (count) ( $\times 10^6/\text{mm}^3$ )	5.4–7.6
Haematocrit/packed cell volume (%)	33–50
Haemoglobin (g/dl)	10.0–17.4
Mean corpuscular volume ( $\mu\text{m}^3$ )	60–69
Mean corpuscular haemoglobin (pg)	19–22
Mean corpuscular haemoglobin concentration (%)	30–35
Leucocytes ( $\times 10^3/\text{mm}^3$ )	5.2–12.5
Lymphocytes (%)	30–85
Neutrophils (%)	20–75
Eosinophils (%)	1–4
Basophils (%)	1–7
Monocytes (%)	1–4
Platelets ( $\times 10^3/\text{mm}^3$ )	250–650

**Table 28.3** Normal values of blood clinical chemistry in rabbits (Jenkins 2008).

Parameter	Values
Alanine aminotransferase (IU/l)	27.4–72.2
Aspartate aminotransferase (IU/l)	10.0–78.0
Creatine kinase (IU/l)	58.6–175.0
Bilirubin (mmol/l)	2.6–17.1
Blood urea nitrogen (mmol/l)	4.6–10.7
Creatinine ( $\mu\text{mol/l}$ )	74–171
Glucose (mmol/l)	5.5–8.2
Calcium (mmol/l)	2.2–3.9
Phosphorus (mmol/l)	1.0–2.2

as after any experimental procedure. Normal haematology values are shown in Table 28.2 and normal values of clinical blood chemistry are shown in Table 28.3.

The body temperature of rabbits varies from 38.5–39.5°C (Ruckebusch *et al.* 1991). A calm and resting rabbit has a lower body temperature than the agitated animal. Rabbits'

ears are richly vascularised and are used in regulating body temperature (Kawoto *et al.* 1989).

It is normal for the urine of rabbits to vary widely in colour, from different shades of yellow, light brown and even reddish; various degrees of turbidity are also normal because of the high concentration of calcium and mucus, among other reasons (Jenkins 2008). Red coloration of urine may result from porphyrins excreted by the kidneys depending on the diet, and this may be mistaken for blood (Jenkins 2008). The urine volume produced daily is 50–75 ml/kg and the urinary pH is 8–9 (Jenkins 2008). Rabbit urine is alkaline due to the herbivorous diet although lower urinary pH can result from high protein intake and catabolic states such as starvation and severe disease (Jenkins 2008).

## Reproduction

The European wild rabbit is a seasonal breeder, with seasonality determined by the interaction of day length, climate, nutrition, population density, social status and other factors (Bell & Webb 1991; Bell 1999). In Australian wild rabbits sexual maturity occurs at the age of 5–7 months in bucks and 9–12 months in does depending on climate (Myers *et al.* 1994). Domestic rabbits of medium size should be at least 5 months of age at the first mating, but they are sexually mature earlier (Bennett 2001). The smaller breeds are sexually mature earlier than the medium and larger breeds (Bennett 2001).

Before mating an elaborate courtship takes place – the rabbits circle around each other, parade side by side, jump over each other and sniff the genital region (Lehmann 1991). Hafez (1960) described seven degrees of sex drive, which ranged from aggressive with immediate mounting and ejaculation to offensive reaction with general smelling of the skin, biting and no ejaculation. When the doe allows mating she raises the hindquarters (Bennett 2001). Mating takes only a few seconds, after which the buck falls to one side or backwards (Bennett 2001). Ovulation is induced by the act of coitus and conception occurs 8–10 h after mating (Bennett 2001). The doe can mate immediately following parturition, and if the young are removed after delivery the doe will be sexually receptive for at least 36 days (Hagen 1974).

Gestation in European wild rabbits lasts 28–30 days (Bell 1999) and in domesticated rabbits 28–34 days, with most litters being born on day 31 (Bennett 2001). In nature, some days before the birth, the doe digs a short underground tunnel or stop either within the main warren or separately from it and within this constructs a nest (Bell 1999). High-ranking does often give birth in a special breeding chamber dug as an extension to the warren, whereas some of the subordinate females are chased away from the warren and forced to give birth in isolated breeding 'stops' (Mykytowycz 1968). The survival rate of the young is much higher for high-ranking than the low-ranking females (Mykytowycz 1968). Does of both European wild rabbits and NZW rabbits collect and carry grass to their burrows and shortly before giving birth pluck their own fur from the belly, sides and dewlap, which is placed on top of the grass (González-Mariscal *et al.* 1994; Bell 1999). When domestic rabbits are kept in cages, the does also construct nests as in the wild,

and often, the better the construction of the nest, the higher the survival rate of the young (Canali *et al.* 1991).

Rabbits are born with no, or only little, hair cover, and are deaf and blind (Batchelor 1999). They weigh around 50 g at birth and gain about 30 g per day (Falkmer & Waller 1984). The size of the litter is five to six young for European wild rabbits (Vaughan *et al.* 2000), and four to twelve young for domesticated rabbits (Batchelor 1999). At birth, the young rabbits are very sensitive to cold but, as their fur starts to grow some days after birth, they become less sensitive (Bennett 2001). The eyes open at 10–11 days (Kersten *et al.* 1989; Batchelor 1999), and hearing develops at the same time. Once the young are born, the doe leaves the burrow and covers the entrance with soil, urine marks it, and then leaves (Mykutowycz 1968). She returns to the burrow once daily, and then digs herself into the burrow and nurses her young for just a few minutes (Bell 1999). In a study of Dutch Belted rabbits the nursing took place in the early morning and lasted for 2.7–4.5 minutes (Zarrow *et al.* 1965). The composition of the milk is very nutritious with 10% protein, 12% fat and 2% lactose (Harkness & Wagner 1995). Does do not retrieve their young if they are placed outside the nest (Ross *et al.* 1959). After 21 days, the doe ceases closing the burrow or breeding stop and the young come up to the surface (Bell 1999). In NZW does, the young are about 18 days old when she stops closing the entrance to the breeding stop and the young are nursed outside (Lehmann 1989).

At 4 weeks of age the young are very mobile, and soon after emergence they leave their breeding stop and do not return to it again (Lloyd & McCowan 1968). They start seeking forage, but continue to suckle for several more weeks. A study on NZW rabbits indicated that the mothers were not preferred social partners for the young except during suckling attempts (Lehmann 1989). Milk production reaches a maximum about 2 weeks after giving birth, then declines during the fourth week, although lactation may continue for an additional 2–4 weeks (Hagen 1974). Lehmann (1989) also found that, in NZW rabbits, nursing was uncommon after 4 weeks and the doe littered again within a few days, although suckling attempts occurred up to 60 days. At 8 weeks of age, the young consume approximately 90% of their intake in the form of plant proteins (Hagen 1974).

### Normal behaviour (wild and captive)

The rabbit is a nocturnal animal, which rests in the burrows of the warren during the day, and emerges in late afternoon (Fraser 1992). The old bucks emerge first, about 4 h before sunset (Mykutowycz & Rowley 1958), and at sunset 90% of the rabbits have emerged from the burrows up to the ground (Fraser 1992). The rabbits are above ground for 11–14 h of the diurnal cycle (Mykutowycz & Rowley 1958). When they are above ground they spend about 44% of their time eating, 33% inactive, 13% moving and 10% on other activities (Gibb 1993). Young NZW rabbits were active for an average of 30% of the daytime, during which, feeding on pellets occupied one third of this time, grazing took one third of this time, and the remaining one third was spent in exploring, gnawing, intensive locomotion and, for the older rabbits, sexual behaviour (Lehmann 1989). The rabbit's choice of

habitat depends on the opportunities to find shelter and protection; where the soil is loose it digs burrows, and where the soil is more compact it often seeks protection in dense vegetation (Kolb 1994).

Foraging is performed over an area known as the home-range; this is much larger than the 'territory' that breeding groups defend. The size of the home-range varies depending on food availability, number of rabbits in the group and other factors (Donnelly 1997). Wild rabbits have been found to gather in large colonies of up to hundreds of animals under good feeding conditions or at high population densities (Myers & Poole 1963). The home-range of European wild rabbits has been found to vary between studies from 5 ha (Myers *et al.* 1994), 0.4–2.0 ha (Cowan & Bell 1986) and 0.8 ha (Vastrade 1987). In nature, rabbits mainly eat grass and herbs, but also fruit, roots, leaves and bark (Cheeke 1987). Rabbits need coarse fibre for their digestion, not just lush grass (Brooks 1997; Meredith 2000). The colon of the rabbit separates faecal waste from the B vitamin-rich faecal pellets, made up of microbes that the rabbit will ingest (Björnhag 1972). These smaller, soft and green coated faecal pellets produced by the caecum 4–8 h after feed intake (Carpenter *et al.* 1995; Brooks 1997) are picked up directly from the anus, whereas the fibrous pellets are placed on specific latrines close to the territory borders (Donnelly 1997).

The rabbit is a prey animal with many enemies. When threatened, rabbits stamp with their hindfeet and show their scut, as warning signals to other rabbits. If it is too late to flee, the rabbit may freeze. Normally, rabbits do not often vocalise within the auditory spectrum of man, but if caught by a predator they may emit a high-pitched distress scream (Cowan & Bell 1986), which may cause the predator to release it. Apart from this and some low sounds during mating and mother–young care, rabbits are silent animals.

Rabbit movement consists of hopping, crawling and intensive locomotion (ie, running, start-and-stop, jumping, double and capriole) (Kraft 1979; Lehmann 1989). Hopping is used to travel longer distances; whereas crawling is performed when feeding on grass or exploring on the spot and during social encounters (Lehmann 1989). Rabbits rear when they are looking at their surroundings (Lockley 1961). The rabbit has a light and fragile skeleton that only makes up 7–8% of the body weight (Donnelly 1997).

Rabbits have good eyesight with a maximum field of vision of almost 360° (Peiffer *et al.* 1994). They use their whiskers, the sensitive lips, scent and taste during foraging (Meredith 2000). The whiskers are also used during orientation in the burrows and dens (Meredith 2000). Scent and taste are more important than vision in identifying members of their own breeding group (Meredith 2000). Rabbits have good hearing, and the big ears make up about 12% of the total body surface area (Meredith 2000). Rabbits regularly perform comfort behaviours such as licking and scratching themselves, shaking the body, rubbing against objects and stretching their body.

### Sources/supply/transport conservation status

Laboratories usually buy rabbits of defined health status from accredited breeders (Townsend 1969; Eveleigh & Pease

1976; Eveleigh *et al.* 1984). During the last 10–15 years there has been a decline in the total number of breeding units in Europe. The reason is mainly the declining use of rabbits in laboratory animal experimentation. Another reason is the higher demands on animal health and health monitoring documentation. Health screening and documentation are expensive and higher hygienic standards are required within the breeding unit. Costs and higher quality requirements have reduced the number of suppliers. The major laboratory animal breeders are somewhat reluctant to breed rabbits because they require careful management, which affects profitability. Several of these breeders have found it difficult to relocate a colony of breeding rabbits because these animals are sensitive to disturbances of their environment, and changes are immediately reflected in their breeding performance.

Most rabbits have to be transported from the breeder to the laboratory, and this may be done by car, truck, railway or plane. The rabbits should be in good condition before transport. Rabbits are most often transported in containers made of sheet metal, fibreglass, fibreboard, rigid plastic, strong welded wire mesh or wood lined with wire mesh (Swallow *et al.* 2005). The minimum stocking density in transport containers can be found in Swallow *et al.* (2005). The height of the container should be restricted to prevent back injury caused by the rabbit kicking out (Swallow *et al.* 2005). If the containers are constructed without a wire mesh liner it must have wire screening cover on all air vents (Swallow *et al.* 2005). A grid floor or area for rabbits to separate excreta from the lying area may be necessary for long journeys (Swallow *et al.* 2005). If journeys are longer than 24h provisions for feeding and watering are needed, even though rabbits rarely eat or drink during a journey (Swallow *et al.* 2005). See also Chapter 13 for a general discussion of transport.

Transportation vehicles should be equipped with devices for monitoring temperature, and provided with ventilation that can cool the air during warm weather and provide heating during cold weather. A source of water, for example a gel, and feed, has to be provided (Batchelor 1999; Olfert *et al.* 1993). After arrival at the new animal housing the rabbits should be checked for any health problems and injuries, which could either be caused by the transport or have been acquired before the transport. Rabbits should be given time for acclimatisation after the transport before they are used for research. The time period needed for acclimatisation depends on the stress that the animals have experienced during transport, which in turn depends on many factors such as the duration of the transport, the age of the animals and the change of the social environment (European Commission 2007). It is also important to match care routines with those of the supplier.

Very little research has been done into the effect of transport on rabbits. Batchelor (1999) found considerable differences in body weight in rabbits that were housed in group pens compared to solitary in cages after transportation. The loss of weight in rabbits after transport is mostly due to a loss of gastrointestinal contents, which account for about 10% of the total body weight (Swallow 1999). These losses are probably maximal after about 15h of transport and similar to depriving animals of food and water for the same time (Swallow 1999). It can take up to 7 days to recover the

loss in live weight (Swallow 1999). Research on the effect of providing male rabbits with or without hay and with change or no change in the feed after a 10h transport by truck, plane and truck showed that the provision of hay significantly reduced the occurrence of diarrhoea (L. Lidfors unpublished observation).

## Uses in the laboratory

The use of laboratory rabbits has declined over the last decade (Swedish Board of Agriculture 2007). A database search shows a gradual and slight decline of the use of polyclonal antibodies produced in rabbits but there is still a need for these antibodies since they are quicker and easier to produce than the monoclonal antibodies (Cooper & Paterson 2008). Rabbits are still being used in pyrogen testing of intravenous fluids and other technical products intended for patients even though other test methods without live animals are being evaluated (Hoffman *et al.* 2005). Rabbits remain popular models for *in vivo* experimentation, for example in the development of bio implant products such as dental implants and devices for orthopaedic surgery (Batchelor 1999).

Rabbits are used in the study of atherosclerosis after being given high-fat and high-cholesterol diets, which lead to the development of atherosclerotic lesions in the major arteries after approximately 2 months. Rabbits of a spontaneously mutated strain called the WHHL (Watanabe heritable hyperlipidaemic) develop atherosclerotic lesions in their blood vessels even without the high-fat diet (Clarkson *et al.* 1974) and a total of 594 scientific papers on this strain of rabbit were produced during the years 2001–2008<sup>4</sup>.

In toxicology, rabbits are used to detect teratogenic effects of candidate drugs because the embryological development of the rabbit foetus is well known, the gestation period is short and rabbits produce a fairly large number of offspring (Wooding & Burton 2008). For the same reasons, rabbits are used in experimental teratology (Hartman 1974). Rabbits have also been used for cardiac surgery and disease, joint surgery, ophthalmology and studies of hypertension.

## Laboratory management and breeding

### Housing

Laboratory rabbits have traditionally been housed individually in cages for up to several years, depending on the research purpose. One reason for individual housing has been the problems with aggression that may arise in group housing, especially between males. Three main types of cages have been used: (1) wire; (2) sheet metal with wire front; and (3) plastic with wire front (Stauffacher *et al.* 1994; Morton *et al.* 1993). In the past, often no enrichments were provided and the cage sizes were such that rabbits were unable to hop around or sit upright with erect ears. Cages with solid sides, back and top tend to isolate the animals,

<sup>4</sup><http://www.med.kobe-u.ac.jp/iea/whhl-1.html>

**Table 28.4** Recommendations for minimum enclosure dimensions and space allowance for one or two socially harmonious rabbits over 10 weeks of age or a doe plus litter with additional area for nest boxes, and optimum shelf size and height from the enclosure floor (Council of Europe 2006; European Commission 2007).

Final body weight (kg)	Minimum floor area (cm <sup>2</sup> )	Minimum height (cm)	Addition for nest boxes (cm <sup>2</sup> )	Optimum shelf size (cm)	Optimum height of shelf (cm)
<3	3500	45	1000	55 × 25	25
3–5	4200	45	1200	55 × 30	25
>5	5400	60	1400	60 × 35	30

**Figure 28.1** A new type of flexible rabbit cage with a pair of rabbits (Photo: Ann-Christine Nordström.)

and prevent them from seeing the source of disturbance, which may cause them to be startled, and in breeding units, lead to losses due to cannibalism (Stauffacher *et al.* 1994). It is therefore recommended that barred 'windows' occupy 30–50 % of the total wall area (Stauffacher *et al.* 1994).

In order to allow rabbits to perform normal hopping movements and to sit upright the regulations in several countries have required larger cages for over 15 years. Appendix A of the European Convention for the protection of vertebrate animals used for experimental and other scientific purposes (Council of Europe (2006) recommends larger areas and heights than in the preceding Convention from 1986, and these have been adopted by the Commission (European Commission 2007). The minimum floor area and minimum height for rabbits over 10 weeks of age and for does with a litter is presented in Table 28.4. These recommendations are for both cages and pens. The weights are for the final body weight that any rabbit will reach in the housing. The minimum floor area is for one or two socially harmonious animals. In cages, a raised area should be provided. If there are scientific or veterinary justifications for not providing a raised area then the floor area should be 33% larger for a single rabbit and 60% larger for two rabbits. Some European countries have previous stronger national regulations for housing laboratory rabbits, whereas others are currently incorporating the new minimum recommendations into their national regulations.

Improved cages have been developed and tested in parallel with the development of new regulations for housing

rabbits. These cages generally have a larger floor area and greater height to enable more upright sitting, a shelf for rabbits to hop up onto or hide under, racks to make hay feeding easier and flexible cage racks so that several cages can be built together (Figure 28.1). A recent resource produced by the RSPCA and UFAW<sup>5</sup> provides practical suggestions on how to house and manage laboratory rabbits based on their needs. Caged rabbits use boxes and shelves as sources of enrichment and lookout posts (Hansen & Berthelsen 2000), and the presence of the shelf reduces restlessness, grooming, bar-gnawing and nervous responses when being captured (Berthelsen & Hansen 1999).

During the last 10–20 years the approach to housing rabbits has changed considerably, and group housing in floor pens has been introduced in many laboratories and countries (Figure 28.2). In the 2003 Guidelines for the Housing of Rabbits in Scientific Institutions in Australia (Animal Research Review Panel 2003)<sup>6</sup> two key recommendations are that 'Rabbits should be housed in groups in pens' and 'Rabbits should not be housed singly in conventional (un-enriched) cages except in exceptional circumstances ...'. European guidelines (Council of Europe 2006; European Commission 2007) also recommend that wherever it is possible, rabbits should be kept in pens. Housing in pens enables rabbits to

<sup>5</sup><http://www.rspca.org.uk/researchrabbits>

**Figure 28.2** Group housing of does in a research laboratory in Sweden (a) and in a pharmaceutical company in Denmark (b) (Photos: a) Lena Lidfors, b) with kind permission of Novo Nordisk A/S.)

express social behaviours and to exercise (Heath & Stott 1990; Batchelor 1991). The RSPCA/UFAW resource recommends that young rabbits and older females should be housed in harmonious pairs or social groups unless veterinary advice or study design recommends differently. Adult entire males should, on the other hand, be singly housed due to their territorial behaviour and the consequent risks of serious injury.

Floor pens should be large enough for the rabbits to be able to carry out basic behaviours such as locomotion, rearing, grooming and avoiding cage mates, etc. European Commission (2007, Table B.1) recommends that rabbits should be provided with the same pen floor area as in cages, and an extra floor area of 3000 cm<sup>2</sup> per rabbit should be added for three to six rabbits and thereafter 2500 cm<sup>2</sup> for every additional rabbit over six. This is much less than recommended by Morton *et al.* (1993), who suggested that group houses should have a clear area of 20 000 cm<sup>2</sup> with an overall minimum floor area of 6000–8000 cm<sup>2</sup> per rabbit for groups up to six rabbits. One problem with using weight as a criterion for determining floor area is that young animals are more active and might need more space to carry out play behaviours (Stauffacher *et al.* 1994). Swiss legislation from 1991 requires that each rabbit must be able to hop for several steps or to jump up and down onto a shelf. This may help to maintain a level of fitness and reduce the occurrence of disuse osteoporosis (Morton *et al.* 1993). European Commission (2007) recommends that rabbits younger than 10 weeks should be provided with a minimum enclosure size of 4000 cm<sup>2</sup> and a minimum floor area per animal of 800 cm<sup>2</sup> from weaning to 7 weeks and 1200 cm<sup>2</sup> from 7–10 weeks.

The height of floor pens should be 1.25 m, and enrichment objects should be placed so that they cannot be used for jumping over walls (Morton *et al.* 1993). Table B.1 in European Commission (2007) recommends the same minimum height for pens as for cages, but this is too low to stop rabbits from jumping out of the pen. The pen should

contain structures that subdivide the space so that the animals are able to initiate or avoid social contact. Examples of group housing of NZW does in a research laboratory are shown in Figure 28.2.

The floor should be solid and provided with bedding or perforated, rather than grid or wire mesh (European Commission 2007). Wire floors should not be used unless a resting area is provided which is large enough to hold all rabbits at any one time (European Commission 2007). Dimple floors were regarded as the best type of floors in metal cages by Morton *et al.* (1993).

### Social housing

The major factors that need to be considered when group-housing rabbits are: compatibility of individual animals; size of pens; stocking density; husbandry practices; and environmental enrichment (Morton *et al.* 1993). Rabbits can either be group-housed in floor pens or in cages. In the latter case, weight and size limitations usually restrict this to pair-housing (Bigler & Oester 1994; Huls *et al.* 1991; Stauffacher 1993). This combines the benefits of cage-housing (eg, hygiene and experimental purposes, with animal welfare interests) and has been established in several countries (Stauffacher *et al.* 1994). While Stauffacher *et al.* (1994) report that groups of up to 20 laboratory rabbits have been successfully managed as stock and for the production of polyclonal antibodies, for monitoring and observation reasons the number of rabbits kept in group pens should not exceed six to eight mature animals (Morton *et al.* 1993; Stauffacher *et al.* 1994).

Incompatible rabbits fight when placed together in a group, and the greatest problems occur when placing adult males together (Morton *et al.* 1993). There are strain differences in aggressiveness: Dutch rabbits are more aggressive than NZW, whereas Lops are more docile (Morton *et al.*

1993). Some of the small strains of rabbits may show more aggression than the larger strains (Stauffacher *et al.* 1994). Individual animals may be highly aggressive, and fights can occur unexpectedly, even in groups that have been stable for a long time and in which an apparently stable dominance hierarchy has formed (Morton *et al.* 1993). Therefore, groups of rabbits need to be carefully selected and regularly monitored. The best option is to form female groups from litter mates which have been kept together from weaning (Zain 1988). Groups of intact, mature females not intended for breeding can be kept together (Morton *et al.* 1993). During resting, does, bucks and older young kept in mixed groups congregate and snuggle against each other or engage in mutual grooming (Stauffacher 1992). Does have demonstrated a weak preference for a large, enriched, solitary pen over a group pen, but a strong preference for a group pen over a smaller, barren, solitary pen (Held *et al.* 1995). Fighting can occur in groups of does, and a dominant female in oestrus can mount and damage the skin on the backs of other females and harass the group (Morton *et al.* 1993). The degree of compatibility of grouped rabbits depends on factors such as strain, individual characteristics, sex, age and weight, size and structuring of pens, methods of husbandry and the interest and ability of the animal care staff (Bell & Bray 1984; Zain 1988; Morton *et al.* 1993; Stauffacher 1993).

From around 10 weeks of age it may be necessary to house males individually to avoid fighting (Morton *et al.* 1993). Groups of males kept in proximity to females tend to fight and urinate more frequently (Portsmouth 1987). Castration of males kept for longer periods in the laboratory may be one solution to keeping them in groups, although this raises ethical issues, as discussed in the RSPCA/UFWA booklet<sup>7</sup>. The practical experience from castration of males is that aggression is reduced and stable for a long time afterwards (L. Lindberg, personal communication). Castration should be carried out only by qualified persons when the males reach sexual maturity and before they start to show aggressive behaviour, about 3–4 weeks after weaning (Morton *et al.* 1993; Stauffacher *et al.* 1994). The testicles move down during sexual maturation, but can be withdrawn again via the cremaster muscle. Another consideration is the type of research the animals will be used for, as castration has an effect on the animal's physiology and behaviour.

When establishing new groups of rabbits in floor pens, the best option is to wean and mix at the same time around 6 weeks of age and to place 6–10 rabbits preferably of the same sex in one group (Morton *et al.* 1993). The easiest approach is to group-house animals which have been kept in groups since birth (Zain 1988; Stauffacher 1993). Smaller groups may be more stable (Love & Hammond 1991). Some animals do not appear to settle well in groups, either because they are too dominant and bully the others or are too timid and prone to be bullied (Morton *et al.* 1993). When grouping rabbits that have been caged for 6 months or more it may be difficult to avoid fighting or self-inflicted injuries (Morton

*et al.* 1993). However, individually caged adult female rabbits of strains that are known to be docile can be paired successfully, preferably in structured cages (Stauffacher 1993). It is very important to provide refuge and hiding places for subordinate animals (Morton *et al.* 1993).

## Environmental enrichment

Abnormal behaviours in rabbits can be reduced by providing environmental enrichment in their cage or floor pen (See also Chapter 10). Roughage, hay blocks and chew sticks are recommended as suitable enrichment (Council of Europe 2006; European Commission 2007). Morton *et al.* (1993) suggested the following enrichment for caged rabbits: straw, hay, hay blocks, hydroponic grass, pieces of wood or chew sticks, hay rack, small cardboard boxes, taking them out of the cage for handling/petting or for exercise and relief of boredom, provision of bedding, vet beds for pregnant and nesting does and background noise. Gunn (1994) found that stereotypic behaviour in caged rabbits was reduced by the provision of hay, wooden sticks and wire balls. Singly housed male rabbits interacted most often with hay, less with hay blocks, even less with a plastic box and least with chewing sticks (Lidfors 1997), and showed the highest preference for hay, then hay blocks, chewing sticks and lastly a plastic box (Lidfors 1996).

The enrichment items used most often are those that the rabbits can chew on (Huls *et al.* 1991; Lidfors 1997; Berthelsen & Hansen 1999) and high-fibre objects are preferred, with hay or straw remaining effective enrichments for long periods (Brummer 1975; Lidfors 1997). If the supplementary hay is ground, it is ineffective at reducing problem behaviours, demonstrating a need for long fibre (Mulder *et al.* 1992). Hay and straw also cause less weight gain than proprietary fibre sticks or compressed grass cubes (Lidfors 1997). Studies on dietary enrichments, including the supply of fibrous food to reduce boredom, are: hay (Berthelsen & Hansen 1999); grass cubes or hay in a bottle (Lidfors 1997); and fresh grass (Leslie *et al.* 2004). Abnormal maternal behaviours and trichophagia or fur-chewing (Brummer 1975; Mulder *et al.* 1992) are eliminated in caged rabbits when hay or straw is given (Beynen *et al.* 1992).

Mirrors placed in the living area of caged rabbits increase the time they spend there, and especially the time that they spend investigating their environment and feeding (Jones & Phillips 2005). The mirrors probably stimulate activity by increasing the amount of movement perceived by the rabbit (Jones & Phillips 2005). If the racks are placed opposite to each other so that the rabbits can see other rabbits that may also be a form of enrichment (Morton *et al.* 1993).

A technique that has been used in certain Swedish animal laboratories for individually caged male rabbits that cannot be castrated, is to place them individually in an exercise arena at regular intervals. This allows them to move around on a larger floor surface, to investigate enrichment objects and to be exposed to odours from other males that have been exercised before them. To the authors' knowledge this has not been scientifically validated, and the procedure could be stimulating or stressful.

## Environmental provisions

### Temperature and humidity

European guidelines recommend a mean room temperature for rabbits of 18°C with a range of 15–21°C (Council of Europe 2006; European Commission 2007). In rabbits the low critical temperature is –7°C and the high critical temperature is 28°C (Spector 1956). Rabbits only have sweat glands on their lips, and are less able to ventilate through their mouth than dogs (Donnelly 1997). Wild rabbits avoid high temperatures and stay away from sunshine, and during the day they stay in the cooler burrows (Gibb *et al.* 1978). The ears of the rabbit are highly vascular and can function as radiators (Harkness & Wagner 1995).

The relative humidity in rabbit facilities should not be less than 45% (European Commission 2007).

### Light and noise

Batchelor (1999) recommends that the rabbit room has a regular light–dark cycle and that it is isolated from external lighting fluctuations. The lights in many laboratories are usually put on a 12h:12h light–dark cycle. Some laboratory facilities have introduced artificial dawn and dusk periods, which usually last 30 minutes. Sudden illumination of active rabbits may cause them to leap and possibly fracture the spine (Adams 1982). If there is a need to observe rabbits during the period of activity a partially reversed lighting schedule can be used, because rabbits are more nocturnal than diurnal in their activity pattern (Batchelor 1999). The normal diurnal cycle can be disrupted by noise or scheduled feeding in the laboratory (Jilge 1991).

According to Iwarsson *et al.* (1994) the optimal light intensity in rabbit rooms should be 200 lux at 1 m above the floor. However, if the illumination level is too high it can lead to retinal degeneration in some albino mammals, which may also apply to NZW rabbits (Batchelor 1999). Cages with solid sides reduce the amount of light, and cages higher up in the rack have a higher light intensity (Batchelor 1999). In floor pens, shelves and boxes may provide hiding places from high light intensity.

The rabbit's hearing threshold has been reported to be 75–50 000 Hz with the most sensitive hearing between 2000 to about 9000 Hz (Iwarsson *et al.* 1994). The rabbit is therefore sensitive to high-pitched sounds (Milligan *et al.* 1993), but sudden noise may scare rabbits and lead to injuries. A common practice is to use background music to attempt to mask sudden sounds, and this is claimed by some to result in lower excitability (Batchelor 1999).

### Ventilation

European guidelines recommend 15–20 air changes per hour (Council of Europe 2006; European Commission 2007). However, it is possible to have 8–10 air changes per hour if cleaning routines are of high standard and stocking density is low (Adams 1982). There should be no draughts or turbulence in the rabbit room. If the ventilation is not working properly, high levels of ammonia and carbon dioxide may become a problem for the rabbits.

Ammonia level should never exceed 10 ppm. High ammonia levels can inactivate the cilia in the airways of rabbits.

The rabbit moults two to three times per year. Rabbit hair may also be released during handling.

## Food and water

Rabbits are nocturnal and in the wild they usually graze during their active periods at dawn and dusk (Lockley 1961), or during early morning and at night (Cheeke 1987). However, laboratory rabbits in cages are almost invariably not fed the diet of grass for which they are adapted. There is little evidence that they prefer a grass diet to one based on compound feed (Leslie *et al.* 2004). Despite this, it is often beneficial to supplement their ration of proprietary compound pellets with dietary enrichment, which as well as providing adequate nutrients (National Research Council (NRC) 1966), in particular fibre (Lehmann 1990), will increase the time spent procuring food and reduce abnormal behaviours such as chewing their cage (Leslie *et al.* 2004). The visual stimulus of a varied diet is particularly important (Ruckebusch *et al.* 1971). A mixed diet is also a feature of natural herbivore feeding behaviour; due to their need to sample regularly in case of the disappearance of one feed (Parsons *et al.* 1994). Hay can make up a larger part of the feed intake of adult rabbits, and at the same time be an important enrichment (see section on Environmental enrichment).

Water should always be available *ad libitum* (Mader 1997). Rabbits fed on dry diets require approximately 120 ml water/kg body weight (Cheeke 1987), or 10% of the body weight per 24 h (Meredith 2000). More water should be provided for growing animals, pregnant and lactating females and for rabbits fed high-fibre diets (Cizek 1961).

## Hygiene

Since rabbits have a sensitive digestive system with intensive interaction between the intestine and its microbiological flora, the hygiene of the cage or pen where the rabbit is held is important. Rabbits are coprophagic, but they ingest only one type of faecal pellet. The remaining faeces may contain coccidia spores and pinworm eggs that can re-infect the animal and the heavy breeds may develop cutaneous infections on their hindlegs from soiled bedding or wire floors (Bergdall & Dysko 1994).

The frequency of cleaning out and disinfection of pen floors, cage waste pans or other areas where the faeces and urine of the animals may accumulate depends on the number of animals in each cage or pen, the sizes of the animals, their diet and on other physical and practical arrangements in the animal rooms such as the efficiency of the ventilation equipment, etc. It is not possible to give specific recommendations because circumstances vary between laboratories. The room air should be perceived as fresh and clean without any smell. If there is any doubt, ammonia levels in the air can be measured. The animals should have clean fur coats and be clinically healthy. Over-zealous cleaning of any animal envi-

ronment could be stressful to the animals because of changes to the olfactory environment (Batchelor 1999).

### Health monitoring, barrier systems and quarantine

High health standards result in good welfare and good science. Today most breeders use barrier breeding systems with regular health monitoring. The biosafety strategy of breeders includes: control of entry of staff and goods into the breeding rooms; procedures for sterilisation of goods such as bedding, diets and other materials; and regular education and awareness training for staff. Strict barrier regimes avoid introduction of animals from elsewhere, but rely on re-deriving rabbit pups from pregnant does by caesarean section, after which the young are hand-reared. Some breeders even have regularly scheduled refurbishments of their breeding units as a part of their biohazard management.

Animal health records should show the frequency and interval of different samples taken, the result of analysis and the methods used as well as which laboratory was used. In Europe FELASA, the Federation of European Laboratory Animal Science Associations, has issued recommendations for health monitoring laboratory animals in different situations, at the breeding site and in the research laboratory (FELASA 2002).

When rabbits are introduced to a colony, quarantine can be used as a precaution if there is any doubt about their health status, but most health problems of laboratory animals nowadays are subclinical. Thus, it is unlikely that there will be clinical signs of disease during the period of quarantine. The establishment's quarantine procedures in combination with serological sampling for the more commonly occurring infectious agents could be used, but this can be time consuming and result in extra costs.

### Breeding

Females can be mated for the first time at 4–5 months if they are of a small breed, 4.5–5 months if they are of a medium breed (for example NZW) and 6–9 months if they are of a large breed (Harkness & Wagner 1995). Bucks are usually used for breeding for the first time at about 6 months of age (Harkness & Wagner 1995). The decision to use a female for breeding is based on her age (4–6 months), clinical condition, weight (3–4 kg for NZW) and observation of periodic congestion of the vulva (Harkness & Wagner 1995).

Follicle-stimulating hormone (FSH) induces growth of ovarian follicles with development of ova, and the follicles produce oestrogens, which cause the female to be receptive to the male (Patton 1994). Follicular development occurs in waves, and follicles at several stages of development are always present (Patton 1994). When follicles reach mature size they produce oestrogens for 12–14 days, but if ovulation does not occur they degenerate with a corresponding reduction in blood concentration of oestrogens and sexual receptivity (Patton 1994). After about 4 days, new follicles start producing oestrogens and the doe becomes receptive again (Patton 1994). This leads to the doe having a cycle of 16–18 days during which she is receptive for 12–14 days followed

by 2–4 days when she refuses to mate (Patton 1994). However, there have been several cases where does have been receptive for 14–16 days followed by a period of non-receptivity for 1–2 days (Patton 1994).

Does may vary in receptivity due to individual differences, sexual stimulation and environmental factors, such as nutrition, light and temperature (Cheeke *et al.* 1987). Sometimes does refuse to mate with a certain buck, possibly because the buck adopts a poor mounting position or because of his aggressiveness (Patton 1994). When the doe is receptive the vulva changes colour (Cheeke *et al.* 1987) and it changes to a darker pink or red and becomes swollen and moist (Patton 1994).

In captivity, the male's courtship behaviour is often restricted to tail flagging, urination and licking the genitalia (Patton 1994). A jet of urine (enurination) may also be directed at a doe (Patton 1994).

For mating, the doe should be taken to the buck's cage to avoid territorial behaviour, ie, either the doe attacking the buck or the buck showing more interest in exploring and marking the new territory (Patton 1994; Bennett 2001). If the doe is not receptive she becomes aggressive and produces a special vocalisation (B.-Å. Sandeberg, personal communication). When a receptive doe has been placed in the buck's cage she raises her hindquarters to allow copulation (see Reproduction section for more details). If copulation does not occur within 2 minutes after the doe has been placed in the buck's cage she should be removed as injuries and stress to both doe and buck may occur if they are left together too long and bucks may become poor breeders if they are repeatedly rejected by does (Patton 1994). Bucks are very fertile, even if they are used daily or several times per day (Patton 1994). If bucks are used several times in a 24 h period they are often rested on the next day, but they can also be used for multiple breeding several days in a row and then be rested for several days (Patton 1994). A common practice is to keep one buck for every 10 does, but many breeding facilities use one buck per 25 does (Patton 1994).

Ovulation is induced by mating, and occurs 10–13 h after coitus (Patton 1994); it may also be induced artificially by injecting luteinising hormone or human chorionic gonadotropin, electrical or mechanical stimulation or after contact with other does (Patton 1994). Some does may fail to ovulate after coitus, possibly as a result of a deficiency of luteinising hormone (Fox & Krinsky 1968). The number of ova released has been found to be correlated with body weight (Staples & Holtkamp 1966), so that heavier does tend to get larger litters compared to does with lighter weights. High ambient temperature has been found to depress the conception rate, especially when the temperature is high for longer periods (Sittman *et al.* 1964).

Pregnancy can be determined by palpating the developing foetuses at 12–14 days of pregnancy (Cheeke *et al.* 1987), looking at swelling of the mammary glands in late gestation (Patton 1994) or by radiographic confirmation after 11 days (Hafez 1970).

The gestation length is 31–32 days (Cheeke *et al.* 1987), and a large-scale study found that 85.5% of NZW litters were born on days 31 and 32 (Templeton 1939). Larger litters were carried for shorter times than smaller litters (Templeton

1939). Parturition usually occurs during the morning (Sawin 1950). The birth of each young takes less than 30 minutes, but young may be born several hours or days apart (3 days for live young (Patton 1994)). Foetuses older than 35 days die, and if they are not expelled can prevent future pregnancy (Adams *et al.* 1967).

Rollins *et al.* (1963) found that the most important influence on litter size was the parity of the doe, with second and third litters having the highest number of young, fewer young in fourth and fifth litters and least young in first litters. Sittman *et al.* (1964) demonstrated seasonal variation in litter size, with the highest born in February and the lowest in September.

Post-partum mating usually occurs 4–8 weeks after birth of a litter, when the young have been weaned (Patton 1994). Does will mate immediately following parturition, and if the young are removed sexual receptivity continues for at least 36 days (Patton 1994). Post-partum receptivity declines during lactation and increases again once the young are feeding themselves (Patton 1994). Females are most difficult to breed at the peak of lactation – approximately the third week (Cheeke *et al.* 1987), which may be a result of loss of body weight (Patton 1994).

Pseudo-pregnancy may be caused by an infertile mating, sexual excitement being caused by one doe mounting or being mounted by another or by injecting luteinising hormone (Patton 1994). It lasts for 16–17 days and ends when the doe attempts to make a nest at 18–22 days (Patton 1994). During pseudo-pregnancy the corpora lutea secrete progesterone, which causes the uterus and mammary glands to grow (Asdell & Salisbury 1933). For more information about maternal behaviour and nursing see the section on Reproduction.

In commercial rabbit breeding, both for laboratory and food production purposes, the young are weaned and separated from the doe at 6–7 weeks of age (Hagen 1974; Bennett 2001), but some commercial breeders of laboratory NZW rabbits wean the young at 5 weeks (B.-Å. Sandeberg, personal communication).

When breeding rabbits are kept in groups, the groups should be composed of four to six females, one male and their offspring until they are weaned at 30 days of age (Stauffacher *et al.* 1994). A group breeding housing and management system has been developed in Switzerland (Stauffacher 1989) and used in agricultural rabbit farming, but not, to the authors' knowledge, for breeding laboratory rabbits.

### Identification and sexing

Young rabbits are weaned at 5–7 weeks. At this time the young are also sexed and males and females placed in separate cages. This procedure requires some training. The male rabbit's penis can be extruded from the age of 2 months which is considerably later than weaning age (Harkness & Wagner 1995).

Many breeders also perform identity marking at weaning using ear tattoos, tags, etc, or subcutaneously implanted microchips. As a general principle the least invasive method, compatible with the end use, should be chosen.

## Laboratory procedures

### Handling

Handlers should keep in mind that rabbits, as prey animals, naturally try to flee if they perceive a threat. Rabbits are able to recognise individual humans which they can recognise by voice. Rabbits are rarely aggressive if handled in a calm and steady manner without intimidating the rabbit by unfamiliar sounds or odours.

To pick up an animal, the scruff of the neck is grasped firmly with one hand; the animal is lifted up, using the other hand to support the body, and placed on the other arm with its head in the opening between the elbow and the body of the handler (Figure 28.3). For transport over a short distance, this lets the animal rest in a normal posture on the forearm of the handler with its head hidden whilst the hand of the handler holds the scruff (Stein & Walshaw 1996). It is also possible to transport the rabbit a very short distance by holding the scruff of the neck with one hand and supporting the rabbit under the hindlegs with the other hand. While handling rabbits, it is advisable to wear long-sleeved garments because the claws of rabbits may scratch the skin of the handler's arms if they are unprotected by clothing (Suckow & Douglas 1997). Because rabbits have a fragile skeleton and strong hindleg muscles, struggling may cause fracture of the spinal vertebrae (Marston *et al.* 1965).

### Training/habituation for procedures

Rabbits can be accustomed to laboratory procedures just as any other animals. It has been shown that early handling of rabbits results in more active, alert and exploratory animals, which approach novel stimuli more often (Harkness & Wagner 1995). Animals which are well acquainted with their handlers and environment are less stressed in experimental situations and this improves the outcome of the scientific work (Toth & January 1990). See also Chapter 16.

### Physiological monitoring

Rabbits are often used in immunisation studies involving blood sampling. General advice on blood sampling techniques can be found in Joint Working Group on Refinement (JWGR) (1993). Blood can be taken from the marginal ear vein (Figure 28.4), from the central artery of the ear or by cardiac puncture. Cardiac puncture is carried out with the animal in dorsal recumbency and only under anaesthesia (Batchelor 1999). After cardiac puncture the animal should be immediately killed because of the risk of damage to the pericardium and subsequent heart tamponade. When using the marginal ear vein, application of a local anaesthetic ointment 15 minutes earlier facilitates the removal of blood from those animals which are distressed by the insertion of the needle into the ear vein (Batchelor 1999).

For collecting larger volumes of blood, the central ear artery is a better choice since the blood flow is stronger here but care must be taken to ensure that the puncture site is compressed afterwards in order to stop the vessel from

**Figure 28.3** A rabbit, its movement restrained (a), taken by the scruff with one hand and carefully moved through the air (b), and held towards the body resting on the other arm with the face tucked under the arm (c). When the rabbit is lifted back to the cage again the other hand supports the body of the rabbit (d). (Photos: Ann-Christine Nordström.)

**Figure 28.4** Collection of blood from the ear vein of a rabbit. (Photo: Ann-Christine Nordström.)

bleeding after sampling. This can be achieved using manual compression or a temporary compression bandage. Up to 10% of the total blood volume of the rabbit can be removed. If multiple samples are taken, the rabbit should have a

recovery period of 2–3 weeks after the maximal amount of 10% of the blood volume has been sampled. Rabbits have 60–70 ml blood per kg body weight.

The body temperature of rabbits should be taken by a suitable thermometer that has been lubricated for ease of introduction into the anus (Batchelor 1999). The rabbit should be gently restrained, the tail lifted and the thermometer inserted without any force. The thermometer should be left *in situ* for 1–2 minutes. In rabbits the normal rectal temperature is 38.5–39.5°C (Ruckebusch *et al.* 1991).

#### Administration of medical treatment or compounds

General advice on the administration of substances can be found in JWGR (2001). Rabbits are easily dosed subcutaneously under the skin of the neck and the upper back area. The drugs or compounds given should be pH neutral because rabbits tend to develop subcutaneous abscesses after injections of irritant substances. Intramuscular injections can be given in the hindleg, in the quadriceps muscle; they can also be given into the dorsal lumbar muscles but there is a risk of damage to the ischiatic nerve running down

the back and lateral part of the hindleg. In general, intramuscular injections should be avoided because they are often painful for the animal and the rate of absorption is not much quicker than from subcutaneous sites.

It is relatively easy to perform intravenous injections with a needle or infusions using an indwelling catheter placed in the marginal ear vein, and this route has many advantages such as quick onset of action of the injected compound.

Intraperitoneal (ip) injections can also be used but there is a great variability in the rate of uptake after injecting ip since there is a likelihood that at least some of the material injected will enter the gut (caecum), fatty tissue or the urinary bladder rather than the serosal cavity. Rabbits which are not trained usually struggle when restrained with their belly upwards for receiving the ip injection and this increases the risk of a less than perfect injection.

For enteral administration, gavage can be performed with a soft tube passed into the rabbit's stomach. This technique must be learnt under supervision of a person skilled in the procedure. Rabbits can be trained to ingest sweetened fluids from a syringe and it is possible to dose rabbits orally by this route, for example to provide post-surgical pain relief.

### Anaesthesia/analgesia

Suitable anaesthetic and analgesic regimes should be chosen in co-operation with the laboratory animal veterinary surgeon. Depending on the equipment available, a regime based on injectables alone or a combination of injectable agents and gaseous anaesthesia may be used. Rabbits are sensitive to smells of anaesthetic gas, which renders induction of the anaesthesia difficult using gaseous agents (Svendsen 1994). Induction by injectable agents is preferable, followed by gaseous anaesthesia, which allows easy control of the depth and length of the anaesthesia (Svendsen 1994). When using only injectable agents, the use of a continuous infusion can be considered because it is easier to adjust the duration of anaesthesia to suit the length of the surgical procedure than with bolus administration (Svendsen 1994). Further advice can be found in Flecknell 2009.

Post-surgical care of rabbits includes placing them in a recovery cage, the box they were placed in before surgery or the home cage which has been lined with a tray liner (Batchelor 1999). The liner may be folded over the animal to minimise hypothermia. Commercially available veterinary bedding may also be used. The liner or bedding should be removed about 30 minutes after the animal has regained consciousness and is sitting up (Batchelor 1999).

If several group-housed animals have undergone surgery, the last animal must be completely conscious before all the animals are returned to the pen simultaneously (Batchelor 1999). If animals are returned to a group pen whilst still recovering consciousness they may be subjected to aggression (Batchelor 1999). Incision sites should be covered with a clear plastic dressing spray. Rabbits may occasionally interfere with their stitches (Batchelor 1999), and if this happens a plastic collar can be used to restrict the animal's access to the surgical wound (Batchelor 1999).

### Euthanasia

Euthanasia of rabbits is most commonly performed by intravenous injection of an overdose of anaesthetic agent, such as sodium pentobarbital or anaesthetic mixtures. Captive bolt followed by exsanguination is another method for euthanasia that can be used by experienced personnel if the use of chemical euthanasia is for some reason unsuitable or contraindicated. Physical dislocation of the neck followed by exsanguination is an option for rabbits up to 1 kg body weight. Concussion and exsanguination can be done on unconscious animals. Decapitation should only be carried out on animals weighing less than 1 kg, which are already unconscious.

### Common welfare problems

#### Health

The clinical health of modern laboratory animals is rarely a major issue; more important are subclinical infections and the ways they may affect and alter research results. For example, it is quite possible for rabbits not to show clinically obvious signs or symptoms of disease unless they are negatively influenced by multiple agents or other stressors simultaneously (Nerem 1980). However, there are some differences between rabbits and more commonly used species – mice and rats. Health management of mice and rats is an issue mainly of maintaining freedom from pathogens of viral, bacterial and more rarely parasitic origin; rabbit health management is mainly concerned with maintaining freedom from parasites and to some degree from bacteria. All major breeders of laboratory rabbits use a health-monitoring programme and these programmes comprise microbiological testing and some pathology surveillance. In Europe the Federation of European Laboratory Animal Associations (FELASA 2002) recommendations are widely accepted

A healthy rabbit has alert and clear eyes and well groomed fur. Even if the animal is well accustomed to being handled by humans, it will jump in an effort to escape if startled by a handler. A daily health check should include observation of the animal's posture, its eyes and nose to look for discharge and the state of the fur. When rabbits are group-housed, a check for wounds inflicted by other animals should also be made at least once daily. The faeces and urine should also be checked for abnormalities. Normal faeces should consist of dry pellets of a uniform size and normal urine can vary in colour from yellow to dark red and is often cloudy due to the excretion of calcium<sup>8</sup>.

The FELASA recommendations are based on the incidence of different infections and vary depending on the size and purpose of each colony. When the FELASA guidelines for health monitoring of laboratory rabbits are followed, the animal can be called a 'health defined rabbit'. There are similar terms of earlier origin that are sometimes used for the same purpose, (SPF, specific pathogen free or VAF, virus antibody free animal). These different terms aim to provide information about the microbiological health status of the

<sup>8</sup><http://www.aquavet.i12.com/Rabbit.htm>

rabbits in a colony. Health monitoring results are always historical and documentation should be read carefully with attention to how often the samples are taken, which method of evaluation has been used and the rationale for why certain agents are or are not evaluated in the specific colony.

## Infectious diseases

### Bacterial agents

The main infective causes of respiratory inflammations are *Pasteurella multocida* and *Bordetella bronchiseptica*, which cause symptoms such as sneezing, coughing, nasal discharge and lethargy. Abscesses in subcutaneous tissues, behind the eye bulb or in internal organs, as well as inflammation of the mucous membranes of the eyes and middle ear are often caused by *Pasteurella multocida* and *Staphylococcus aureus*. Bacterial eye infections by *Moraxella catarrhalis* can also occur in laboratory rabbits.

Young rabbits are particularly susceptible to bacterial imbalances within the intestine leading to conditions such as mucoid enteritis. Depression, anorexia, diarrhoea and mucus in the stool are the main symptoms; the cause is multifactorial with the bacterium *Clostridium spiroforme* being one of the major factors (Peeters 1986). Bacterial enteritis associated with diarrhoea as main symptom may also be caused by *Escherichia coli* and other strains of clostridia. Nutritional imbalance and lack of dietary fibre can predispose rabbits to enteritis.

### Viral infections

Even though viral infections are not a major problem in barrier-bred laboratory rabbits, it is important to be aware of the potential of viral causes of disease. Mild diarrhoea may be caused by rotavirus and rabbit enteric coronavirus. Breeders and owners of pet rabbits fear rabbit viral hemorrhagic disease (RVHD). The symptoms of RVHD include lethargy, anorexia, diarrhoea and haemorrhage from body openings such as the nose and urogenital openings. This disease is unlikely to occur within a modern laboratory rabbit colony. Myxoma virus can be transferred to laboratory rabbits by vectors such as fleas and other insects. Because myxomatosis is common in wild rabbits it is possible for laboratory rabbit colonies located in areas with large populations of wild rabbits to be infected.

### Parasites

Endoparasites (parasites inside the body) are more common than ectoparasites in laboratory rabbits; among endoparasites, coccidiosis is the greatest problem. This disease is caused by different strains of *Eimeria*. For example, *E. stiedae* is a strain infecting the liver and causes a wide range of symptoms from slight growth retardation to death. Several *Eimeria* strains such as *E. perforans* and *E. magna* affect the intestine of rabbits. The symptoms of coccidiosis depend on the location and number of coccidia in the gut and on the susceptibility of the animal. Younger animals more often show symptoms such as weight loss and mild to severe

intermittent diarrhoea, whereas older animals rarely show any signs at all (Peeters 1986).

*Passalurus ambiguus*, the rabbit's pinworm, can colonise the caecum and colon and its eggs are passed in the faeces but these infections seldom affect the animals to such a degree that signs can be seen.

*Encephalitozoon cuniculi*, an intracellular protozoan, gives rise to a disease called encephalitozoonosis or nosematosis. This disease is common in pet and wild rabbits and regularly occurs in laboratory rabbits. The parasite is transmitted by the urine of infected animals via the oral route to the intestine and tissues of susceptible rabbits. Clinical signs are not always apparent, but heavy infections damage the kidneys and the brain of infected animals.

The two most common ectoparasites of pet rabbits are ear mites and fur mites, although these are rare in laboratory rabbit colonies. *Psoroptes cuniculi*, the ear mite, causes wounds on and around the ears. The fur mite, *Cheyletiella parasitivorax*, along with other mites, fleas and lice of rabbits, can cause considerable suffering and may induce self-inflicted wounds. Itching and anaemia caused by these blood-sucking insects result in poor general condition in the rabbit.

### Traumatic injuries

Among animals that are housed in pairs or groups, the most common cause of traumatic injury is fighting. Both sexually mature males and females that are not acquainted with each other can fight aggressively. The likelihood of fighting increases when groups of animals are housed in overcrowded pens with too few water bottles or food hoppers. The wounds inflicted by fighting males can be severe and need suturing but may often be concealed by the fur of the animal if they are small.

The skeleton of rabbits is fragile in comparison to its muscular hindleg strength (Rothfritz *et al.* 1992), and rabbits which are not accustomed to handling by humans may struggle forcefully when picked up in the cage, resulting in vertebral fracture.

### Diseases associated with housing, feeding and breeding regimes

The standards of housing, maintenance routines, hygiene measures and feeding and watering regimes all affect the health and well-being of rabbits. Animals held in pens on floor or in solid-bottom cages need management and thorough cleaning and disinfection of the pen or cage in order to minimise the spread of intestinal parasites and bacteria. Keeping the litter dry prevents coccidia from multiplying and minimises the need for frequent changes, which may then be as low as once monthly. Perforated cage floors that allow droppings to fall down onto a tray underneath help reduce the number of coccidian spores and bacteria in the immediate environment of the animal.

If larger rabbit breeds are kept in poorly designed perforated or wire mesh floors 'sore hocks' or pododermatitis can occur. Some individuals seem to be sensitive to wood shavings and other materials commonly used as bedding material in pens or solid-bottom cages. Inadequate hygiene is a predisposing

factor. Symptoms include bleeding and chronic wounds on the hindfeet of affected animals. Softer bedding material and improved hygiene will be beneficial to these animals.

Dietary fibre concentration is critical for the intestinal flora and the intestinal morphology of rabbits (Tawfik *et al.* 1997). Young animals are most sensitive to imbalances caused by lack of fibre. Sufficient dietary fibre is essential to keep the animals from developing soft stools or diarrhoea.

Health problems may also arise from the feeding of modified laboratory diets during investigations, where the aim may be to produce metabolic changes in the rabbit. For example, diets containing high concentrations of fatty acids and cholesterol intended to produce atherosclerosis during long-term studies, may cause the deposition of fat in the liver and cholesterol in different parts of the body.

### Behavioural abnormalities

Laboratory rabbits kept in small or barren cages may develop stereotyped behaviour, for example, wire-gnawing and excessive wall-pawing (Lehmann & Wieser 1985; Wieser 1986; Bigler & Lehmann 1991; Loeffler *et al.* 1991; Stauffacher 1992). Wall-pawing, which is derived from digging, may be constrained by the solid floor of the cage (Podberscek *et al.* 1991). Individually caged rabbits can show changes in their behaviours such as somersaulting, no full hops, less activity than group-penned rabbits, and less marking and investigatory behaviour than in group pens (Podberscek *et al.* 1991). Social isolation can induce physiological symptoms of stress, which may be relieved by the presence of conspecifics (Held *et al.* 1995). Stereotypic behaviour may indicate frustration, anxiety or boredom, and develop through a number of stages involving a progressive narrowing of the behavioural repertoire (Gunn 1994).

Singly housed laboratory rabbits in barren environments often show signs interpreted as boredom, such as hunched posture (Gunn & Morton 1995a, 1995b), inertia (Metz 1984), and a staring coat and dull eyes (Wallace *et al.* 1990). Chu *et al.* (2003) found that singly housed rabbits showed more abnormal behaviour and less movement than pair-housed rabbits. Prolonged inactivity associated with unresponsiveness may occur as well as, or in place of stereotypic behaviour, and is thought to be associated with changes in brain chemistry intended to help alleviate boredom (Broom 1988). Under-grooming may lead to development of a staring coat (Gunn & Morton 1995a), whereas over-grooming may result in development of hair-balls in the stomach (gastric trichobezoars) which in turn may cause intestinal stasis (Jackson 1991) and, if uncorrected, lead to death (Wagner *et al.* 1974). Other behavioural problems include under-eating and over-eating, associated with weight loss and obesity, respectively (Gunn & Morton 1995a).

The freedom of movement of rabbits housed in cages is very limited; for example normal hopping is impossible. This causes changes in the muscles, joints and bones (Lehmann 1989; Stauffacher 1992); and changes in the bone structure particularly evident in the femur proximalis (thinner and less strong bone) and the vertebral column (Lehmann 1989; Drescher & Loeffler 1991a, 1991b). Growing rabbits kept in cages perform almost no hopping or inten-

sive locomotion, for example associated with play, when compared to those reared in outdoor enclosures (Lehmann 1989). The most common movement pattern, crawling, occurs at a slightly lower frequency in the cages (Lehmann 1989). In cages, rabbits often perform interrupted jumps, where the hindlegs are only lifted slightly and then put down again, so that the musculoskeletal system is not used as in normal hopping (Lehmann 1989). Rabbits may also show abnormal postures because of spatial constraints, for example when lying stretched out during resting or when performing stretching behaviour (Gunn 1994).

Rabbits may also show restlessness, such as non-functional bouts of activity with disconnected elements of feeding, comfort, resting, alertness and withdrawal behaviour alternating with locomotion with social and temporal disorder in behaviour, and panic (Lehmann & Wieser 1985; Bigler & Lehmann 1991; Stauffacher 1992).

A variety of disturbances to sexual behaviour have been described, some of which may lead to low conception rates (30–70%) (Stauffacher 1992). For example, abnormal mating behaviour following placement of the doe into the buck's cage has been described as rape (Stauffacher 1992). The doe may show disturbed nesting behaviour and nesting stereotypes which may lead to rearing losses (Wieser 1986; Wullschleger 1987; Loeffler *et al.* 1991). In addition, the doe may show disturbed nursing and cannibalism associated with restlessness which may also increase rearing losses (Bigler 1986; Brummer 1986; Stauffacher 1992).

### Acknowledgements

The authors want to thank AstraZeneca R&D Mölndal for letting Lena Lidfors carry out research on improving the housing of laboratory rabbits and for financing the time for Therese Edström to write this chapter. They also want to thank the Department of Animal Environment and Health for financing the time Lena Lidfors has used to write this chapter. They send a special thanks to Bengt-Åke Sandeberg at KB Lidköpings Rabbit Farm for sharing his knowledge on breeding laboratory rabbits with them. Special thanks are also sent to Ann-Christine Nordström at Astra Zeneca for taking some of the photos for this chapter.

## The ferret

Michael Plant and Maggie Lloyd

### Biological overview

#### General biology

The domestic ferret belongs to the family Mustelidae which includes stoats, weasels, badgers and mink. All mustelids secrete a strong-smelling musk from their anal glands, and ferrets are no exception. They have the Latin name *Mustela putorius furo*, which translates as 'stinky raging thief'.

Ferrets are thought to be a domesticated form of the European polecat (*Mustela putorius putorius*), with which they can interbreed, although their masks are different and polecats have darker fur (Ryland & Gorham 1978). Ferrets are more docile than polecats, but have retained many of their natural behaviour patterns. Different varieties of domestic ferret can be distinguished based on fur coloration. The most common or wild type variety is known as 'fitch' or 'polecat' (black guard hair, cream undercoat, black points, lighter facial fur with dark mask, dark brown or black eyes). This fur pattern is very similar to that of the wild European polecat, and has led to confusion between feral pigmented ferrets and wild polecats. Other colours include cinnamon (beige guard hair, cream undercoat, no mask) and the albino, or English ferret. Albinos have yellow or white fur and pink eyes. The albino variety is genetically recessive to the pigmented wild type.

Both male and female ferrets show marked seasonal variations in coat and body weight (Lloyd 1999). The overall coat colour and pigment distribution are similar throughout the year, although under natural lighting conditions they moult in the autumn. The coat in males is usually not fully replaced until the end of the breeding season. In females, a moult follows the first ovulation of the season and usually subsequent ones, but may be delayed during lactation. Moulting can sometimes result in marked alopecia.

The natural history of the domestic ferret is uncertain due to the lack of written records, but it is likely that ferrets have been domesticated for at least 2500 years (Lloyd 1999; Porter & Brown 1997). Early Greek and Roman records describe an animal that was almost certainly the ferret, and pictures have been found in Egyptian tombs of ferret-like animals on leads. It is not certain for what purpose the ferret was originally domesticated, but they have been used for hunting small game such as rabbits, and for the control of rodents and snakes. The general external morphology of the ferret resembles that of other members of the family Mustelidae,

having the typical characteristics of a sleek, flexible, elongated tubular body, relatively short legs and small rounded ears. These characteristics allow the animal to work in confined spaces, as they can move freely and turn round in narrow tunnels. Ferrets can be trained to work on leads or lines and to come to call and have been used to lay cables. They have also been bred for their fur, known as fitch. Ferrets are still used for hunting today but increasingly are kept simply as pets.

Ferrets are highly intelligent, agile, lively, playful and curious. Their natural instinct is to explore and, if kept and handled appropriately, they do not develop a fear of humans or human environments (Porter & Brown 1997). Their motivation to explore needs to be taken into consideration when designing cages and pens, as the curious nature of these animals leads them to test all avenues of escape and adventure. Any hole large enough to get a head through will allow the animal to escape, with potentially tragic consequences for the ferret itself or neighbouring rodent or bird populations (Lewington 2000). Cage furniture should also take this inquisitiveness into account. Tubes, tunnels, boxes and paper bags can all help to provide a more interesting and stimulating environment, which is essential for the well-being of ferrets, but must be designed such that the animals cannot chew and swallow them, leading to gastrointestinal foreign bodies.

Ferrets have an undeserved reputation for being aggressive. Ferrets certainly play roughly with each other, dragging other ferrets by the neck and ears with lots of squealing, and may mistake a tentatively approaching hand for food, but they respond well to frequent handling and rapidly become friendly. Properly handled and well kept ferrets are neither smelly nor aggressive.

#### Size range and lifespan

Ferrets vary considerably in size according to season, sex and reproductive status. Both sexes show seasonal fluctuations in body weight of up to 30–40%, as subcutaneous fat is laid down in the autumn and shed in the spring (Burke 1988; Lloyd 1999). They range from 0.5 kg (females) to 2.5 kg (males) (see Table 29.1). They measure between 44 cm and 60 cm in length, including their tails. Their normal lifespan is 5–10 years but under favourable conditions some may live considerably longer.

**Table 29.1** Standard biological data for the ferret (Fox 1998; Lloyd 1999).

Parameter	Value
Adult weight <sup>a</sup>	
Male (kg)	1–2
Female (g)	600–900
Life-span (average) (years)	5–11
Body temperature (°C)	38.8 (37.8–40)
Chromosome number (diploid)	40
Blood pressure systole (mmHg)	140 +/- 35
Blood pressure diastole (mmHg)	110 +/- 31 Mean diastolic
Heart rate (beats/min)	110–125 (anaesthetised)
Cardiac output (ml/mm)	200–400
Circulation time (s)	139
Blood volume (ml/kg)	45–70
Male	60
Female	40
Respiratory frequency (breaths/min)	33–36
Dental formula	
Permanent	$I^3C^1_1Pm^3_3M^1_2$
Deciduous	$I^4C^1_1Pm^3_3$
Vertebral formula	C7, T15, L5(6), S3, Cy18
Puberty (months)	8–12
Length of breeding life (years)	2–5
Gestation (days)	42 ± 2
Litter size	
Average	8
Range	1–14
Birth weight (g)	6–12
Eyes open (days)	34
Onset of hearing (days)	32
Weaning (weeks)	6–8
Food consumption (g/24 h) <sup>b</sup>	50–75
Water intake (ml/24 h)	75–100
Urine volume (ml/24 h)	26–28
Urine pH	6.5–7.5

<sup>a</sup>Both sexes show seasonal weight fluctuation of 30–40%. Fat is laid down in autumn and lost in winter.

<sup>b</sup>Dry carnivore pelleted diet. Soak in hot water to form a paste, give 140–190 g daily.

## Social organisation

Ferrets are domesticated animals, and are not generally found in the wild. Being closely related to polecats, ferrets can interbreed with them, and this has occasionally resulted in feral colonies of ferret–polecat hybrids. What is known of the natural social organisation of ferrets comes from studies of these feral ferrets and of the European polecat. These studies lead to the conclusion that wild ferrets are largely solitary (Clapperton 2001). The males, or hobs, occupy large territories, which usually include those of several females, or jills with whom he mates. Young ferrets are born in the spring or summer, and initially accompany their mother on

hunting expeditions. They may remain together as a group after weaning until they finally disperse in the spring following their birth and establish their own territories. However, domestic ferrets are sociable and gregarious, and seem to benefit from being kept in compatible groups in captivity, where interaction with other animals provides environmental enrichment. Groups of jills without litters, young animals and castrated males (hobbles) can be kept together, although group housing is not advisable for adult hobs, jills with litters and females that are in oestrus or have been mated, which should be kept separately.

## Standard biological data

Standard biological data for ferrets is shown in Table 29.1.

## Reproduction

Ferrets, like wild polecats, are seasonal breeders. They become sexually mature in the spring following birth, at between 8 and 12 months of age (Burke 1988). The breeding season is determined by photoperiod, responses being mediated via the pineal body. Males are light-negative: they begin coming into season as the day shortens, whereas females are light-positive, responding to increasing day length. In the northern hemisphere, males are in breeding condition between December and July, and females between March and September. The seasonal nature of breeding means that ferrets generally have one litter per year, in the late spring or early summer, and may sometimes have a second litter at the end of the summer, although first litters are generally superior in vigour to subsequent ones.

Females in oestrus develop vulval swelling which peaks 1 month after the onset of oestrus and is easily identified. Ferrets are induced ovulators, and remain in oestrus until mated, or until the end of the breeding season when the days begin to shorten, causing them to enter a period of anoestrus. Oestrous females are exposed to prolonged high oestrogen levels, which lead to weight loss, alopecia and even bone marrow depression. All bone marrow blood cell series may be affected, causing leucopenia, thrombocytopenia, or anaemia. It is recommended that females which are not to be used for breeding are spayed at 6–8 months of age (Burke 1988; Lloyd 1999).

During the non-breeding season, the testes of the male recede into his body, becoming almost invisible under the heavy winter coat. About the time of the shortest day, they begin to move back into the scrotum. The males need to come into season about 4 weeks prior to the females to allow for sperm maturation. The male reaches his sexual peak in March or April as the females begin to come into season, remaining in breeding condition until the end of the summer, when the testes begin to withdraw back into the body cavity.

The female is responsive to the male when there are about 14–15 h of daylight. Conception can occur soon after the onset of vulval swelling, but the optimum time is 14 days after vulval swelling appears. Mating is vigorous, prolonged and noisy. The male will grasp the jill by the scruff of the neck and drag her around for up to 1 hour before coitus,

which can then take up to a further 3h. Ovulation occurs 30–35h after mating. The vulval swelling recedes within a few days of mating.

Gestation lasts for 40–44 days and, assuming an early mating, litters are born in early summer when the days are at their longest and warmest. Up to 14 young can be produced, the average litter being seven, each kit weighing around 6–12g. All kits have white hair regardless of their eventual coat colour. Jills have eight nipples but can feed more kits if the milk supply is good. Ferret milk contains 23.5% solids, composed of 34% fat, 25.5% protein and 16.2% carbohydrate (Lloyd 1999). Kits have voracious appetites, and they develop rapidly, doubling their birth weight in 5 days. Although their eyes are closed until around 34 days, they are active from about 14–21 days. At this point they start to eat solids, and the jill can be seen taking food to the kits. Growth is gradual up to weaning at about 6–8 weeks of age, when body weight reaches at least 200–250g. At this point kits fed *ad libitum* eat approximately 30g of solid food and drink about 125ml daily. The kits are weaned at the end of the summer and can build up their supply of body fat during the autumn for the coming winter. Adult weight is reached at approximately 16 weeks.

Breeding performance declines after approximately 3 years of age in males, or after three or four litters in females.

### Normal behaviour

Ferrets spend up to 75% of the day asleep, and typically are very active for short periods then sleep soundly for several hours. They are more active at night (Hillyer & Quesenberry, 1997). They like to sleep in dark, enclosed areas such as wooden or cardboard boxes, and will even sleep in paper bags. The remainder of their time is spent actively exploring the environment and playing and interacting with other ferrets. They spend much time burrowing through their bedding, which often leads to bouts of sneezing, which is normal unless persistent. Exercise periods often coincide with feeding time.

Young ferrets play constantly. Mock aggression, play chasing, wrestling and pouncing may be commonly observed. They will nip at anything and often bite when first handled, but become more friendly if handled frequently.

Ferrets are able to vocalise and produce a number of different sounds. When playing, they may hiss and chuckle, and when frightened or threatened they may scream. When foraging, they may produce a low-pitched grumble.

### Sources of supply

The best sources of ferrets are specialist laboratory animal breeders or other laboratories. Although they are also available through the pet trade, from specialist breeders of working ferrets and private owners, such sources are not recommended for laboratories as there may be little quality control with regard to pedigree and disease status (see section on common diseases). In the UK it is a requirement that ferrets are obtained only from breeders or suppliers

designated under the Animals (Scientific Procedures) Act 1986.

### Uses in the laboratory

The ferret is not commonly used in the laboratory. Uses of the ferret include research into viral diseases such as influenza, gastrointestinal disorders, neuroscience and auditory physiology, and pharmacological studies for which rodents are not suitable, such as emesis. The ferret has also been used in toxicology and teratology.

### Laboratory management and breeding

#### General husbandry

#### Housing

When designing housing for ferrets, as natural an environment as possible should be provided, with sufficient room for all their different needs. Given the choice, a ferret will build a burrow incorporating a sleeping area, a larder for food storage, several escape holes and a latrine area, usually a vertical surface against which defecation takes place.

Ferrets are inquisitive animals with an amazing ability to escape, and will readily destroy a cage which has any holes or edges unprotected (Moody *et al.* 1985). Cages can be made from various materials, for example wood, plastic, metal (sheet or wire) or fibreglass, with solid floors. Ferrets adapt very well to floor pens, which allow for a far more varied environment. Enclosures should have a minimum height of 50 cm and a floor area of 4500 cm<sup>2</sup>, depending on the number and type of animals held (see Table 29.2). Solid floors should be provided wherever possible, to allow for the provision of bedding material. In cages with wire fronts, a strip of solid edging around the cage may help to retain the bedding, which is otherwise likely to be thrown out of the cage during normal burrowing behaviour.

Ferrets are intelligent and inquisitive and their housing needs a sufficient degree of complexity to cater for their needs. Failure to provide for these needs results in poor psychological well-being and ferrets may develop stereotypic behaviour. The inclusion of cardboard or rigid plastic tubes, containers of various materials and paper bags provides interest and stimulates both investigation and play.

**Table 29.2** Minimum space recommendations for ferrets (European Commission 2007).

Animals	Minimum enclosure size (cm <sup>2</sup> )	Minimum floor area per animal (cm <sup>2</sup> )
Animals up to 600g	4500	1500
Animals over 600g	4500	3000
Adult male*	6000	6000
Jill and litter*	5400	5400

\*Single housing recommended

Deep littering of group animals can also provide a stimulating and hygienic environment. Although ferrets spend a large proportion of the day sleeping, the active periods can be frantic times, even in adult animals, and an imaginative approach on the part of the carers can improve the welfare of the animals.

Taking into account that hobs can be twice the size of jills, the housing must provide adequate space for movement and ample height to allow the animal to stand on its back legs. The minimum height recommended in the revised European Directive Annex II is 50 cm (European Commission 2007).

### Environmental provisions

The ferret is a resilient animal that can tolerate a wide range of temperatures, although because ferrets have poorly developed sweat glands they tolerate extreme heat poorly and they are susceptible to heat exhaustion when exposed to very high temperatures. Experience suggests that a temperature range of 15–24°C with approximately 10–15 air changes per hour and a relative humidity range of 40–60% are satisfactory. Unweaned young should be kept above 15°C.

### Identification

Ferrets can be identified using a number of different methods. Collars can be used for short-term identification, but the narrow head of the ferret makes it difficult to keep collars in place. Tattooing provides a permanent method of identification, and the best site is on the inside of the thigh. Young animals (6–8 weeks) can be tattooed when conscious. Electronic microchips are probably the most effective method for identification, and these can be inserted at any age without sedation or anaesthesia. There are numerous systems available.

The ears of ferrets are small and so do not lend themselves to tattooing and ear tags are liable to tear out. Albino ferrets may be identified using dyes, but dyes have to be renewed on a regular basis, and care must be taken when animals are in moult.

### Sexing

Males are usually called hobs, and females jills. Sexing mature ferrets is relatively easy. In mature male animals the tip of the penis opens onto the abdominal surface at a point about 5 cm from the base of the tail. This opening is usually obvious, but in animals with particularly long fur it may be partially obscured. As with other mustelidae, the male ferret has a penile bone (baculum) which is about 3–4 cm long in the adult animal. The testes become enlarged during the mating season and are visible for 5–6 months starting in late winter. In anoestrous females the anogenital distance is about 1–2 cm. Females in oestrus exhibit a significantly enlarged vulva.

### Transport

A major consideration when transporting ferrets is their susceptibility to heat exhaustion. Their bodies can only be

**Table 29.3** Transport containers for ferrets.

<i>Weight of animals (g)</i>	<2000	2001–5000
Maximum number per compartment	4	2
Space per animal (cm <sup>2</sup> )	770	970–1160
Height of box (cm)	20	25

cooled by heat loss from respiration, therefore air-conditioned vehicles may be required in hot weather to prevent heat stroke.

Travel boxes with adequate ventilation must be provided, and care should be taken when stacking boxes to allow air circulation. Commercial plastic boxes with mesh liners provide adequate transport accommodation for one adult ferret, and single housed animals will invariably travel without problems, whereas multiple housed animals may fight or be unlikely to settle on a journey. It is important that a mesh liner is used to cover all vents, because ferrets will chew any material to assist escape.

Current International Air Transport Association Live Animal Regulations suggest the density guidelines given in Table 29.3. See also Chapter 13.

### Breeding

Ferrets reach sexual maturity at 8–12 months and are then seasonal breeders, however this can be altered by manipulating the light cycle. Care must be taken to provide an appropriate light cycle however, or problems may ensue. Rearing females from birth in short day conditions until 90 days then exposing them to long days can induce them to reach sexual maturity by as early as 4–5 months of age. If reared on long days, the onset of oestrus can be delayed until the animal is around 1 year old, although some females may remain anoestrous thereafter. Adult females kept continually in stimulatory photoperiods (14 h light) will have three or four litters in succession, then reproductive performance declines and eventually they fail to conceive. A period of 5–6 weeks in a winter photoperiod (6–8 h light) is then required. Mated and lactating females need to be maintained on long day cycles, otherwise the animals will fail to reproduce or maintain lactation. Males kept on short days of around 8 h light may remain in breeding condition for more than a year, but they then need a rest period of 5–6 weeks in a long photoperiod to maintain breeding efficiency.

Ferret breeding can be maintained throughout the year by careful manipulation of the lighting. Maintaining males in short photoperiods (8 h) ensures they are available for breeding throughout the year. Each male should have an annual period of rest for 5–6 weeks in a long photoperiod (14 h). Females can also be kept in short photoperiod, and moved into long photoperiod to bring them into season as required. Females begin their season after 6–8 weeks on long days. Having two ferret breeding rooms, one on northern hemisphere light cycles and one on southern hemisphere light cycles or one winter and one summer, allows for year-round breeding.

The condition of the jill should always be checked prior to mating, and only animals in good condition should be mated. The birth process is particularly demanding on jills, and an unfit female is more likely to have problems during pregnancy and birth, and as a result produce small, weak young.

The female should be taken to the male and left for 2 days. Mating is a very noisy and prolonged affair, with the male biting the female's neck and dragging her around. This is entirely natural and the skin on the back of the jill's neck is sufficiently thick to withstand this behaviour, but injuries may be inflicted on occasion.

After mating, jills should be housed away from stud males, to reduce the risk of disturbance to the jill leading to cannibalism of the young, and they should not return to the same enclosure as unmated cage mates, as this can cause pseudopregnancy in the unmated females. Pregnant females should be moved into their littering cages about 2–3 weeks prior to parturition. They should be provided with a nest box and suitable nesting material such as shredded paper, wood shavings or soft straw. Jills lose their winter coat and may look rather scruffy during gestation, and it is important that they get adequate nutrition. She should be fed *ad libitum* a diet of 35–40% protein and 18–20% fat during pregnancy, increasing the fat content to 30% during lactation. Nutritional supplementation may be required (Besch-Williford 1987).

Technicians should be wary when handling pregnant females, as they become more aggressive as gestation progresses. Jills are very protective of their young.

Dystocia is common, and neonatal mortality can reach 8–10%, due to stillbirths, congenital defects and cannibalism (Besch-Williford 1987; Lewington 2000). Cannibalism is common with larger litters, but can also be an inherited trait. Hypothermia or bloat caused by poor hygiene or overeating may also lead to neonatal death. Mortality declines after 5 days, and deaths after this time may be due to maternal neglect or agalactia, often caused by a return to oestrus. With litters larger than five, oestrus is usually suppressed, but with small litters the jill may return to oestrus before weaning. In this case she should be mated again, as high oestrogen levels suppress the milk supply. The jill may also kill a small litter, allowing her to return into season.

Good management can reduce problems encountered in the periparturient period. The jill should be left undisturbed for several days post-partum, and given adequate nutrition, with increasing quantities of food offered from 2–3 days after birth. Calcium supplementation may be needed to prevent hypocalcaemia, which can occur at peak lactation 3–4 weeks after birth.

## Nutrition

The ferret is an obligate carnivore, their natural diet consisting mainly of small mammals, with some fish, birds, amphibia and even invertebrates. Under natural conditions they may eat up to nine or ten small meals a day, although twice daily feeding is adequate. Little research has been done on their exact nutritional needs, but important considerations seem to be the energy concentration of the diet, the amino acid composition and the digestibility of dietary

protein (Porter & Brown 1997). Ferrets need a diet high in protein and fat but low in fibre, and have little absolute requirement for carbohydrate provided there is sufficient protein and fat to provide substrates for gluconeogenesis. They have little capacity to digest complex carbohydrates. They eat to calorie requirements, and their short gut transit time means they need highly digestible diets with high energy density and protein levels (Porter & Brown 1997; Lloyd 1999; Lewington 2000). Requirements for a typical ferret diet are shown in Table 29.4.

Commercial ferret diets are available. Ferrets need 840–1260 kJ/kg body weight (200–300 kcal/kg) daily, and diets with up to 21 000 kJ/kg diet (500 kcal/kg) may be needed for growth and reproduction. The diet should contain 30–40% protein, with a minimum level of 35% protein for breeding and young animals. The primary protein should be of animal origin, as the ferret digestive system is relatively inefficient at absorbing vegetable protein, and plant-derived proteins are associated with the formation of uroliths in mustelids. Breeding animals may fail to conceive or may suffer from lactation failure following parturition if fed insufficient animal protein (Burke 1988; Lloyd 1999).

A fat content of 18–20% is sufficient, and linoleic acid should account for 7–15% of total fat (Fox 1998). Unsaturated fats have a tendency to become rancid, which reduces palatability and leads to destruction of vitamin E, so ferret diets should contain adequate levels of vitamin E and be stored correctly to prevent this. A ratio of tocopherol (vitamin E): polyunsaturates (mg:g) of at least 0.5 is recommended to prevent vitamin E deficiency. Vitamin E deficiency leads to steatitis (yellow fat disease).

**Table 29.4** Requirements for a typical ferret diet (Lloyd 1999; Fox 1998).

Diet component	Quantity
Energy (kJ/kg diet)	21 000
Protein (%)	30–40 (min 35% for production)
Fibre (%)	2 (low level required)
Carbohydrate (%)	22–44 (no absolute requirement)
Fat (%)	18–20
Vitamin A (IU/kg)	33 600
Vitamin D3 (IU/kg)	3667 (depends on Ca and P levels and exposure to UV light)
Vitamin E (IU/kg)	125 (need at least 0.5 mg vitamin E per g unsaturated fat in diet)
Thiamine (B1) (mg/kg)	8.4–97.8
Riboflavin (B2) (mg/kg)	1.5–3
Niacin (B3) (mg/kg)	80
Calcium (%)	1.1–2.2
Phosphorus (%)	0.9–1.2 (need Ca:P of at least 1:2 and adequate vitamin D)
Sodium chloride (%)	≤1
Zinc (mg/kg)	105–215 (deficiency can lead to skin lesions in kits, excess causes toxicity)
Copper (mg/kg)	15

Ferrets can do well on pelleted cat or kitten food with an appropriate protein level, which can be soaked and fed as a stiff paste. Tinned diets may also be used, provided that the protein content is derived from animal protein and the total protein level is in excess of 30%. Raw fish and eggs should be avoided, because they contain an excess of thiaminase and may predispose the ferret to thiamine deficiency. Raw fish may also contain high levels of nitrates. Feeding utensils should be in good condition, and the use of galvanised bowls should be avoided, as ferrets are susceptible to zinc toxicity.

For pregnant and lactating females, commercial pelleted diets may be supplemented with tinned food to give a higher level of nutrition and allow for weanling animals to feed at 3–4 weeks of age. Females take meat to the litter to encourage feeding, and weanling animals may not easily consume pelleted diet. Soaking pelleted diets in clean water and presenting it as a mash may enable weanlings to increase their food intake. Dead mice, pinkies or day-old chicks may also be offered in addition to commercial diet, but care must be taken to ensure that any uneaten carcasses are removed, as ferrets are notorious hoarders of food and will bury them in the bedding.

## Laboratory procedures

### Handling and training

Ferrets are considered to be fairly placid and friendly animals that respond well to frequent handling. It is important that ferrets are handled sensitively and frequently from an early age. Ferrets are hunters with relatively poor eyesight, and their reactions are reflex and instant. They may mistake a hesitantly approaching finger for prey, and are likely to bite it, but a well handled ferret approached correctly will not bite. The important rules when handling ferrets are:

1. Be positive, calm and confident.
2. Know what you are doing.
3. Keep movements smooth and decisive.
4. Use your voice as well as your hands (Lloyd 2002a).

This way, the ferret will not be startled. All movements should be confident, steady and deliberate.

Two main methods are used for picking the animals up. Ferrets that have often been handled may be restrained by simply slipping a hand under the animal just behind the forelegs, supporting the rump with the other hand once the animal is away from the surface. Alternatively, distract the ferret with one hand and then quickly place the other hand over its shoulders and place a finger under the jaw to provide additional control. Again, support the animal's weight by placing a hand under the rump.

When dealing with unknown or frightened animals it may be advisable to wear protective gloves. Females with young and sick animals are more likely to bite and should always be treated with care. From the handler's point of view practice makes perfect, and from the animal's point of view frequent handling decreases the likelihood of an aggressive response. A ferret's bite can easily penetrate

down to the bone. Ferrets have a tenacious grip and do not let go easily, especially if their feet are not touching the ground. If this occurs, place the animal's feet onto a solid surface and try to prise the jaws apart. If this fails, apply gentle pressure on the bridge of the nose, place some isopropyl alcohol on the gum, pinch the foot pad, or in extreme cases place the animal's head under cold running water to encourage them to let go.

Ferrets handled regularly can become really affectionate and amply repay the time and effort spent on them. Ferrets also respond well to positive reinforcement: food, treats or interaction with the handler can be used as rewards when training ferrets to co-operate with the handler.

## Physiological monitoring

### Temperature

Core temperature can be monitored by the insertion of a thermometer into the rectum, but the probe should be less than 3 mm in diameter and penetration should be no more than 1–2 cm. Larger probes can cause discomfort and may elicit retching and defecation. Ferrets generally struggle when having their temperature taken and readings may be artificially elevated.

## Collection of samples

### Blood

Small volumes can be collected by clipping a toenail or pricking a footpad (local anaesthetic cream or spray may be applied first) and collecting the blood in a capillary tube. When clipping the toenail, ensure that only the very end of the quick is cut. The use of local anaesthetic is advised for this. Alternatively, the cephalic or saphenous veins can be used (Lloyd 1999; Lloyd 2002a; Hillyer & Quesenberry 1997; Joint Working Group on Refinement (JWGR) 1993).

The cephalic vein is located on the upper surface of the forelimb and is one of the most accessible veins in the conscious ferret. The procedure is best performed by three people, one to hold the ferret by the neck and abdomen, one to hold one forelimb and the third to hold the other forelimb and take the sample. The limb should be shaved and swabbed. Small scissors are more suitable than clippers, which are noisy and tend to agitate the animal. Raise the vein by applying gentle pressure on the proximal part of the dorsal surface of the limb. This can be difficult because of the short legs of the ferret, and it may be most effectively achieved by using a quick-release tourniquet. The vein should then be palpable and a 25G or 27G needle or 24G over-the-needle cannula can be inserted.

The saphenous vein is found on the lateral surface of the distal hindleg. The overlying fur should be shaved, then the vessel can be raised by applying a quick-release tourniquet above the stifle. A 23G or 25G needle can then be inserted into the vein. Alternatively the vein can be cannulated with a 24G over-the-needle cannula. This is made easier if the skin over the vein is nicked with a needle or scalpel blade before trying to insert the cannula.

Larger samples can be taken from the jugular or tail veins. Jugular venepuncture is usually best achieved by having the person performing the technique standing with the animal's head facing towards them, and an assistant restraining the animal in dorsal recumbency. The animal is firmly grasped around the anterior thorax and the forelegs extended down along its body, then a towel is tightly wound around the body, leaving the head and neck uncovered so the head can be extended backwards. Alternatively, the animal can be held prone with neck extended upwards to access the vein. The vein is raised by supporting the animal's neck and applying pressure at the thoracic inlet. The vessels run cranio-laterally from the midline at the thoracic inlet to a point just below the base of the ears. A 21 G or 23 G needle can then be inserted into the vein facing towards the heart. The skin is very thick and venepuncture may be facilitated by bending the needle upwards by approximately 30°, and by putting the needle through the skin lateral to the vein first and then into the vein itself.

The ventral tail vein and artery can be accessed by restraining the ferret in dorsal recumbency (this can be facilitated using a restraining tube). The ventral aspect of the proximal tail is shaved. The tail has a flattened area on the ventral side for the first 4–5 cm, representing the ventral concavity of the caudal vertebrae. The artery lies 2–3 mm beneath the surface, flanked by two smaller veins. The skin is swabbed, then the tail is held in one hand and a 23 or 21 G needle inserted at a shallow angle towards the body in the midline, 3–4 cm from the base of the tail. As the needle enters the vessel, blood appears in the hub of the needle.

Ferrets have a high packed cell volume (PCV) and a slow erythrocyte sedimentation rate. When collecting serum or plasma or measuring the PCV, the blood must be centrifuged for 20% longer than for other species, and three times the required plasma volume must be collected. Normal values for haematology and biochemistry and sample volumes may be found in Table 29.5.

#### Faeces and urine

The ferret normally defecates in one particular corner of its cage, and this facilitates collection of faecal samples. If fresh specimens are required, defecation can be readily stimulated by the insertion of a small blunt probe into the rectum. Ferrets can be induced to urinate in the same manner as the rat (ie, by gentle pressure on the abdomen overlying the bladder). Faeces-free urine samples may also be obtained by placing the animal in a metabolism cage. Sterile urine samples can be obtained by cystocentesis in the sedated or anaesthetised animal.

#### Administration of substances

This section draws on Hillyer and Quesenberry (1997); Fox (1998); and Lloyd (1999). See also JWGR (2001).

#### Intravenous administration

Intravenous injections can be made into the cephalic, saphenous, jugular or tail veins, as described for blood sample collection above.

**Table 29.5** Haematological and biochemical parameters (Fox *et al.* 1984; Fox 1998; Lloyd 1999).

Parameter	Value
PCV (%)	42–61 (varies with sex and strain of animal)
Haemoglobin (g/dl)	12.0–18.2
RBC ( $10^6/\text{mm}^3$ )	6.77–13.2
Platelets ( $10^3/\text{mm}^3$ )	297–910
WBC ( $10^3/\text{mm}^3$ )	4.4–19.1
Reticulocytes (%)	1–14
Neutrophils (%)	11–84
Lymphocytes (%)	12–69
Monocytes (%)	0–8
Eosinophils (%)	0–7
Basophils (%)	0–2
Blood volume (ml/kg)	70
Safe volume of single bleed (ml/kg)	7
Sodium (mmol/l)	137–162
Potassium (mmol/l)	4.5–7.7
Chloride (mmol/l)	102–125
Calcium (mg/dl)	8–11.8
Phosphorous (mg/dl)	4–9.5
Glucose (mg/dl)	62–207
Urea nitrogen (mg/dl)	10–45
Creatinine (mg/dl)	0.2–0.6
Total protein (g/dl)	3.5–7.4
Albumin (g/dl)	2.6–4.1
Globulin (g/dl)	2.5–4.8
Total bilirubin (mg/dl)	0–0.4
Cholesterol (mg/dl)	34–296
ALP (iu/l)	9–120
ALT (iu/l)	82–289
AST (iu/l)	28–248

#### Intramuscular and subcutaneous injection

Small volumes can be given into the quadriceps muscle on the anterior aspect of the hindleg, or into the muscles each side of the lumbar spine using a 25 G needle. Subcutaneous injections can be given under the skin of the scruff of the neck. The skin of the ferret is particularly thick in this area and a 23 G or even 21 G needle may be required.

#### Intraperitoneal

This route of administration is particularly useful when it is necessary to administer the drug in a large volume. With the animal held firmly, a 23 G 2.5 cm needle is inserted at a shallow angle into the caudal abdomen, 6–8 cm below the xiphisternum, slightly to one side of the midline. The needle should penetrate no more than 2 cm.

### Oral

Ferrets will readily accept palatable medicines in feed or dissolved in milk. Liquids or suspensions can be administered by holding the animal vertically or in dorsal recumbency, and inserting a suitable strong pipette into the angle of the mouth between the upper teeth and the dorsal surface of the tongue. Fluids may be given directly orally into the stomach by inserting a gastric tube through a hole in a spatula inserted between the jaws. The diameter of the gastric tube used should not exceed 5 mm. Ferrets retch readily and occasionally vomit on insertion of a tube into the oesophagus, and it may be necessary to sedate the animal to minimise trauma and facilitate administration. A maximum volume of 100 ml can be administered by this method.

### Intranasal

The animal is held in a vertical position using the usual grip around the neck, and the substance is placed drop by drop in the nose. Administration must be slow and in small drops, or the animal will sneeze. This method can be used on conscious animals if they are accustomed to handling, but anaesthetic can be given in case of difficulty. Aerosols can be administered either directly via a face mask, or indirectly by placing the animal in a closed environment to which the aerosol has been added. With the latter method it is difficult to administer a standard dose.

### Anaesthesia

#### Pre-anaesthetic considerations

In healthy ferrets, anaesthesia should not be difficult or risky. First the cardiovascular and respiratory systems should be checked, and an accurate weight obtained, since a thick coat may lead to over-estimation of body weight and overdose of anaesthetic. Ferrets vomit readily, and should be fasted for up to 4 h prior to anaesthesia. Due to the short gut transit time, longer periods of fasting may lead to hypoglycaemia. Free access to water should be given until immediately prior to induction.

The animal should be calm before anaesthesia; premedicants can be used if required, as stress increases the risk of problems. For short, non-painful procedures, diazepam may be sufficient. For major surgical procedures, combinations including an analgesic are recommended. Since the airways are small and easily blocked, drying agents should be given before general anaesthesia. Table 29.6 gives suggested doses of sedatives and premedicants.

#### General anaesthesia

General anaesthesia may be induced by intravenous or intramuscular injection. Administration by intravenous injection can be difficult in the conscious animal, and therefore preference is usually given to agents that can be administered by a different route. Injectable agents should be dosed by weight, but account should be taken of the time of year, since in the winter ferrets accumulate fat and may

**Table 29.6** Sedatives and premedicants. Note that these doses are only intended as a guideline and there may be considerable variation between animals depending on their body weight, sex and general health (Lloyd 1999; Marini & Fox 1998; Hillyer & Quesenberry 1997). These products may not have licences for use in ferrets. Rules regarding their use should be checked with the relevant competent authority.

Drug	Dose	Comments
Midazolam with ketamine	0.2 mg/kg with 10 mg/kg im	Mix in same syringe. Short-term sedation with relaxation
Medetomidine	0.1 mg/kg iv, im or sc	Reverse with atipamezole. Useful for minor procedures or premedication
Diazepam or midazolam	2 mg/kg im	Reduces anxiety and produces relaxation. Can be hypotensive
Xylazine	1 mg/kg iv, im or sc	Hypotensive. Not recommended for use alone
Ketamine	20–30 mg/kg im	Poor muscle relaxation if used alone
Fentanyl/fluanisone	0.5 ml/kg im	Neuroleptanalgesia with poor muscle relaxation. Can reverse with opioid antagonists/partial agonists
Acepromazine	0.05–0.5 mg/kg sc or im	Hypotensive
Atropine	0.05 mg/kg sc	Dries airway secretions
Glycopyrolate	0.01 mg/kg sc	As above

require relatively more anaesthetic. Always administer oxygen, since many anaesthetics cause respiratory depression. Respiratory failure is a common cause of anaesthetic emergencies in ferrets. Suitable drug combinations for anaesthesia are given in Table 29.7. See also Flecknell (2009).

Anaesthesia can be induced in friendly or sedated ferrets by intravenous injection of alphaxolone or propofol. Alternatively, intramuscular injection of ketamine in combination with xylazine, medetomidine, diazepam or acepromazine can produce 20–30 minutes of surgical anaesthesia.

Volatile anaesthetics can be used for both induction (after sedation if required) and maintenance. Isoflurane is recommended, with nitrous oxide for additional analgesia. If using an induction chamber, the same chamber that is used for rodents should not be used, since the smell of the ferret will cause distress to any rodents placed in the chamber subsequently. Induction takes 1–2 minutes. Anaesthesia is maintained using a low-resistance circuit, such as a T-piece. For short procedures a face mask can be used for maintenance of anaesthesia, but for longer procedures, endotracheal intubation is recommended using a 2.5–4 mm tube or a modified urinary catheter. The animal is placed in sternal recumbency and an assistant bends the head upwards as far as possible by placing thumb and forefinger in the corners of the mouth. The tongue is pulled forwards and over the lower incisors to depress the mandible. The lubricated tube

**Table 29.7** Drug combinations suitable for anaesthesia in ferrets (Lloyd 2002b). The doses may have to be modified if given after premedication. All the times are approximate. These products may not have licences for use in ferrets. Rules regarding their use should be checked with the relevant competent authority.

Drug	Dose	Comments
Isoflurane	3–4% induction, 1.5–3% for maintenance	
Halothane	2–4% induction, 0.8–2% for maintenance	
Medetomidine with ketamine	50–100 µg/kg with 4–8 mg/kg	Mix in same syringe, administer im for 30–60 minutes surgical anaesthesia. Can reverse with atipamezole, 0.25–0.5 mg/kg im
Xylazine with ketamine	1–4 mg/kg with 25 mg/kg im	As above but with more respiratory depression
Alphaxalone	8.2–11 mg/kg im or iv	Premedicate with diazepam. Short anaesthesia with good relaxation. Incremental doses 6–8 mg/kg iv for prolonged anaesthesia
Ketamine with diazepam	25 mg/kg with 2 mg/kg im	Surgical anaesthesia for approx. 30 minutes. Less respiratory depression than with $\alpha_2$ agonists
Ketamine with acepromazine	25 mg/kg with 0.25 mg/kg im	As above
Propofol	10 mg/kg iv	Can be used for total intravenous anaesthesia

is advanced into the mouth (a laryngoscope may help to visualise the larynx) and the tube is gently slid through the glottis.

At the conclusion of the procedure, the animal should be allowed to breathe oxygen only for a few minutes to flush out the nitrous oxide. Animals usually recover consciousness in about 5 minutes.

## Surgery

Ferrets have thick skin and thin abdominal musculature. They are keen suture chewers and are unforgiving if sutures are uncomfortable so care must be taken to ensure that the sutures are secure. Wounds in the neck appear to irritate more than abdominal ones, although ferrets are prone to the development of a serosanguinous discharge from the wound following abdominal surgery, which is normally self-limiting (Hillyer & Quesenberry 1997; Lloyd 1999). It is recommended that subcuticular sutures using fine synthetic absorbable suture materials are placed in the skin to reduce the likelihood of wound breakdown.

Antibiotic therapy should not normally be required after surgery provided aseptic techniques are employed. If

**Table 29.8** Analgesics (Lloyd 1999; Lloyd 2002a). These products may not have licences for use in ferrets. Rules regarding their use should be checked with the relevant competent authority.

Drug	Dose	Comments
Buprenorphine	0.05 mg/kg sc or im	Lasts up to 12 h
Butorphanol	0.25 mg/kg sc or im	Lasts 2–4 h
Morphine	0.5–2 mg/kg sc or im, 1 mg/kg iv	Lasts 3–4 h
Carprofen	1 mg/kg po or sc	Repeat after 12–24 h
Meloxicam	0.2 mg/kg sc or im, 0.3 mg/kg po	Lasts 24 h
Ketoprofen	2 mg/kg sc	Administer once daily
Flunixin	0.5–2 mg/kg sc	Do not administer under anaesthesia
Aspirin	200 mg/kg po	

required, treatment with clavulanate/amoxicillin (12.5/50 mg/ml) (0.2 ml/kg oral suspension twice daily), amoxicillin (10–25 mg/kg orally or by subcutaneous injection once daily), or enrofloxacin (3–5 mg/kg orally twice daily) can be given.

## Post-operative care and analgesia

Hypothermia under anaesthesia is common. The animal should be kept warm throughout the procedure by wrapping it up and providing supplementary heating if necessary. Following surgery, the body temperature should be kept up until the animal has fully regained consciousness. It is also important to maintain fluid balance to prevent dehydration. The daily fluid requirement is approximately 75–100 ml/kg and, in addition, any blood or fluid losses during surgery should be replaced. Warmed fluids can be given by slow intravenous injection into the cephalic or saphenous veins.

Ferrets are stoic animals and will mask signs of pain, so they should be given the benefit of the doubt and analgesics should be administered routinely after surgery to avoid unnecessary pain. Doses of suitable analgesics are given in Table 29.8.

Post-operatively the appetite may be decreased, and solid food may be refused. Small amounts of liquid diet, soaked maintenance diet or convalescent diet for dogs and cats should be offered. Anorexic animals may need to be force-fed meat-based baby food or convalescent diet or given nutritional supplements until the appetite has returned to normal. After abdominal surgery, food should be given in small amounts until digestive functions have returned to normal.

## Common disease problems

### Disease control, vaccinations and routine health checks

A programme of routine preventive care should be implemented, to allow for prevention and early detection of dis-

eases. Young ferrets should be given a health check and first vaccination at 6–8 weeks of age, and then an annual check until 4–5 years old. Older animals are more prone to diseases, and benefit from twice-yearly health checks. Table 29.9 gives an example of a health monitoring protocol for ferrets.

It is recommended that ferrets acquired from dealers or other laboratories should be quarantined for 40 days before introduction to a colony, to minimise the risk of introducing infections.

Ferrets should be vaccinated against canine distemper (Burke 1988; Oxenham 1990; Lloyd 1999). No vaccines are currently licensed for use in ferrets in the UK. Vaccine production changes continually and it is wise to check with the manufacturer, since insufficiently attenuated vaccines may cause disease. Ferrets are not susceptible to feline panleucopenia, canine parvovirus, leptospirosis or mink enteritis.

Ferrets of unknown health status should be tested on acquisition for Aleutian disease. Positive animals should not enter a colony since they present a health risk for the other animals, even if overtly well.

## Signs of disease

Ferrets are stoic animals and often do not show clinical signs until a disease has reached an advanced stage. It is important that handlers can recognise the slightest changes. Diseased animals become lethargic, uninterested in their surroundings and have a reduced food intake. Grooming behaviour may decrease and as a result the animal may appear dishevelled. The animal will offer little resistance to being handled, unless there is a tumour or abscess, which is sensitive to touch. Weight loss is also a sign of disease and can be confirmed by weighing the animal over several days. It is possible for the animal to lose weight if it is diseased (for example with a tumour) even with a normal food intake. Vomiting does not appear to be a commonly observed symptom of disease, however a sudden change in the bulk, colour or consistency of the faeces not associated with a change in diet may indicate illness.

**Table 29.9** Routine health monitoring schedule. Routine health checks are recommended annually until 4–5 years of age, then every 6 months. Animals of unknown origin should be tested for Aleutian disease virus (Lloyd 2002a).

Age (weeks)	Procedure
6 or 8*	First distemper vaccine if needed (endemic areas), faecal screen
10–12*	Second distemper vaccine if needed
12–14	First (or third) distemper vaccine, rabies vaccine if required, faecal screen
26–32	Spay or castrate, faecal screen
1 year	Rabies booster if required (annual)
3 years	Distemper booster (every 1–3 years)

\*Earlier vaccination for kits of non-vaccinated dams and in endemic areas.

Animals should first be inspected in their home cages for observation of natural behaviour and signs of illness, before being removed from the cage to make an assessment of provoked behaviour. Normal ferrets exhibit exploratory behaviour: if this is absent it may be a sign of illness. The gait of the animal can also be observed for hindlimb paresis and other musculoskeletal or neurological disturbances such as generalised tremor.

## Viral diseases

Ferrets are prone to several viral diseases, the most significant of which are Aleutian disease, canine distemper and influenza.

### Aleutian disease

Aleutian disease is caused by a parvovirus, and although originally a disease of mink it is increasingly diagnosed in ferrets (Welchman *et al.* 1993). Following infection there is persistent viraemia and hypergammaglobulinaemia, leading to immune complex deposition in many organs including liver, kidneys, spleen and thyroid. Clinical signs depend on the organs most affected. Frequently, there is central nervous involvement, with a non-suppurative encephalomyelitis. The virus can spread both vertically and horizontally, although the transmission rate appears to be low.

There may be no clinical signs, or variable signs including anorexia, posterior paralysis and ataxia, quadriplegia, chronic wasting, cachexia, melaena, ill-thrift, poor reproductive performance, collapse and sudden death. Animals may have repeated episodes of posterior paresis but remain bright and alert and otherwise unaffected. Clinical disease can be precipitated by stress. Infection may also increase the animal's susceptibility to other diseases. Animals of any age may be affected, and the signs may develop over 24 h or progress over several months.

Diagnosis can be made by counter-immunoelectrophoresis (CIEP) on a sample of plasma, raised plasma globulin, or by histopathology of affected tissues. However, there may be no histopathological changes, and there are no consistent haematological changes.

There is no treatment. Animals may respond to supportive therapy, corticosteroids and antibiotics although they will remain infected and present a risk to other animals. Culling of infected animals is recommended. Since the transmission rate is low, it is possible to test individual animals, and cull those testing positive. Two tests 3 weeks apart should allow the virus to be eradicated from a colony.

### Canine distemper virus

Canine distemper virus (CDV) produces an acute disease with nearly 100% mortality (Burke 1988; Lloyd 1999). Transmission is by contact or droplet infection, with an incubation period of 10–12 days. There is fever, loss of appetite, and an initially serous then mucopurulent ocular and nasal discharge, which can stick the eyelids together. There may be photophobia and blepharospasm. A rash develops under the chin and in the inguinal area on day 10–12, and there

may be keratitis of the footpads producing classical hardpad. The disease progresses to tracheitis, bronchitis and severe bronchopneumonia. Death usually follows on day 12–25 depending on the strain. If animals survive this phase, they develop a central nervous system (CNS) phase within a few weeks, characterised by hyperexcitability, excess salivation, muscle tremor, convulsion, coma and death. Vomiting and diarrhoea are uncommon. CDV causes suppression of cell-mediated immunity, predisposing to secondary bacterial infection.

CDV should be suspected in unvaccinated ferrets showing the typical signs. This can be confirmed by virus isolation, immunofluorescence on smears of conjunctival epithelium, blood, lymph node, bladder epithelium or cerebellum or examination of conjunctival, bladder or tracheal epithelium for typical distemper inclusion bodies.

There is no treatment, and affected animals should be euthanased. In the face of an outbreak, affected animals should be separated and healthy animals vaccinated immediately. The virus is labile and easily destroyed by disinfecting the environment. Cages, equipment and rooms should be disinfected and sterilised, and the source of infection identified and eliminated.

### Influenza

Ferrets can catch influenza from people, and it can then be spread by droplets from ferret to ferret, or back to people. The disease in adult ferrets is usually mild, but it can cause mortality in kits. The virus causes catarrhal inflammation in the upper respiratory tract leading to congestion, oedema and some necrosis in the nasal mucosa.

Clinical signs may develop within 48h. Affected animals develop a biphasic fever (40–41°C), they become anorexic and listless, then begin sneezing and coughing, with a nasal discharge. There may be sensitivity to light. The disease rarely progresses further, and recovery usually begins after the second pyrexia episode. Supportive therapy and occasionally antibiotics may be needed to control secondary infection. Recovery is followed by a short-lived period of immunity to reinfection by the same strain of virus. Occasionally, the disease may progress to pneumonia.

Diagnosis can be confirmed by virus isolation or rising antibody titres. Vaccination is not indicated, since protection is short lived and there are many antigenically distinct strains of the virus.

### Bacterial diseases

#### *Helicobacter mustelae* and gastroduodenal ulcers

*H. mustelae* is increasingly implicated in gastroduodenal ulceration in ferrets (Lloyd 1999). It is found in the pyloric area in up to 100% of animals, and although clinical disease is rare it can produce ulceration and death, particularly at times of stress. Large ulcers can erode into submucosal blood vessels causing rapid death. Ulcers cause anorexia and stress, leading to further development of the disease and a progressive deterioration in the animal's condition.

Clinical signs include lethargy, anorexia and weight loss, vomiting, ptyalism and tooth grinding. Chronic cases may be dehydrated. There may also be melaena, peripheral lymphocytosis and regenerative anaemia. The presence of black tarry stools with tooth grinding are highly suggestive of gastroduodenal ulceration.

If the animal is not vomiting, frequent, small meals of a bland, highly digestible diet can encourage the animal to eat and break the cycle that allows ulcers to form. If the animal is vomiting, food should first be withheld for 6–12h until vomiting ceases. Parenteral fluids and electrolytes may be needed. *Helicobacter mustelae* can be treated using a combination of antimicrobials and bismuth subsalicylate for at least 14 days. It may take 4 weeks or more for ulcers to heal completely and recurrence is common.

### Botulism

Ferrets are susceptible to botulism, and care must be taken in feeding raw meat (Ryland & Bernard 1983). The disease is usually fatal. The symptoms of muscular stiffness and coordination appear 12–96h after eating contaminated food. The animal eventually dies of anoxia due to paralysis of the respiratory muscles.

### Abscesses

Subcutaneous abscesses in group-housed ferrets are common and are often associated with staphylococcal or streptococcal infections in skin wounds resulting from neck biting during the early breeding season (Burke 1988). Abscesses seen in this region are manifested by large swellings that may involve the salivary glands and even erosion of bone at the base of the skull.

### Vaginitis and pyometra

Vaginitis and pyometra may be seen in oestrous females, secondary to immune suppression (Burke 1988; Lloyd 1999). Jills produce a mucoserous discharge during oestrus which causes the perineal area to become wet, predisposing to infection. Vaginitis may also be caused by irritation from bedding adhering to the vulva. Pyometra leads to lethargy, and there may be a purulent discharge from the vagina and enlarged uterine horns. Treatment consists of removal of the source of irritation, and the use of broad-spectrum antibiotics.

### Mastitis

Mastitis is quite common in ferrets, occurring immediately after parturition or at peak lactation. It can manifest as cellulitis, mammary abscesses, necrotic mastitis or chronic mastitis. Necrotic mastitis presents rapidly with large areas of liquefactive necrosis extending into surrounding tissues. Affected areas can become gangrenous within hours of infection and the jill can become very ill. Immediate surgical

treatment may be required to remove the affected areas. In chronic mastitis, mammary tissue is gradually replaced by fibrous tissue and milk production falls, resulting in the loss of the litter and possibly the jill herself. Antibiotic therapy and possibly surgical removal of the affected glands may be necessary. Mastitis is usually very infectious, and sucking kits can transfer infection from one gland to another. Affected jills should be isolated from the remainder of the colony to avoid spreading infection, and should not be used for breeding again. Kits should be left with their mother while she is undergoing treatment: fostering them may spread the infection to other jills, and removing the milk from affected glands aids recovery.

## Parasitic diseases

### Ear mites

*Otodectes cynotis* is common in ferrets, particularly young kits and old animals. The adult mite spreads by direct contact. Often, there are no signs, or there may be pruritus, rubbing the ears or head shaking, leading to reddening and ulceration of the pinna. Secondary bacterial infection can lead to otitis media and a head tilt. There is inflammation of the ear canal with a thick, brown or black waxy exudate. Adult mites, larvae and eggs are visible in the exudate under a microscope.

All susceptible animals should be treated concurrently. The ears of affected animals should be cleaned using a proprietary cleaner (usually under general anaesthesia) before using an insecticide such as ivermectin, topically or by parenteral administration. Eradication of *Otodectes cynotis* from a ferret colony can be achieved by treatment of all individuals in the colony with ivermectin every 3 weeks for three or four treatments (authors).

### Endoparasites

In general endoparasitic infestation is comparatively rare in the ferret under hygienic conditions. Ferrets may be experimentally infected with *Dirofilaria immitis* (dog heart worm) (Burke 1988), and coccidiosis, *Toxoplasma gondii* and various gastrointestinal helminths have been reported in ferrets (Thornton & Cook 1986; Rehg *et al.* 1988; Lewington 2000).

## Non-infectious diseases

### Hyperoestrogenism

Jills are induced ovulators, and if not bred may remain in oestrus for the duration of the breeding season. The high levels of oestrogens produced may cause bone marrow depression, with leucopenia, thrombocytopenia and aplastic anaemia. All jills develop a mild anaemia during oestrus at some point, and up to 50% of jills with prolonged oestrus will develop aplastic anaemia. If animals remain in oestrus for more than 2 months, the reduction in platelet count may lead to haemorrhage and death (Lloyd 1999; Hillyer & Quesenberry 1997; Lewington 2000).

The signs include a bilaterally symmetrical alopecia on the ventral abdomen and tail, weight loss, enlarged vulva and a serous or mucopurulent vaginal discharge. This may progress to anorexia, depression and lethargy, and generalised weakness. There may be pale mucous membranes, haemorrhages, a systolic murmur and secondary bacterial infections. Subdural haematomas may lead to posterior paralysis.

The diagnosis can be made on history and clinical signs, and confirmed by haematology. A PCV of less than 20% with depression of all blood cell series is highly indicative.

Ovariohysterectomy is the fastest way to remove the source of oestrogens, although initial treatment must be dictated by the PCV. In severe cases, a blood transfusion may be required first. Ferrets have no detectable blood groups, and there is little risk of a transfusion reaction. In milder cases, hormone treatments (such as proligestone (Delvosteron, Intervet) 0.5 ml sc) can be used to induce ovulation before ovariohysterectomy. The vulva will soften within 3–4 days and all signs of oestrus will then abate usually within 10–11 days, sometimes up to 3–4 weeks. Supportive treatments may be necessary, and it may take up to 4 months for the anaemia to resolve.

The prognosis depends on the length of time the animal has been in oestrus, and on the PCV on presentation. If the PCV is 25% or above, the prognosis is good. If it is below 15%, the outlook is poor and very intensive therapy including multiple blood transfusions will be required for several months.

To prevent a recurrence, females should not remain in heat for longer than 1 month. Ovariohysterectomy at 6–8 months of age is recommended for jills that are not to be bred. Ovulation can be induced by mating jills in oestrus with a vasectomised male. Hormone treatments can also be used to postpone oestrus until the following breeding season.

### Dilated/congestive cardiomyopathy

This is increasingly recognised in middle-aged to older animals (Lloyd 2002b). Affected animals develop lethargy, weight loss, anorexia, depression, exercise intolerance and respiratory distress over a period of several months. The condition can be diagnosed by radiography, ultrasound or on electrocardiogram (ECG).

Treatment is aimed at maintaining cardiac output. Oxygen, vasodilators, positive inotropes and diuretics may be beneficial, and thoracocentesis may be required to remove pleural fluid. A low salt diet and exercise restriction can be of benefit. Treatment failure is not uncommon.

### Foreign bodies

Intestinal foreign bodies are common in ferrets, because they are inquisitive and playful. Gastric foreign bodies may cause lethargy, inappetence, diarrhoea with or without tarry stools, weakness and dehydration. Vomiting is uncommon, although nausea can lead to ptyalism and face rubbing. Foreign bodies lodged at the pylorus can ulcerate through the stomach wall. Intestinal foreign bodies may cause sudden collapse with a painful abdomen.

The diagnosis may be made on the history, clinical signs and a careful clinical examination. Radiography is essential.

Foreign bodies rarely pass unaided and removal under general anaesthesia is usually required after the animal has been stabilised. Prevention of a recurrence may be achieved by 'ferret-proofing' the environment carefully, and by the regular use of a palatable cat laxative if necessary to reduce the formation of hairballs.

### Posterior paresis and ataxia

Posterior paresis and ataxia are common in ferrets. The animal presents with abducted, uncoordinated hindlimbs, or a frog-legged appearance. The body may lose its curved appearance as the animal is unable to flex the spine as much as usual. The withdrawal and placing reflexes may be absent, and the animal may be incontinent. Often, the animal remains bright and alert and otherwise normal. There are many possible causes, including neurological conditions (eg, intervertebral disc disease or Aleutian disease), diseases causing generalised weakness, cardiac disease, abdominal pain, and metabolic diseases (eg, hypocalcaemia, thiamine deficiency and hypoglycaemia).

Specific treatment depends on the diagnosis. Non-specific supportive therapy, cage rest and prednisolone may be effective in cases of disc disease, or viral myelitis. However, recurrence is common and the prognosis is guarded.

### Milk fever

Milk fever may occur at peak lactation, 3–4 weeks postpartum. It can lead to posterior paralysis and convulsions. Treatment with calcium borogluconate is usually successful.

### Neoplasia

Reports of neoplasia in ferrets are increasing (Beach & Greenwood 1993; Lloyd 1999). Primary neoplasms have been reported in all organ systems except the cardiovascular system, although tumours of the respiratory tract and CNS are extremely rare. Tumours of the reproductive tract and lymphoid system occur most commonly in the UK. It is quite common for two or more different neoplasms to be found in the same animal. Nearly half of all tumours reported have been malignant.

Most cases occur in ferrets between 4 and 7 years of age, but some have occurred in younger animals. Any neoplasm may metastasise, although it is rare for abdominal tumours to spread into the chest cavity, and vice versa. Resection of the tumour is usually the best treatment, however recurrences at the site or in local lymph nodes may occur. Neoplasms in the distal forelimb may best be treated by amputation, and ferrets can do well with only three legs.

### Lymphosarcoma

Lymphosarcoma is relatively common in ferrets, and there may be solid tumours in parenchymal organs, disseminated lesions throughout the body, or leukaemic spread (Fox

1998). Animals less than 1 year old tend to develop an acute lymphoblastic form with thymic involvement, and animals over 2 years old tend to develop a more chronic lymphocytic disease with lymphadenopathy. Males and females are equally affected, as are neutered and entire animals. The leukaemic form is relatively rare, but may be seen in the later stages of both juvenile and adult forms of the disease.

The clinical signs depend upon the site of the lesion and are often non-specific. In the acute lymphoblastic form, animals exhibit a rapidly progressive loss of condition, with anorexia, weakness and lethargy. Dyspnoea is common, but lymphadenopathy is rare. Young animals are more likely to die from the disease than adults are.

In adults, there is usually peripheral and visceral lymphadenopathy, with some organ involvement later in the course of disease. Animals may have cycles of non-specific signs such as recurrent infections, anorexia, weight loss and lethargy over months or years. Splenomegaly is common.

Diagnosis can be difficult. Lymphosarcoma may be diagnosed provisionally on the history and clinical signs, and confirmed by cytology or histology on blood, tissue aspirates or biopsies.

The choices for treatment are surgery, chemotherapy, radiotherapy or combinations of these. However, the prognosis is guarded since, even if there appears to be only one organ affected, the disease is likely to be systemic.

### Insulinoma

Tumours of the  $\beta$ -cells of the islets of Langerhans are reportedly common in the USA. They produce excess insulin, leading to hypoglycaemia. It is commonly seen in animals of 4–5 years. Animals present with variable neurological signs caused by hypoglycaemia, such as weakness, apparent blindness, muscle twitches, or seizures. Signs are intermittent initially and may become more prolonged as the disease progresses. Diagnosis is made on clinical signs and on measurement of blood sugar. Medical treatments can be used in older animals or those with intercurrent disease, although surgical removal is indicated in young animals (Lewington 2000).

### Adrenal-related endocrinopathy

Adrenal tumours are again reportedly common in the USA but are rare in Europe. This may be due to differences in husbandry: early neutering and housing in artificial light cycles appear to predispose to the condition. Animals over 2 years of age are typically affected. One or both adrenals may be affected, and tumours typically secrete androgens, oestrogens or progestagens, rather than glucocorticoids, so the signs are similar to those of hyperoestrogenism rather than typical Cushing's syndrome (Hillyer & Quesenberry 1997). Increased aggression, bilaterally symmetrical alopecia and pruritus are common. Females may develop vulval swelling, and males stranguria due to prostatic cysts. Vulval swelling that does not respond to hormone treatment may be due to an adrenal tumour rather than hyperoestrogenism.

Diagnosis can be made on clinical signs and analysis of hormone levels. Surgery to remove the affected glands is

recommended in young animals, older animals may be treated medically.

# 30 The laboratory dog

Judy MacArthur Clark and C. Jane Pomeroy

## Biological overview

### General biology

The dog (*Canis familiaris*), which has been domesticated for at least 14000 years (Clutton-Brock 1995), is a monogastric carnivore, capable of exploiting a wide range of food types. As a result of selection by man, the species has diversified immensely from its assumed ancestor, the Asiatic wolf (*Canis lupus pallipes*).

The anatomy of the dog is comprehensively described by Evans (1993). The purebred dog population consists of over 300 partially inbred genetic isolates known as breeds. A comprehensive review of the genetics of different breeds and strains is provided by Willis (1989). The canine karyotype consists of 78 chromosomes.

### Size range and lifespan

The life expectancy of a dog is around 12–16 years with larger breeds tending to have a shorter lifespan. The purpose-bred beagle is most commonly used in research owing to its compact shape and size (adult weight is generally between 7 and 17kg), short coat, co-operative and docile nature, proclivity for large kennel environments, regulatory requirements regarding its use for toxicology studies and because of the wealth of background data on this breed.

### Social organisation

Dogs are highly gregarious mammals with complex social behaviour (Serpell 1995). Most breeds of domesticated dog have a looser pack structure than their wild predecessors (Boitani *et al.* 1995; MacDonald & Carr 1995) and are able to readily form social relationships with human beings as well as with conspecifics (Fox 1975).

Communication is important in developing social relationships in a kennel environment and consideration should be given to allowing this through appropriate housing design Joint Working Group on Refinement (JWGR 2004). Auditory signals are important and a dog's hearing may be particularly sensitive to the frequency range of maximum energy in the bark (Sales *et al.* 1996). It also appears that visual signals are important in canine communication, and ensuring that dogs

in a kennel environment have clear lines of sight to each other may reduce barking. In addition to being a nuisance and a health hazard for people, barking can be an indication that a dog is anxious about a potential threat.

The significance of olfactory signals, including urination, which dogs use to communicate sexual and social status and to mark territory, is often underestimated (Sommerville & Broom 1998).

### Standard biological data

A wealth of biological data can be found in Altman and Dittmer (1972, 1973, 1974). Some of the more commonly needed values are shown in Table 30.1. Values for haematology can be found in Spurling (1977), while Kaneko *et al.* (2008) and Loeb and Quimby (1989) have provided comprehensive reference values for the clinical chemistry of canine body fluids. An analysis of cerebrospinal fluid can be found in Rushton (1981). Wherever possible, reference values derived from the source colony and analysing laboratory should be used for comparison.

### Reproduction

Some reproduction data for the laboratory beagle are summarised in Table 30.2. Allen (1992) provides a detailed review of fertility and obstetrics in the dog. Pre-weaning losses in beagles (including stillbirths and neonatal losses) should be less than 12% of all births.

### Normal behaviour

Dogs have a rich repertoire of visual and vocal displays. These are illustrated in Shepherd (2002) and handlers should become familiar with the patterns of behaviour associated with greeting, sexual behaviour, nervousness, submission and aggression. Similar signals are used towards both humans and conspecifics and the displays are good predictors of future behaviour. For example, a young dog that comes forward confidently to greet human visitors to its kennel is likely to adapt well to a laboratory environment.

It is now well accepted that there is a critical period between 3 and 13 weeks of age during which puppies should

**Table 30.1** Some typical physiological values for the laboratory beagle.

Parameter	Normal value
Adult weight (kg)	7–17
Life span (years)	10–15
Rectal temperature	37.5–39.2 °C (99.5–102.5 °F)
Mean heart rate (beats per minute)	60–120
Mean arterial blood pressure (mmHg)	90–120
Arterial blood pH	7.36–7.46
PaO <sub>2</sub> (mmHg)	85–105
PaCO <sub>2</sub> (mmHg)	30–44
Respiratory rate (breaths per minute)	10–30
Tidal volume (ml/kg)	10–15

**Table 30.2** Breeding data for the laboratory beagle.

Parameter	Normal value
Age at puberty (months):	
Male	7–8
Female	8–14
Gestation period (days)	63 ± 4
Oestrus interval (months)	7–8
Average litters born per bitch per year	1.3
Average litter size (puppies):	
Born	6.6
Weaned	6.2

be familiarised with humans. Handling and socialisation should start from birth and training for experimental procedures from about 3 weeks of age (Boxall *et al.* 2004) including exposure to novel toys, brushes, bins, coverall suits, clippers and handlers with glasses. By 14 weeks, a dog deprived of such socialisation may show fear-motivated aggression, timidity or hyperactivity and may become stressed and experience poor welfare when subjected to even simple, non-invasive procedures (reviewed in Hubrecht 1995). Physiological values in such dogs may fall outside normal limits (Vanderlip *et al.* 1985a, 1985b).

### Sources of supply

Dogs are, by nature, pack animals and usually live well in a kennel environment with a defined social order. Purpose-bred animals develop within this background and are likely to be, temperamentally, more suited to the laboratory environment than those with either a free-ranging or domestic history such as stray animals or pets. For the most part, purpose-bred animals are used, particularly for pharmacological and toxicological experiments. For example, a total of 4271 dogs were used in the UK in 2008 of which 4240 were purpose-bred beagles, and only 31 were other breeds which may not have been purpose-bred (Home Office 2009).

The number of dogs used in research has been on a downward trend over the last 20 years. Figures for the UK show some 20 500 procedures performed on carnivores (the majority being dogs) in 1988 compared with 9000 in 2007 and a similar decline in numbers is also seen in the USA. An estimated 140 000 dogs are used worldwide in research and testing every year (JWGR 2004). Nevertheless, the species represents a very small proportion of overall animals used – less than 0.25% in the UK (Home Office 2009). This probably reflects the widespread view, also embodied in many regulatory systems, that alternative species should be used wherever possible.

In Europe, there is a legal requirement that prevents the use of non-purpose bred animals unless the proposed use is carefully justified on scientific and welfare grounds (European Community 1986, 2008). In the USA, a committee of the Institute for Laboratory Animal Research (ILAR) concluded that, under some circumstances, dogs with qualities of random source animals may be desirable and necessary. However, it was not necessary to obtain such dogs from dealers since direct acquisition from breeders, individual owners, or from shelters was both preferable and feasible as an option (National Research Council 2009). JWGR (2004) provide a helpful comparison of the benefits of purpose-bred dogs over dogs from random sources.

If it is proposed to use non-purpose-bred animals, there should be strong justification for this use, such as in the study of a genetic defect only seen in a breed not available from a purpose-bred colony. Economic reasons alone are not sufficient. It is advisable to obtain written confirmation from the supplier that the animal has been obtained legally. Even so, it is important to appreciate the reasons for widespread public concern surrounding such acquisitions.

The option of homing dogs at the end of their experimental use is being increasingly considered, although experience has shown that this is not always an easy task. It is important to consider the temperament of each individual in deciding whether this is feasible. A veterinary certificate of health and suitability is desirable and, in some countries, may be a legal requirement. After selection, a socialisation programme should be used to prepare the animal psychologically for its new environment (Laboratory Animal Science Association (LASA) 2004).

### Transport

General advice on transport is provided in LASA (2005), and see also Chapter 13. Transport of animals causes stress and ideally only healthy subjects should be moved, even for short distances. Prior to their journey, dogs should be habituated to their crate to minimise fear and apprehension. This can be done by placing the crate in the dog's pen. Social groupings can be conserved by selecting dogs to travel in compatible pairs or small groups, although it may be safer to transport each dog in its own crate.

Acceptable designs and dimensions for crates for transport by air are detailed in International Air Transport Association (IATA) Live Animals Regulations (2009), which take the size of dog into account in their recommendations. These standards may also be suitable for dogs travelling by

sea, road or rail. It is generally recommended that any crate used for transport, no matter how brief the journey, should be large enough to allow the dog to stand in a natural position, turn around and lie down (Animal Transportation Association 2000).

Glass fibre and rigid plastic are the best materials for transport crates. Commercially manufactured models are available that come in a range of sizes, are designed for the purpose and can be readily sanitised. Particular care should be taken to ensure adequate ventilation, usually by making the whole of one end of the crate open with a mesh door that is nose and paw proof. The crate should be designed to prevent adjacent crates being stacked too close together and there should be side ventilation.

Road vehicles, trains and boats should be ventilated with air of adequate quality. Airlines should always place dogs in pressurised compartments. Prolonged exposure to temperatures below 7°C or above 29°C should be avoided during transport, ideally by using temperature-controlled vehicles.

In many countries, it is illegal to transport puppies under 8 weeks of age without their mother. With this exception, puppies under 4 months old should not be transported in the same primary container as adult dogs. Pregnant bitches should not normally be more than two thirds of the way through pregnancy and should be accompanied by a veterinary certificate stating that there is no expectation of birth occurring during transit. It is advisable that all transported dogs should undergo a veterinary examination within a few days beforehand to ensure they are fit for the proposed journey. For international transportation, this examination is often specified by the importing country's regulations. A journey plan should be prepared, and it is advisable, and in some countries mandatory, to use an authorised animal transporter.

Adult dogs should be fed about 2h before despatch and gently exercised to encourage defecation before being placed in the crate. An interval of up to 24h can elapse between feeds for adult dogs but puppies require feeding at shorter intervals (up to 12h depending on age) and this should be taken into account when planning journeys of more than 8h duration.

For long journeys, water should be offered at intervals or provided in a spill-proof container. Written instructions for feeding and watering in transit, together with any instructions for special care, should be attached to the primary container in such a way that they can be easily seen and read. Food and water deprivation are major contributors to the accumulated stress of transport.

## Uses in the laboratory

The Committee on Dogs of the US National Research Council has reviewed a range of research areas in which the dog is commonly used (National Research Council 1994). The review not only expands on the uses, but also on the special considerations for husbandry and veterinary care of dogs during such studies.

The dog has many physiological functions similar to those of humans and so can be used as a model for many condi-

tions including those associated with complex genetic traits. Mapping techniques, such as linkage disequilibrium and whole-genome radiation hybrids, have identified some 724 markers (235 genes and 489 microsatellites) (Ostrander & Wayne 2005). Over 360 genetic disorders in dogs have been described, at least half of which resemble specific human disorders (Patterson 2000).

Among those disorders for which the mode of inheritance is known, over 70% are inherited as autosomal recessive, X-linked, or genetically complex traits and 46% are believed to occur predominantly or exclusively in one or a few breeds. This is the largest set of genetic disorders in any non-human species and, together with the mapping information, presents opportunities for research relevant to human disease (Switonski 2004).

The range of research areas in which the dog has played a role is very extensive, including studies of:

- degenerative problems and carcinogenesis;
- aging and its associated disorders;
- cardiovascular diseases, both congenital and induced, including hypertension and heart failure;
- haematological disorders and immunodeficiencies, including autoimmune diseases;
- organ transplantation and open-heart surgery;
- neurological, ophthalmological and orthopaedic disorders;
- radiation-induced injuries;
- early studies of gene transfer and genetic modification which have paved the way for human clinical gene therapy.

Laboratory dogs are also used to develop and test veterinary products for companion dogs such as vaccines, worming and flea treatments, antibiotics, non-steroidal anti-inflammatory drugs (NSAIDs), cardiac drugs and prescription diets.

Increasing pressure to justify the selection of the dog in all research means that other species such as the minipig are being selected where appropriate. In the UK, over 80% of procedures using dogs are for toxicology tests, most of which are performed to satisfy legislative requirements. In a recent study (Olson *et al.* 2000), it was found that non-rodents (primarily dogs) predicted 63% of human toxicities observed in clinical studies for pharmaceuticals compared with only 43% in rodents.

## Laboratory management and breeding

### General husbandry

#### Enclosures

Housing systems in Europe have undergone significant change over the last two decades based upon greater understanding of the natural behaviour of the laboratory dog. These changes have been reflected in new guidelines and regulations (Council of Europe 2006; European Community 2008). Hubrecht and Buckwell (2004) provide extensive information about appropriate housing and care systems for laboratory dogs, largely based upon behavioural

considerations. In addition, JWGR (2004) describe a range of refinements to dog husbandry and care and provide a number of recommendations that are now becoming widely accepted.

In general, dogs should be housed in indoor pens, preferably with adjacent outdoor runs for exercise. Where the exercise run is outdoors and in a populated area, consideration should be given to the noise nuisance in the neighbourhood. Such a problem is not sufficient grounds for 'debarking' dogs. Some recent facility designs based upon indoor housing also offer secure outdoor exercise areas by locating them within the perimeter of the building (Figure 30.1).

Outdoor access helps to provide a stimulating environment for dogs so it is unfortunate that the actions of extremists in some countries (or the fears of such action) have led to the common practice of housing dogs entirely indoors. In such situations, some access to daylight is desirable, either through windows or skylights, and access to an indoor run, in which individuals or small groups of dogs can regularly exercise, is essential.

Exercise runs, whether indoors or outdoors, should be designed to provide a stimulating environment (Figure 30.2), and human contact during exercise periods should be encouraged. In some countries, climates are sufficiently mild that dogs can be housed almost entirely outdoors, nonetheless, they should still be given access to protective shelter at all times.

Floor materials for dog facilities are often a problem. These should be smooth and resistant to corrosion, denting, cracking or chipping. Sealed junctions between floor and walls are important with coving to ensure dirt traps are avoided. Modern epoxy finishes can be ideal but, if inadequately installed, may cause costly long-term problems.

Bare solid floors, particularly with under-floor heating, may present a cleaning problem since faeces and urine will accumulate. Experience has shown that even a small amount of substrate, such as sawdust or woodchips scattered on a solid floor, will help with cleaning and assist the animal in maintaining a healthy coat and paws.

Open flooring (perforated, grids or mesh) has been subject to criticism since the animal's weight is borne on a relatively small area of the foot pad. Such flooring should not be used without strong justification and never for pre-weaning pups, lactating or periparturient bitches. If its use can be justified, it is generally accepted that it should be covered with smooth, soft plastic for tactile warmth as well as improved cleanliness and dogs should also have access to a solid floor over part of the available living area.

### Environmental provisions and enrichment

Modern dog pens are designed to allow flexibility with respect to pen size and interconnections between pens. Thus pens designed to separate single animals for short periods (eg, for feeding) can be readily reconnected to maintain social groups. Stainless steel is generally used for structural frames in preference to galvanised metal which may have toxic effects due to the surface zinc.

Materials used in panels between pens may consist of stainless steel rods, strengthened glass, or plastics (which must be of Food Grade Approved standard), which are warmer to touch and absorb some of the noise generated by barking. Horizontal bars are preferred in panels over mesh (which creates a visual barrier) or vertical bars (which provide no support for the dogs' paws, and which reduce lateral visibility through the bars).

It is important to ensure that each pen has sufficient space and resources to provide for all the functional requirements of the occupants. This should include separate areas for urination and defecation, for resting or sleeping, for breeding where appropriate, and for social interaction such as play. Good modern dog enclosures are sub-divided and furniture is provided. These allow for normal behaviour patterns (see Figures 30.2 and 30.3) including avoidance of aggressive encounters and play behaviour.

Hubrecht and Buckwell (2004) have suggested that practical experience indicates that a dog pen of 4.5m<sup>2</sup> (as used in the UK at the time of writing) provides sufficient space for

**Figure 30.1** A secure outdoor run provided within the perimeter of the surrounding building. (Reproduced with permission of Astra Zeneca.)

**Figure 30.2** Suitable equipment in an exercise area will stimulate play behaviour. Active human contact is also important. (Reproduced with permission of Astra Zeneca.)

**Figure 30.3** Glass panels between pens can improve overall visibility and reduce levels of barking. (Reproduced with permission of Astra Zeneca.)

sub-division and enrichment to allow functional use of space for two adult beagle dogs. Within Europe somewhat smaller minimum dimensions of 4m<sup>2</sup> (representing a doubling of the existing single housing) have been recommended for one or two dogs in order to encourage social housing without requiring an increase in existing building sizes (European Commission 2007). If an animal must be single-housed, it should be provided with the same space (Council of Europe 2006). It should also be remembered that these are minimum dimensions and it is possible that dogs benefit from the greater opportunities for enrichment and activity that are possible in larger enclosures.

Enrichment within the enclosure is critically important. It is important that the pen design incorporates features that are stimulating to the occupants. Hubrecht (1993) has dem-

onstrated the clear benefits of enriched environments for dogs, including the desirability of providing raised platforms in pens and areas of restricted visibility into which dogs can withdraw or hide. These allow the occupants to make choices in relation to the complexity of their environment, permit use of the third dimension of height, and can be designed to not disrupt routine husbandry practices and animal observation.

Dogs are naturally inquisitive and actively seek information about their environment. The use of a raised platform and ramp is especially beneficial allowing some privacy from neighbouring dogs but also allowing good vision of the surroundings (Figure 30.3). Since dogs naturally chew, objects which are safe and possibly flavoured, such as rawhide or other commercially produced chews, may be suspended within the pen enclosure (Hubrecht 1993, 1995) avoiding monopolisation, soiling or the blocking of drains.

Dogs need a warm dry area for sleeping. In pens with under-floor heating this may be an intrinsic part of the design. In other housing systems a raised bed should be provided, preferably made of a plastic material such as polyethylene or polypropylene, or a high-quality compacted building panel which is resistant to chemicals. Wood can be difficult to sanitise but, in some situations, it may be acceptable to provide wooden beds that are routinely replaced. If wood is used, the life may be extended by framing the edges of the beds in stainless steel to reduce damage from chewing. The size of the bed will vary with the size of the dog but it is not normally necessary to allow for the dog to fully stretch out. Thus a bed area of 0.5m<sup>2</sup> is adequate for an adult beagle. Soft veterinary bedding material may be appropriate but it will be damaged by chewing and need to be regularly cleaned. An alternative is commercially available shredded paper bedding.

Although dogs may have been kept in cages in the past, such conditions are not able to meet their essential needs in relation to space for locomotion, social contact with conspecifics and environmental enrichment. Dogs are members of a family of active, cursorial mammals so should preferably be housed in floor pens with environmental choice incorporated into their design. Bebak and Beck (1993) have looked at the effect of cage size on play and aggression and shown the benefits of spacious environments for beagles. If dogs must be caged for anything more than the briefest of periods, there should be an opportunity for vigorous activity at least once a day for not less than 30 minutes (O'Donoghue 1993).

Visual contact with other dogs and humans is very important and singly housed or caged dogs should be visited and handled regularly throughout the day to reduce the development of stereotypical behaviour which may persist even after the animal is returned to its pen. Strict limits should always apply to the maximum acceptable periods in single housing or cages and this should be considered as part of the 'cost' to the animals in a cost-benefit analysis.

Metabolism cages for dogs allow separate collection of faeces and urine but inevitably restrict the animal's movement and use of space. Recent moves toward larger cage areas have led to designs for folding metabolism cages

which provide more generous space for the dog (up to 2m<sup>2</sup>) yet can be moved through doorways and packed away when not in use. These larger folding cages can often be located in the animal's home pen so that visual contact with familiar animals is maintained. Alternatively it may be possible to locate metabolism cages within a laboratory area so dogs have human company for large parts of the day or are within sight of other dogs in similar cages.

Facilities must also be available for the isolation of sick animals or those needing special attention. These are normally cages made of fibreglass or similar warm material with a mesh front to permit easy observation. Cages designed for clinical veterinary practice are suitable.

### Feeding and watering

Dogs vary enormously in both adult size and in absolute growth rate but most will grow to at least 40 times their birth weight during their first year. Beagles, and dogs of similar size, reach their mature weight at about 18 months of age, so experimental animals below this age will require a diet capable of supporting growth during the experiment. Pregnant and lactating bitches have special nutritional requirements but a carefully balanced diet is also needed during the non-productive periods if the bitch is to achieve her full breeding potential.

### Natural and laboratory diets

Most laboratory dogs have all their dietary needs provided in the form of a commercially prepared dried diet. The dried diets are generally produced in an expanded form and should be fed with free access to drinking water since they themselves contribute negligible water. Ideally, dried diets should be available *ad libitum* enabling the animal to develop a nibbling pattern of feeding. In many dogs, this leads to obesity so that restricted meals offered once or twice daily become preferable (Markwell & Butterwick 1994). Dried diet has the advantage that it can be fed from a hopper where it will remain fresh for several days.

Alternatively, a satisfactory diet can be provided in canned or semi-moist form. Some canned diets contain added cereals so that they constitute a complete diet, whilst others with a higher protein content are intended to be fed together with a cereal biscuit. The semi-moist diets usually constitute a complete diet and should be fed with an ample supply of drinking water. Both canned and semi-moist diets have the disadvantage of being perishable so that they must be provided fresh each day. Diets should be fed according to the manufacturers' recommendations with regular body condition scoring to ensure optimal weight.

The nature of the diet may influence the incidence of dental disease with the accumulation of tartar. This can be a significant problem in dogs in colonies from as early as 1 year of age with a reported 84% incidence in beagles aged more than 3 years (Kortegaard *et al.* 2008). Problems occur both directly through dental disease and indirectly through possible systemic effects leading to histopathological changes in kidney, myocardium and liver (DeBowes *et al.* 1996). Regular dental checks should be performed.

### Dietary requirements

The dietary requirements of dogs are detailed by the US National Research Council (1985) together with specific procedures to be followed to ensure that foods do not become nutritionally deficient during storage. Essentially, a maintenance diet should provide 22% digestible protein and 5% fat, when calculated on a dry matter basis.

Because the dog is an extremely adaptable animal, deficiencies of nutrients are unusual except in highly productive or rapidly growing animals. For example, the dog can use over 96% of its dietary fat and the essential fatty acids are all interconvertible in the tissues. Therapeutic diets are available for dogs with special nutrient requirements caused by disease but these should only be used under veterinary direction. For example, low-salt diets are useful in the management of experimentally hypertensive dogs. Simpson and Anderson (1993) describe clinical aspects of nutrition in the dog.

### Water

The water content of the diet will vary between about 80% in canned diets and less than 10% in dried diets. Thus the need for drinking water will vary not only with the size of the dog and its water loss through urine, faeces and expired air, but also with its type of food. The total daily water requirement in a temperate environment is 70–80ml/kg body weight. It is essential to provide unrestricted drinking water.

### Presentation of food and water

Feeding bowls should have broad flat bases for stability and be made of a material that will resist chewing. Stainless steel is the most satisfactory. A metal retaining device can be used to prevent movement of the bowl during eating. Alternatively, a stainless steel food hopper can be incorporated into the design of the pen. Food dispensers should be positioned so as to prevent soiling. Hoppers should be inspected at least daily to ensure they do not contain caked or unfit food. This creates a useful opportunity to socialise with the dogs associated with feeding. Hoppers should also be emptied and thoroughly cleaned at least twice weekly.

Dried diet can be fed *ad libitum* from a food hopper but this may promote obesity and increased oral bacterial growth and tartar production. In the wild or feral state, a significant proportion of a dog's day might be spent acquiring food by hunting and scavenging. It may be beneficial in the captive environment to simulate this, for example with pet toys made of natural rubber into which food can be inserted, since it may reduce boredom. However these products may be rapidly destroyed by chewing. It is also important to avoid competitive aggression over restricted food supplies and careful supervision during feeding times is important. Pen mates may need to be separated during feeding. Diet aversion can occur if a diet becomes associated with negative physiological effects, such as with a drug dose with unpleasant consequences (JWGR 2004).

Water should be constantly available either from a fixed water bowl, or preferably from an automatic drinking

system. Dogs will rapidly learn to drink from such a system, which has the advantage of avoiding static water in bowls which may become soiled. Pipework used for drinking water systems should be of high-quality stainless steel to prevent corrosion and contamination of the water. Drinking valves are generally reliable and rarely block or leak but it is essential to check the operation of each valve at least twice daily, and always when dogs are placed in a previously vacant pen to ensure that an intact water supply exists.

### Social housing

Social housing is always preferable to single housing. Hetts *et al.* (1992) examined the influence of single housing conditions on beagle behaviour and found that solitary dogs have a reduced behavioural repertoire, sleep less and tend to vocalise more than dogs with social contact.

Puppies should be reared in groups which provide both the opportunity to interact with peers and a situation in which they can indulge in complex social play. Being naturally gregarious animals, older dogs should be kept in pairs or small groups though separation may be necessary during feeding unless the diet is supplied *ad libitum*. Male dogs are generally more aggressive than bitches and as they pass through puberty they may become more hostile to other males. Different breeds of dog vary in their reactions to other dogs and in some cases unfamiliar adults are hostile and cannot easily be introduced into a group without fighting. When dogs are kept socially, care should be taken to ensure that low-ranking individuals are not deprived of resources such as food or access to a resting area.

In some experimental situations it may be useful to be aware of the individual's social status as this can affect physiological measures such as corticosteroid levels and resting heart rate. Klumpp *et al.* (2006) showed that housing with a familiar conspecific resulted in lower haemodynamic parameters and fewer vocalisations.

Dogs should not be housed singly unless there is strong scientific justification or in the interests of animal welfare (eg, following anaesthesia and surgery). Where it is necessary to singly house a dog, the housing should be designed so that the isolated animal is always able to choose visual contact with other dogs and receives regular contact with humans. A good relationship with humans will be invaluable during experimental procedures.

Surgically prepared dogs with exteriorised implanted devices may need to be isolated although totally implantable devices are now available and should be used wherever possible. If this is not possible, other means of protecting the protruding devices, such as tethers or jackets, should be used if necessary.

In toxicity trials, dogs are usually housed in pairs or small groups though separation for short periods (4h or less is common practice) should be feasible for feeding and dosing and for individual observation. However, it is preferable not to separate dogs for individual food and water consumption unless absolutely necessary. In many cases, comparative consumption data across entire dose groups can be used.

### Identification

In the past, puppies have been permanently marked at 4–6 weeks of age using tattooing forceps on the ear flap. This causes significant discomfort and the technique has been superseded by microchipping.

Electronic microchips have been shown to provide reliable identification over prolonged periods. Microchips can be obtained pre-programmed with identification codes, or can be programmed at the time of insertion. Special chips are also available which indicate the dog's body temperature in addition to its unique identifier. These may be useful during clinical examinations and during surgery. Microchips are inserted subcutaneously, usually in the scruff of the neck between the shoulder blades, without the need for anaesthesia. A reader is used to scan the microchip. There are occasional problems of migration or chip failure that make scanning difficult or impossible. However, the incidence of total loss of microchips is very low making this the method of choice for identification.

### Physical environment

#### Temperature

Dogs are extremely adaptable with regard to their temperature requirements and thrive in climatic conditions ranging from the arctic to the tropics. Dramatic changes in the ambient temperature should be avoided. At lower temperatures it is important that dogs should have access to a shelter, preferably with a source of heat. In hot environments, access to a shaded shelter is essential.

The temperature of indoor dog pens is usually kept between 18°C and 21°C. It is important to avoid extreme fluctuations in the temperature though grouped animals in pens will usually be better able to cope with lower temperatures than animals housed singly.

#### Ventilation and relative humidity

A ventilation rate of 10–12 air changes per hour should be provided in all indoor accommodation. Provided the air is evenly distributed, this will prevent unacceptable build-up of foul odours at recommended stocking densities. Air-handling devices should be designed to avoid draughts and to distribute the air evenly to all of the animal area. It is best to provide 100% fresh air to the ventilation system. If recirculation units are used, effective air cleaning and filtration should take place to remove smell, moisture and chemicals such as ammonia, as well as potential pathogens.

Extremes of humidity should be avoided but this may be difficult during cold weather where cleaning is performed by hosing down. Not only will high levels of humidity predispose dogs to respiratory infections, but the effects of condensation on the building structure can also be very damaging.

## Lighting

Lighting systems should provide sufficient illumination for easy observation of animals and a safe working environment for personnel performing husbandry and hygiene tasks (National Research Council 1996). Natural lighting, with its seasonal variation, is normally acceptable though this may affect breeding patterns. In artificial lighting, the daylight period should be at least 10h and normally 12h in duration. Simulating dawn and dusk by slowly increasing or decreasing light intensity can avoid startling dogs with sudden changes.

A thoughtful approach to the use of lighting, which is functional yet attractive, can provide a congenial environment both for staff and animals. This can be important to create good staff morale which may reflect a more caring approach to husbandry. Attractive features such as bright wall colours, decorative tiles, glass and colourful plastic panels, skylights, murals and appropriately placed vegetation can all be used to good effect without major additional cost. Such an approach has been exemplified very well by Loveridge (1994).

## Noise

There is currently a lack of adequate guidelines for noise in dog kennels in spite of the recognition that noise levels regularly reach values between 85 and 122 decibels throughout a working day. These levels will cause annoyance, stress and damage to human hearing and personal protective equipment should be provided for personnel. There is increasing evidence that excessive noise in the kennel environment may be a welfare issue (Sales *et al.* 1997). Hubrecht *et al.* (1997) measured noise levels and made some useful recommendations to reduce levels in kennels using sound-absorbent materials and small group sizes.

Barking is often triggered by human activity and changes to husbandry practices may reduce noise levels. Recent experience using glass partitions that allow dogs to have clear vision of the activity of humans and of other dogs across an entire kennel area suggest that barking is reduced in such environments (Figure 30.3). Herringbone patterns allow dogs to see activity in the room from within the pen and may reduce barking. Further studies need to be done to confirm these approaches, which may result from animals not being surprised by events in their surroundings.

## Hygiene

Faecal material should be regularly removed throughout the day from indoor pens. Dogs tend to defecate shortly after feeding and so removal is especially required during this period. Thorough washing of the pen should also be carried out daily. Where possible, pen washing, particularly where pressure hoses are used, should be performed when dogs are outside the pen, either socialising or undergoing procedures. If sawdust is used on the floor, this should be swept up prior to washing and replaced after the pen is dry.

Disinfectants should be chosen and used carefully to avoid skin irritation. Ideally, complete rooms of dog pens

should be emptied periodically, deep cleaned and disinfected thoroughly. This may be feasible between studies especially in toxicology facilities.

If access to the outside is constantly available, an adult dog will usually not soil its indoor pen. Faecal material should be removed from the outside run regularly throughout the day and the floor and walls should be washed daily. Puppies are less fastidious in their habits and a pen containing a group of weanling animals may need to be thoroughly cleaned many times during the day.

## Health monitoring, quarantine and barrier systems

Laboratory dog colonies can be divided into two main categories with regard to health monitoring and disease control. The first, and most common, is the closed or semi-closed colony (eg, a breeding colony or a long-term experimental colony) where few introductions of new animals occur and always from reliable sources. In such a colony, the major threat is from new dogs, which should always have been effectively immunised against the common canine infectious diseases in compliance with the vaccine manufacturers' data sheets or according to the WSAVA Guidelines for the Vaccination of Dogs and Cats (Day *et al.* 2007). A well managed personnel barrier, involving at least a change of outer clothing and hand-washing, is also important to avoid humans acting as vectors of disease.

Some infectious pathogens are of particular concern to breeding colonies such as canine herpesvirus (CHV) which can cause abortions and neonatal deaths and *Brucella canis* which is also a zoonosis. Since no vaccine is available against the latter, a serological sample collected on arrival may be checked for antibodies.

The second type of colony receives frequent introductions of new dogs, some of which may be from sources where the health status is unreliable. Effective quarantine may be very difficult but should always be the aim. Newly arrived dogs should be housed in groups according to their source and receive a veterinary examination soon after arrival. Unvaccinated dogs should not normally be accepted and must be kept in strict isolation and immunised as soon as possible.

Health monitoring of established colonies should follow a defined programme of sample collection including faecal and blood samples (Federation of European Laboratory Animal Science Associations (FELASA) 1998). In a breeding colony, careful examination of breeding and puppy growth data is also important.

A health programme should also be implemented to protect personnel based upon medical advice. As a minimum, this should include tetanus vaccination for all personnel. In countries where rabies occurs, vaccination against rabies should also be considered, and special attention should be paid to any scratch or bite injuries to ensure personnel receive prompt medical attention.

A quarantine facility should be designed to provide physical barriers to disease spread, including the possibility of air-borne spread, and should preferably have its own animal care staff. Dogs should be checked at regular intervals

throughout the day (*Department for Environment, Food and Rural Affairs (DEFRA) 2007*).

## Breeding

### Identifying the fertile state

Dogs become sexually mature at 6–12 months of age; small breeds normally reach puberty earlier than large breeds. Following puberty in the bitch, oestrous cycles continue throughout life, each cycle being divided into four stages: pro-oestrus, the beginning of the sexual season; oestrus, the period of receptivity; metoestrus, the period of subsiding activity; and anoestrus, the period of quiescence.

The bitch is monoestrous since several months of sexual inactivity elapse between breeding periods regardless of pregnancy. The concept of two oestrous cycles a year is erroneous since most reports give an average oestrous interval of 7–8 months, but with a variation ranging from 4–14 months reported.

Colony breeding data tend to show some seasonal influence, with increased incidence of oestrus in late winter and spring. This implies that either light intensity or duration affects the breeding cycle of the bitch.

Pro-oestrus is flagged by enlargement of the external genitalia. Within 2–4 days a sanguinous discharge appears from the vulva, usually regarded as the first day of pro-oestrus. Discharge continues for 6–10 days during which the female is attractive to, but will not accept, the male. When oestrus commences, the female will accept the male showing a characteristic stance of arched back and elevated tail. At the same time, the sanguinous discharge begins to subside. Following acceptance of the male with intromission, the two usually remain 'tied' in the coital lock for 10–40 minutes.

Oestrus lasts from 6–12 days during which time the female may continue to allow coitus. Ovulation normally occurs within 1–2 days after first acceptance of the male and is spontaneous. The female refusing coitus marks the start of metoestrus and is characterised by a gradual decrease in size and turgidity of the vulva. A portion of the metoestrus may be associated with pregnancy or pseudopregnancy and anoestrus commences when the desquamated endometrial lining has been regenerated.

The female, when approaching puberty, may occasionally show an episode of false pro-oestrus with an increase in turgidity of the vestibular wall sometimes accompanied by a slight sanguinous discharge. Acceptance of the male does not occur and it is usually several weeks before true pro-oestrus begins. The condition does not recur at later oestruses and fertility is not affected (Harvey 1998).

Vaginal cytology can be used to estimate the best time for breeding. The technique has been described by Concannon and DiGregorio (1986) and the following microscopical features may be seen:

- pro-oestrus – abundant erythrocytes and 'cornified' cells with pyknotic nuclei, leucocytes sparse;
- oestrus – abundant 'cornified' cells, many without nuclei, and a moderate number of erythrocytes, few leucocytes;

- metoestrus – epithelial cells of varying size and shape, variable number of leucocytes and debris;
- anoestrus – epithelial cells with cytoplasmic granules or vacuoles, variable number of leucocytes.

Additionally, plasma progesterone concentrations can be used to augment the assessment of vaginal cytology; concentration is low during anoestrus and pro-oestrus, increasing when pre-ovulatory follicular luteinisation occurs, followed by a rapid rise after ovulation (England 1998a).

### Breeding systems

Dogs will breed in groups of one stud male with up to 12 bitches. If several bitches are in oestrus simultaneously, the male may be unable to impregnate all of them. Once each bitch is obviously pregnant she should be removed to separate accommodation for whelping. This system has the advantage that oestrus detection by animal care staff is unnecessary.

An alternative system involves examining each bitch daily for signs of pro-oestrus. A bitch is then put with a male on about the 10th day following pro-oestrus detection and remains for about 5 days. Bitches normally ovulate about 2 days after a surge of luteinising hormone which may occur as early as 5 days after the onset of pro-oestrus or as late as 21 days (Wright & Watts 1998). To address this variation, introductions can be made daily over this period, lasting for about 1 hour each day, until a successful mating has been observed on at least two occasions.

A variation of this system would involve housing the bitch with the male from the onset of pro-oestrus until several matings have been observed. Some bitches have a short interval from onset of observable pro-oestrus to their fertile period so that waiting until 10 days after the start of pro-oestrus may result in no pregnancy. However this system has the disadvantage that a stud male can cover only one bitch at a time.

### Conception and pregnancy

Canine spermatozoa can survive for many days in the uterus and are only able to fertilise the ovum some 2–3 days following ovulation.

The preferred imaging technique for pregnancy detection is ultrasonography, which allows foetuses to be seen from 15 days after ovulation (England 1998a). It is difficult to count foetuses precisely ultrasonographically but this can best be done about 1 month after conception with significantly lower accuracy in late pregnancy. The gestation period in the bitch, if measured from mating to parturition, is variable due to the delay which occurs between insemination and fertilisation. Yeager and Concannon (1990) demonstrated ultrasonographic detection of pregnancy from day 16 and noted that gestational age was best estimated based upon the day of the preovulatory surge of luteinising hormone. Embryonic mass and heart beat were first detected at 23–25 days after the LH surge. Kutzler *et al.* (2003) were able to predict parturition date very accurately (85% accuracy within  $\pm 2$  days) using foetal measurements obtained by ultrasonography.

Manual palpation of the standing bitch can be used at 28–32 days after ovulation when foetuses may be felt as a chain of discrete firm swellings, each about 2 cm in diameter. After 32 days, palpation becomes increasingly difficult until very late in pregnancy when the foetal heads may be felt. By this time, mammary development is also obvious.

There is little difference in progesterone concentration between pregnant and non-pregnant bitches (England 1998a).

### Parturition

Signs of impending parturition (whelping) in the bitch have been described by Johnson (1986). A fall in body temperature to less than 37.2°C normally occurs within 24 h before parturition accompanied by palpable relaxation of pelvic and abdominal musculature. Increased friendliness, restlessness and loss of appetite may also occur. For several days prior to expected parturition, a bed should be provided using a bedding material that is designed to drain fluid to the base of the bed leaving the bitch and puppies relatively dry.

Jones and Joshua (1988) have described the pattern of normal whelping together with excellent advice on coping with problems which may arise. The first stage of parturition begins with the onset of uterine contractions. This may last for 6–12 h during which time the bitch may appear agitated.

Stage two commences when the cervix is fully dilated. The allantochorion or 'water bag' of the first foetus appears at the vulva and is often ruptured by the bitch. By now, the bitch is exerting obvious abdominal contractions. Shortly after, the first foetus is presented in the cervix and expulsion may take from only a few minutes to a couple of hours. It is natural for the bitch to chew the umbilical cord and eat the placenta. Her continual licking of the puppy stimulates respiration during the first few minutes of independent life. Further puppies will follow at intervals of 20–60 minutes (maybe as long as 2 h). A non-purulent greenish discharge may precede the first and subsequent foetuses.

Stage three begins after delivery of the puppies and ends with the passage of all placentae. A bitch with multiple puppies may alternate between stages two and three.

Commonly the foetal head will present towards the maternal pelvis, although many foetuses in other presentations are delivered unassisted and should not be considered abnormal. Difficulties may be encountered if the first foetus is in posterior presentation since the dilating affect of the head on the cervix and vagina will be absent. The following are indications of a difficult birth (dystocia) that may require intervention (Tilley & Smith 2004b):

- 30 minutes of strong persistent abdominal contractions or straining without delivering a puppy;
- more than 4 h from the onset of stage two to the delivery of the first puppy;
- more than 2 h between the birth of each puppy;
- failure to deliver more than 24 h after the rectal temperature falls to less than 37.2°C or within 36 h of serum progesterone being less than 2 ng/ml;
- the bitch shows visible signs of pain or is constantly licking the vulva while attempting to deliver;

- prolonged gestation – greater than 70 days from first mating, or 59 days from first day of cytological dioestrus, or 66+ days from the luteinising hormone peak.

### Nutrition during pregnancy and lactation

During the first 5–6 weeks of pregnancy, a bitch can be fed the same amount as before mating. During the last 3–4 weeks, the foetal puppies are growing very rapidly and the diet must be increased according to the manufacturers' recommendations. The gravid uterus often limits intake so this should be provided in small frequent meals.

Lactation is nutritionally very demanding and the bitch will require 3–4 times her maintenance level of food when milk production reaches its peak 3–4 weeks post-partum. This should be fed as frequent small meals.

### Reproductive problems

Pseudopregnancy is a common reproductive problem, occurring in about 16% of bitches during metoestrus, the incidence increasing with age. It is characterised by a varying degree of abdominal distension and mammary development, some bitches actually lactating about 60 days after ovulation. It is thought that falling progesterone precipitates a rise in prolactin in affected animals. The condition is self-limiting and does not usually require intervention (Feldman & Nelson 1987). Cabergoline can be used to selectively inhibit prolactin in bitches distressed by false pregnancy.

False oestrus has been reported (Shille *et al.* 1984) in which the bitch will mate but fail to conceive since no ovulation occurs. This may be followed a few weeks later by true oestrus. Bitches which repeatedly show this pattern can have a very disruptive effect on a breeding colony and should normally be culled, unless of special value. Culling based on small litter size, problems with whelping or maternal behaviour, chronic infertility, age or persistent anoestrus is also appropriate.

Methods for the assessment and treatment of infertility in both the male and female dog have been reviewed by Johnston and Romagnoli (1991).

### Rearing the young

#### Early development

Cannibalism of puppies is unusual though a bitch will often reject a weak or 'runted' offspring, thus allowing it to die. Primigravid bitches are sometimes apprehensive of their litter initially, but usually settle down once the puppies start sucking. Sedation (eg, acepromazine) may be useful for these first hours, once parturition has been completed.

Newborn puppies do not have fully developed temperature control and require a higher ambient temperature than adults to avoid hypothermia. Some of this warmth can be provided by the bitch and littermates but an ambient temperature of 26–28°C will be needed for at least the first 5–10 days. Local heat, using an infra-red lamp, is suitable but the lamp and flex should be hung out of reach of the bitch and at least 1 m above the litter.

Newborn puppies commence sucking immediately after they have been licked clean by the bitch. During the first

week, sucking occurs about every 2h after which the frequency reduces to every 4h. It is very important that puppies feed adequately during the first 24h of life as it is during this time that they receive high levels of colostrum which provides important passive immunity. Puppies are born with their eyes and ears closed. The eyelids gradually separate until the eyes are fully open by day 10–14. By this time the ears are also patent. Puppies are usually able to stand by day 10 and walk steadily by day 21. Voluntary control of micturition and defecation begins between days 16 and 21.

#### Hand rearing

By far the best method of hand rearing puppies is by fostering onto a lactating female. Docile bitches with a litter of similar age and size, or a pseudopregnant bitch, will often accept one or more foster puppies. Puppies can be successfully hand reared using a commercial milk substitute formulated for dogs.

It is vital to provide an environmental temperature of 30–32°C for newborn orphan puppies. After 7 days this can gradually be lowered to about 24°C by 4 weeks of age. At these temperatures, the puppy should be fed at 3-hourly intervals between 08.00 and midnight for the first 3 weeks. At lower temperatures, an overnight feed will be necessary. Thereafter feeds should be reduced in frequency to four times daily by 6 weeks of age. Solid food should be offered from 4 weeks of age. A detailed review of rearing orphaned puppies is given by Edney (1982).

#### Weaning and rearing

Puppies will start eating solid food at about 3 weeks of age and can be separated from the bitch at 7–8 weeks. The nutrient requirements of the weaned puppy are about double those of an adult dog of the same weight. This food should be given in several small meals as shown in Table 30.3. Commercial puppy foods should be fed according to the manufacturer's recommendations. Acceptability and palatability of the food is most important during this period of rapid growth and, if biscuit or a dried diet is used it may be moistened to soften it prior to feeding.

#### Selection of breeding stock

Future breeders should be selected on the basis of parental performance, temperament and conformation. Litters from primiparous females should be avoided since parental performance will not yet have been adequately assessed. Detailed records must be maintained for each breeding animal showing date and size of litters born, stillbirths, neonatal deaths, size of litters weaned, sex of offspring

and identity of the sire. If oestrus detection is being practised, the frequency of oestrus must be recorded together with dates of mating. All these records must be considered in assessing parental performance when selecting bitches.

Standard growth curves<sup>1</sup> of a colony can be maintained to ensure selection from healthy stock of near average weight. Individual examination is of paramount importance to assess the temperament of the animal and to ensure good health and avoid detectable inherited defects.

Selection of good-quality stud males is of even greater importance due to the wider impact on the colony compared with bitch selection. In addition to many of the selection criteria mentioned above, potential studs can have semen samples collected by manual ejaculation and testicular ultrasound can also be performed to evaluate fertility. Once selected, the libido of a stud male should be assessed at regular intervals.

Care must be taken to avoid unintentional inbreeding, particularly in a small breeding colony where random mating would lead to a significant increase in inbreeding coefficient. It has been estimated that a ratio greater than two males for each 10 females is needed to prevent an increase in the coefficient of inbreeding (Shultz 1970). Unrelated stud dogs should also be selected to mitigate against this effect.

The ability of female beagles to breed reaches a peak at 3 years of age and then wanes from 4–8 years of age (Andersen & Simpson 1973). During this latter period there is an increase in the number of mated females who fail to whelp, a decrease in the number of pups born per litter and an increase in the pre-weaning losses. Extended oestrous cycles, 1 year or more in length, are common in beagles over 8 years of age.

#### Production of gnotobiotic and specific pathogen free (SPF) stock

Griesemar and Gibson (1963) have described techniques for obtaining gnotobiotic puppies. It would appear that the last few days *in utero* are important for the production of vigorous puppies. Therefore the accurate detection of imminent parturition is essential to ensure correct timing of the hysterectomy. Gnotobiotic puppies are commonly infected with the roundworm *Toxocara canis* and, in countries where it is endemic, the hookworm *Ancylostoma caninum* but this should be a limited contamination if appropriate sterile hysterectomy techniques are used. Dosing with an appropriate anthelmintic (eg, fenbendazole 50 mg/kg/day) during pregnancy will significantly reduce this parasite burden in the puppies after the hysterectomy (Burke & Roberson 1983; Fisher 2001).

Since they have never been exposed, either naturally or through vaccination, to the relevant infectious agents, SPF dogs can be used for research into canine infectious diseases and for vaccine development and testing. It may also be preferable to use SPF dogs in transplantation studies since

**Table 30.3** Frequency of meals for puppies after weaning.

Age (months)	Meals per day
1½–3	4
3–4	3
4–6	2
Over 6	1 or 2

<sup>1</sup>[http://www.marshallbio.com/docs/pub/Refdata/Reference\\_b\\_growth.pdf](http://www.marshallbio.com/docs/pub/Refdata/Reference_b_growth.pdf)

latent viruses in non-SPF dogs may be activated during profound immunosuppression and cause disease.

### Artificial insemination

Methods of collection, storage and insemination of canine semen have been described by Farstad (1998). Semen samples can be evaluated for a variety of characteristics including motility, sperm count, pH and live to dead ratio. Canine semen is ejaculated in three fractions: the second, the sperm-rich fraction, is used for insemination. Fresh semen can be stored at 4 °C. If appropriately diluted, sperm motility remains almost normal for 3–4 days and for 1 day if stored undiluted (Morton & Bruce 1989). Alternatively, semen can be stored frozen. Freezing techniques have stringent requirements for rate of thawing, dilution and site of deposition which must be followed (England 1993). Sperm normally die within a few hours of thawing so precise timing of insemination is critical to success.

In nature, the semen is deposited into the anterior vagina, but reaches the uterus and oviducts within 1–2 minutes post-coitus. Concannon and Battista (1989) have described a technique of intrauterine artificial insemination with a 50–90% conception rate. Kim *et al.* (2007) compared intrauterine and intratubal insemination and showed low conception rates (20%) with the latter technique. The best time for insemination is usually shortly after oocyte maturation which occurs 5–6 days after the initial rise in progesterone and around the time of the surge in luteinising hormone. Most successful inseminations take place 2–4 days before the decrease in vaginal cornification.

### Oestrus control and impact on research

England (1998b) has comprehensively reviewed the pharmacological control of oestrus in the bitch. Oestrus can be postponed or prevented in the bitch. Progesterone or progestagens are most commonly used and are available in a variety of formulations, including depot preparations and tablets, to be given orally. Androgens may also be given in anoestrus to prevent the return to cyclical activity, either as a prolonged release implant or as a depot injection of mixed testosterone esters. The mechanism of action of androgens is not clear.

Kutzler (2005) reviewed methods of oestrus induction and synchronisation of ovulation for embryo transfer programmes. He concluded that methods vary widely in efficacy of inducing oestrus as well as fertility. Chandra and Adler (2008) reviewed the frequency of different oestrus stages to permit interpretation of morphological changes in toxicity studies. They found that more than 80% of the animals studied were in the anoestrus–dioestrus stage at the time of autopsy.

## Laboratory procedures

### Handling and training

Puppies should be handled frequently to accustom them to human company. Purchased animals should be given

similar attention in their breeding facility and during quarantine when they are adapting to their new environment. Dogs are generally amenable creatures and any tendency to aggression is usually due to nervousness. A quiet, gentle approach will frequently overcome any problems. Rarely, nervous dogs may snap at their handlers and need to be muzzled for minor procedures. Use of such dogs should be avoided, especially for long-term procedures. If a dog develops nervousness over time, sensitive remedial training may be able to resolve the problem.

Dogs can easily be trained to walk on a lead and this experience is beneficial in bonding the dog with its handlers. This may be facilitated by use of head collars designed to prevent pulling. Dogs not so trained, and weighing up to about 15 kg, may be carried (Figure 30.4). Larger animals should be moved in a wheeled box or crate to which they should be habituated.

In addition to lead training, dogs can readily be trained to relax in a body sling or small study cubicle for periods of 8h or more. This is important where animals have been surgically instrumented to permit monitoring of physiological parameters whilst fully conscious. These and other forms of training, including habituation to electric clippers, and sitting still for blood sampling, provide environmental enrichment for these intelligent animals and give opportunities for close human contact. JWGR (2004) provide useful advice on socialisation, habituation and training of laboratory dogs and the benefits which accrue.

## Physiological monitoring

### Recording body temperatures

Rectal temperature can be measured with a digital or mercury thermometer. The normal range is 38–39 °C. The

**Figure 30.4** The correct way of carrying a medium-sized dog. (Crown copyright.)

technique is slow since the thermometer should be placed in the rectum for at least 2 minutes before being read. Continuous or remote recordings are not possible by this method. Microchips which include a temperature sensor are available for subdermal implantation but may be less reliable than rectal probes due to their peripheral position.

In anaesthetised animals, temperature probes may be sited in the rectum or lower oesophagus for core temperature measurements. A nasopharyngeal reading can be taken as an estimate of brain temperature. Inspired and expired air temperature can be measured by a probe placed in the trachea.

### Telemetry

Telemetric devices can be surgically implanted for recording physiological values such as body temperature, electrocardiogram (ECG), blood pressure (arterial, venous and left ventricular), intraocular pressure, kidney pressure, electromyogram, electroencephalogram (EEG), electro-oculogram, respiratory rate and motor activity in the conscious dog. Texts are available to assist the interpretation of these recordings including for ECGs (Tilley 1992) and EEGs (Redding & Knecht 1983).

Telemetric methods are used widely to monitor cardiovascular and neurobehavioural effects of potential pharmaceuticals (Tontodonati *et al.* 2007). By mounting the receiver above the pen, recovered animals can move freely whilst continuous remote recordings are taken. A significant advantage is that results are not masked by the effects of handling stress. Recording can also be conducted for prolonged periods without human presence.

Careful consideration should be given to housing a companion animal with the telemetered animal for social enrichment and to inhibit development of stereotypic behaviour. Many modern telemetry devices have batteries which can be switched on and off giving 3–5 years' service before the implant fails. Repeat surgery for battery replacement may become necessary but strict limits should be applied to the number of times this may be done with up to two replacement surgeries normally considered to be maximum.

In many countries it is permitted to re-use animals in telemetry and other monitoring studies under strict regulatory controls. The rationale is that, once a dog has been surgically prepared, it can be used for a number of studies with minimal distress. If a fresh animal was surgically prepared for each use, the overall distress would be greater. Furthermore, an animal can act as its own control, thereby reducing the number required for statistical significance. It is important that there should be frequent veterinary checks to ensure dogs remain fit for subsequent use, and only dogs selected for a temperament which suits them for laboratory life should be used.

A new approach to gastrointestinal (GI) monitoring uses an ingestible wireless capsule that can measure pressure, pH and temperature as it transits the GI tract. This can be used to provide gastric emptying time, combined small and large intestine transit time, pressure contraction patterns and motility indices. The data receiver can be fitted into a jacket for protection.

### Collection of specimens

#### Blood

General advice on blood sampling is available in JWGR (1993). Blood samples may be conveniently and safely taken from three veins in the dog, namely, the cephalic, external jugular and lateral saphenous veins.

The cephalic vein runs along the dorsal surface of the forelimb from the medial to the lateral side. It can be dilated by compressing the upper surface of the limb at the elbow as shown in Figure 30.5. Blood can be collected by syringe and needle (0.6mm outside diameter (od) × 16mm or 0.8mm × 16mm) using a steady gentle pull on the plunger. Compression of the vessel should be maintained during collection of the sample, but relaxed before the needle is withdrawn. Compression should then be applied over the puncture site for about a minute to prevent haemorrhage and haematoma formation. When repeated samples are required it is better to place a flexible cannula in the vein. This can be fixed in place with adhesive tape and, provided it is flushed with heparinised saline (5IU/ml) about every 4h, it will remain patent for 24h or more. Bandaging may prevent some dogs removing the cannula but must not tightly encircle the limb as venous drainage will be occluded. Alternatively, a dog can be fitted with a protective plastic collar and singly housed to prevent itself or other dogs chewing the cannula.

The external jugular vein is a larger vessel and is appropriate for routine blood sampling as well as catheterisation of the right heart and pulmonary artery. The dog is held either sitting or standing as in Figure 30.6 and the vessel is dilated by applying pressure in the jugular furrow at the base of the neck. Venepuncture is made from the lateral side directed cranially for a venous sample or caudally for catheterisation.

The lateral saphenous vein is less easily stabilised for puncture but is a useful alternative for single samples. The animal is held as in Figure 30.7. It is also useful for catheterisation, especially for dogs supported in slings.

Figure 30.5 Collection of blood from the cephalic vein. (Crown copyright.)

**Figure 30.6** Collection of blood from the external jugular vein. (Crown copyright.)

**Figure 30.7** Collection of blood from the lateral saphenous vein. (Crown copyright.)

Venepuncture should normally be performed under aseptic conditions. This would usually involve careful clipping and antiseptic swabbing of the puncture area and the use of sterile syringes, needles and catheters. If repeated samples are required, it is preferable to insert a catheter to avoid repeated application of antiseptic and venepuncture, both of which may cause irritation.

#### *Bone marrow*

Bone marrow can be removed under general anaesthesia or sedation with local anaesthesia, normally from the dorsal iliac crest. Full surgical asepsis is essential which includes clipping the site, scrubbing and draping. A bone marrow biopsy needle 25–45 mm long and about 2.5 mm internal diameter is used. The technique is described in detail by Raskin (1993).

#### *Urine*

A metabolism cage which incorporates adequate separation of faeces and urine should be used for the collection of a 24 h urine sample. However, it will not be suitable for bacteriological examination, this requiring a sample obtained by cystocentesis to ensure no contamination. Sterile plastic catheters are available for both the dog and the bitch and should be used with full aseptic technique to prevent infection of the urinary tract. Repeated catheterisation is unwise as the abrasive effect on the urethra may predispose to pain and infection.

#### *Faeces*

Faeces can be collected in a metabolism cage, or from the floor of an ordinary cage or pen soon after defecation. Alternatively, a spatula or gloved finger can be used to gently ease faeces out of the rectum.

#### *Abdominal organ biopsy*

A percutaneous method of sampling one or more abdominal organs under ultrasound guidance is described by Barr (1995). Tissue core samples of good quality can be obtained from both liver and kidney. Endoscopic biopsy of the small intestine is described by Hall (1994) but is prone to artefacts due to the small sample size which may include only mucosa and submucosa. Biopsy of the intestine by laparotomy allows full-thickness samples to be obtained (Tobias 2007) and visual inspection of the alimentary tract and other organs.

### Administration of substances

See JWGR (2001) for general advice on the administration of substances.

#### **Intravenous route**

The techniques for intravenous injections are similar to those described for blood sampling. Compression of the vessel should be relaxed prior to injecting the material.

#### **Intramuscular route**

Intramuscular injection can be made into the quadriceps muscle of the hindleg or the lumbar musculature, pushing the needle (0.8 mm od × 16 mm or 25 mm) into the body of the muscle before injecting the material. Kruesi (2004) describes the lumbar technique with helpful photographs.

#### **Subcutaneous route**

Subcutaneous injection is made under the loose skin above the shoulder blades. A three-cornered fold of skin is raised with the thumb and two fingers. The needle (0.8 mm od × 16 mm) penetrates the dog's skin under the thumb, pointing towards the two fingers and slightly downwards (Figure 30.8). This technique avoids the possibility of double penetration of a simple skin fold which would result in loss of injected material.

**Figure 30.8** Raising a three-cornered fold of skin for a subcutaneous injection. (Crown copyright.)

### Intraperitoneal route

The intraperitoneal route is not commonly used and is not normally recommended in the dog. The site for injection is 2–3 cm lateral to the umbilicus with the animal standing or in dorsal recumbency. The needle should be introduced at least 2 cm and the syringe plunger pulled back to ensure no blood, urine or other fluid enters the barrel. If this occurs, reposition the needle before injecting. It is unwise to attempt intraperitoneal injections in bitches during the last 2 weeks of pregnancy.

### Oral route

If the pharmacokinetics of the product allow, oral doses can often be administered by mixing the dose with the normal diet without altering acceptability, or by concealing it within a treat. The giving of treats may, of course, be impractical if it is in conflict with an experimental protocol. If this is not possible, tablets or capsules can be placed on the back of the dog's tongue and will be swallowed if the jaw is held closed. Swallowing can be induced by massaging the dog's throat. This procedure is more stressful to both animal and handler particularly in nervous animals.

Fluids can be poured into the labial pouch at the angle of the jaw with the muzzle held upwards. The fluid should be given in small aliquots to permit swallowing and avoid choking.

Alternatively, fluids can be orally administered by stomach tube which may be passed easily in trained dogs. A flexible rubber or plastic tube (9 mm od) should be used in animals weighing over 6 kg. The length is marked in advance by measuring the distance from the nose, via the acromion of the shoulder, to the tenth costochondral junction. The first few centimetres of the tube should be lubricated with an appropriate water-soluble jelly.

The muzzle of the dog is lifted to point upwards and the jaws opened. The tube will then pass easily over the back of the tongue and into the oesophagus until the mark is level with the incisors. If there is any resistance, the tube should be withdrawn and the procedure repeated. When the tube is correctly placed, the odour of gastric contents will be

easily smelt. A small amount of fluid should initially be administered and, in the absence of any choking, the remainder given steadily. The tube should then be flushed before being gently withdrawn to avoid reflex vomiting or regurgitation.

### Anaesthesia, analgesia and post-operative care

Basic principles and procedures for anaesthesia and analgesia are described by Seymour and Gleed (1999) while Hall *et al.* (2001) include descriptions of anaesthesia for specialised techniques such as obstetrics and intrathoracic surgery. Flecknell (2009) considers the particular anaesthetic needs of the laboratory dog. Healthy dogs can readily be anaesthetised and present few problems. Anaesthetic techniques require considerable expertise and should not be contemplated by an inexperienced anaesthetist.

Prior to administering a general anaesthetic, a thorough pre-operative assessment should be carried out to ensure the dog is fit for anaesthesia. Food should be withheld for at least 6 h beforehand to reduce the risk of regurgitation.

Pre-anaesthetic medication is advisable, even in quiet animals, for the following reasons:

- to alleviate anxiety;
- to provide muscle relaxation and analgesia;
- to suppress vomiting and regurgitation;
- to provide smoother induction and recovery;
- to reduce the dose of anaesthetic required.

A premedicant combination of an opioid analgesic and a sedative may also produce moderate to deep sedation enabling minor procedures such as radiography to be undertaken. Opioid analgesics are best administered pre-operatively prior to more major surgery since evidence suggests that pain, once experienced, becomes more difficult to control. The analgesic effect may also continue into the immediate post-surgery period thus aiding a smooth recovery.

General anaesthesia can be maintained by intravenous and inhaled agents either separately or in combination. The former are usually administered via an in-dwelling cannula placed in the cephalic, external jugular or lateral saphenous vein (Figures 30.5, 30.6 and 30.7). Table 30.4 lists anaesthetic agents and adjuncts suitable for the dog with their doses, routes of administration and special considerations.

The anaesthetist should also be responsible for monitoring and maintaining body temperature during the procedure. Heat loss is especially significant in small breeds, immature subjects or during prolonged anaesthesia and recovery. Maintenance fluids appropriate to the procedure should be given and fluid loss by bleeding should be monitored and appropriately replaced. Tear formation may be reduced so it is beneficial to protect the animal's eyes with sterile lubricant.

Post-operative analgesia must be provided for as long as is needed. The opioid analgesics, for example buprenorphine, are suitable with the first dose being given as part of the pre-medicant. Individual responses to all opioids are variable, making ongoing assessment of pain imperative to inform subsequent requirements. Opioid analgesics can also

**Table 30.4** Some anaesthetic agents and adjuncts suitable for the laboratory dog.

Agent	Dose	Route	Effect	Comment
Acepromazine	0.01–0.1 mg/kg	im, sc or slow iv	Sedative	Dose dependent on route. Onset 20–30 mins after im administration
Morphine	0.5 mg/kg	im, iv	Opioid analgesic	Continuous rate infusion 0.15–0.2 mg/kg/hr iv
Methadone	0.1–0.5 mg/kg	im	Opioid analgesic	Duration of action 3–4 h
Buprenorphine	5–20 µg/kg	im, iv or sc	Opioid analgesic	Duration ~6 h but individual variation
Medetomidine	10–30 µg/kg	iv, im or sc	Premedication, sedative	Used alone or in combination with an opioid analgesic
Propofol	1–4 mg/kg in premedicated animal	iv	Induction agent	Can be used to maintain anaesthesia by continuous infusion or intermittent boluses. Smooth, rapid recovery
Alfaxalone	2 mg/kg in premedicated animal	Slow iv	Induction agent	Can be used to maintain anaesthesia by continuous infusion or intermittent boluses
Sevoflurane	7–8% for induction; 2–3% for maintenance	Inhaled	Fully potent anaesthetic	Good analgesia and muscle relaxation. Use dedicated calibrated vaporisers
Isoflurane	4–5% for induction; 2–3% for maintenance	Inhaled	Fully potent anaesthetic	Good analgesia and muscle relaxation. Use dedicated calibrated vaporisers
Pancuronium	0.06 mg/kg	iv	Non-depolarising muscle relaxant	May require specific licence authority; demands skilled assessment of anaesthesia and analgesia
Alphachloralose	80 mg/kg	Slow iv	Long-lasting anaesthetic	Duration 6–10 h. <b>Non-recovery only</b>
Urethane	1000 mg/kg	Slow iv	Long-lasting anaesthetic	Duration 6–10 h. <b>Non-recovery only</b>

be injected epidurally (Campoy 2004) to control post-surgical pain for extended periods, for example, after thoracotomy, with minimal systemic effects (Popilskis *et al.* 1991). Modern NSAIDs such as meloxicam, ketoprofen and carprofen can provide excellent relief of post-operative pain (Lascelles *et al.* 1994) and can be used either alone or in combination with opioids. Tramadol is an opioid agonist that inhibits the reuptake of noradrenaline and 5-HT, and stimulates pre-synaptic 5-HT release. It provides an alternative pathway for analgesia involving the descending inhibitory pathways within the spinal cord. It is available in a variety of formulations for human use but not yet widely used in dogs. However, it may be useful for the control of post-operative and chronic pain and avoid some of the side effects of NSAIDs.

An animal that has undergone surgery is vulnerable during the immediate post-operative period and it is essential that adequate facilities and care are available at this time. Even in the absence of emergencies, each animal should receive individual attention to ensure its safe recovery. Of paramount importance is the provision of warmth in the pen or cage. Adult dogs require an ambient temperature of 25 °C and puppies 32 °C and a heated mat may be used to provide local warmth. Food and water bowls should not be placed in the pen until the dog is aware of its surroundings, and no other animal should be present to interfere with the patient during the recovery period.

If an endotracheal tube has been used, this should be left in place until the swallowing reflex has returned, when it can be gently withdrawn. If recovery is prolonged, the animal should be turned from side to side every 30 minutes to prevent postural hypostatic lung congestion.

Regional nerve blocks can be used both during and after surgery to decrease the amount of other anaesthetic drugs needed and to lower the post-operative requirement for analgesics. Many minor surgical procedures can be performed under local or regional analgesia although it is usually necessary to provide sedation as an adjunct. Specific techniques for regional anaesthesia are described by Hall *et al.* (2001).

In the days following surgery, the dog should be observed to ensure that it is eating, drinking, defecating and urinating normally. Pain control should be carefully assessed. The surgical wound should be inspected daily and any sutures or staples removed 10 days post-operatively. Exercise should be restricted until this time.

## Euthanasia

Euthanasia should be performed in the most humane manner possible to minimise both mental and physical suffering and should be carried out by trained and experienced personnel, preferably familiar with the animal to minimise the distress of being handled by a stranger. The bereavement distress to handlers can be considerable and should not be ignored (Arluke 1988). The World Society for the Protection of Animals (WSPA) provides excellent guidance on methods of euthanasia suitable for dogs (WSPA 2005) indicating those which are recommended, acceptable, conditionally acceptable and not acceptable. Any method used should produce rapid unconsciousness and subsequent death without evidence of pain or distress. It should be safe for the handlers, easy to perform and cause death without

producing changes in tissues that might interfere with experimental results.

Intravenous injection of a lethal dose of barbiturate is the most common method of euthanasia of conscious dogs, normally by using a 20% pentobarbital solution rapidly injected at 150 mg/kg. The animal becomes anaesthetised within seconds and undergoes no pain or distress. Venepuncture is easily performed on most reasonably docile dogs by trained and experienced personnel. In anaesthetised animals, euthanasia can be carried out by overdose of barbiturates as above or by increasing the anaesthetic dose to a lethal level.

Physical methods of euthanasia such as shooting and electrocution are distasteful and dangerous to the operator and are no longer considered acceptable. Decapitation and drowning are not acceptable, even for very young puppies, and both are illegal in many countries.

Following euthanasia, death should always be verified (if necessary by waiting for rigor mortis to set in) before disposing of the carcass.

## Common welfare problems

### Health and disease

#### Prophylaxis

Dogs that are not in good health are always unsuitable for experimental work except in the investigation of naturally acquired or induced disease.

Dogs should be visually assessed daily to look for signs of health or disease (Table 30.5). It is important that carers are aware of differences in temperament and behaviour between individual dogs so that deviations from the norm are promptly recognised.

Regular, more detailed, health checks may be performed by trained technical staff and might include body weight, body condition, nail clipping, dental checks and ear cleaning. Blood samples might be taken for biochemical and haematological examination to assess health status. Routine prophylactic treatments might accompany such examinations and any necessary vaccinations administered and recorded.

In the event of concern, a veterinary surgeon should be consulted. This is important not only for the welfare of the animals involved, but also to prevent the spread of disease to other animals. In addition, the veterinary surgeon should regularly visit all areas to assure the quality of health and welfare of the dogs. The veterinary surgeon should also be responsible for the maintenance of comprehensive and accurate clinical records.

In addition, the environment should also be checked daily and recorded eg, temperature, humidity and effectiveness of ventilation.

#### Common diseases

Table 30.6 summarises significant infectious diseases in the dog. Clinical texts (Chandler 1994; Ettinger & Feldman 1994; Gaskell & Bennett 1996; Ramsey & Tennant 2001) should be consulted for a more comprehensive description including methods of diagnosis, prevention and treatment whilst

**Table 30.5** Signs of health in the dog.

<i>Sign</i>	<i>Description</i>
General appearance	Active, alert, responds to presence of humans and conspecifics. Stands on all four limbs evenly and is neither lame nor stiff, especially after rest. Responds normally to being handled. No uncharacteristic vocalisations
Appetite and weight	Good appetite. Some dogs are slow eaters whilst others consume their ration immediately. Not obese or thin. Normal water requirement varies (eg, with diet). Beware of sudden changes in weight, drinking or eating behaviour
Mouth	Teeth firm and clean. Gums pink, smooth and moist. Inflammation absent especially at gum margins. Absence of offensive smell
Eyes	Bright, clear; symmetrical appearance; absence of inflammation, discharge, irritation or opacities of the cornea or lens
Ears	Clean, non-irritant; absence of inflammation and offensive smell or discharge
Skin	Freely moveable, ribs and spine easily felt. No scratching; inflammation and lesions absent. Coat clean, unmatted and free from parasites and excessive scurf. No swellings or masses. No areas of hair loss
Respiration	Regular, effortless even after moderate exercise. Absence of cough. No nasal discharge
Urine	Clean, straw coloured. Pus and blood absent. No pain or straining or altered frequency of urination. Normal urine marking behaviour
Faeces	Firm, dark brown (colour and consistency varies with diet but should not be pale and bulky). Free from blood or mucus. No pain or straining on defecation

Tilley and Smith (2004a) provide a simple reference handbook. Many diseases can vary in the severity of their clinical signs and thus in the presenting picture. Hence, an early diagnosis may be difficult but is essential if spread of disease to neighbouring animals is to be avoided. The diagnosis must normally be confirmed by laboratory tests and treatment and a strategy for control implemented immediately. For these reasons, laboratory dogs, whether in a breeding colony or involved in an experiment, should always be under the care of a veterinary surgeon with direct responsibility for their health and welfare.

These infectious diseases are generally of low incidence in well managed laboratory dog colonies. More common clinical problems may include fight wounds, lameness, dental disease, ear inflammation, hernias, histiocytomas and cryptorchidism as well as complications from experimental procedures. It is important that all such conditions are promptly identified as part of routine health checks and appropriately treated. Diarrhoea is a common clinical sign with a multitude of possible causes including a wide range of infectious agents as well as stressors, such as change of diet or accommodation, and experimental procedures –

**Table 30.6** Infectious diseases of the laboratory dog.

Name	Causal agent	Clinical picture	Prevention	Comment
Infectious canine hepatitis (ICH)	Adenovirus	Pyrexia, anorexia, vomiting and diarrhoea, general malaise. Congested mucosae, leucopenia; raised liver enzymes. Late stage 'blue-eye'	Vaccination	Following recovery, virus is eliminated in urine for several months
Canine distemper	Morbillivirus (paramyxovirus)	Pyrexia, oculonasal discharge, anorexia and diarrhoea. May be secondary pneumonia. Enamel hypoplasia; hardening of footpads and nose	Vaccination	Neurological signs may appear in adults following an earlier episode of the generalised disease
Canine parvovirus	Parvovirus	Vomiting, diarrhoea and dysentery with rapid dehydration	Vaccination	Disease not seen prior to 1978. Susceptible very young puppies may develop myocarditis with acute heart failure
Infectious canine tracheobronchitis (kennel cough)	<i>Bordetella bronchiseptica</i> , several viruses, ? <i>Mycoplasma</i> spp.	Sporadic outbreaks of mild respiratory disease with coughing	Vaccination available for <i>B. bronchiseptica</i> and parainfluenza virus	Occurs in kennels when dogs from different sources are mixed
Canine herpes virus (CHV)	Herpesvirus	Infertility, abortions, stillbirths. Neonatal neurological signs and death	Vaccination of bitch to protect puppies	Clinical disease rare in dogs older than 3–4 weeks
Rabies	Rhabdovirus	Usual route of infection via bite; neurological signs; fits or moroseness	Vaccination	Fatal zoonosis; invariably fatal in dogs
Leptospirosis	<i>Leptospira</i> serovars inc. <i>L. canicola</i> & <i>L. icterohaemorrhagiae</i>	Acute or chronic renal failure. Jaundice, severe depression and death	Vaccination together with rodent control	Chronic disease may occur following an earlier acute episode. Organism may be carried by rats
Brucellosis	<i>Brucella canis</i>	Abortion in female; orchitis in male	Screen new breeders	Zoonosis reported. Uncommon but problematical in a breeding colony
Ascariasis	Helminths, mainly <i>Toxocara canis</i>	Unthriftiness and diarrhoea in puppies. Abdominal distension	Regular anthelmintic treatment	Zoonotic. Treat pregnant and lactating bitch. Other helminths such as hookworm and lungworm as well as tapeworm also occur
Mange	Various mites inc. <i>Sarcoptes scabiei</i> , <i>Cheyletiella</i> spp. <i>Otodectes cynotis</i> and <i>Demodex canis</i>	Pruritis, alopecia and skin thickening. May become pustular. Infestation of ear causes severe irritation	Strict hygiene together with rodent and fox control. Topically applied acaricides	May be zoonotic. Examine incoming dogs very carefully to avoid introduction of mites
Ringworm	<i>Microsporum canis</i> & <i>Trichophyton</i> spp.	Discrete areas of alopecia and broken hairs	Isolation and disinfection	May be zoonotic. Treat systemically or topically

notably toxicology studies. Faecal examination may be revealing but the problem will often resolve spontaneously or with removal of the stressor.

Several spontaneously occurring disorders occur among laboratory dogs and are considered to have a genetic basis, including hypothyroidism due to lymphocytic thyroiditis, beagle neck pain syndrome (also known as neck pain syndrome, steroid responsive meningitis and necrotising vasculitis), distichiasis, cryptorchidism, prolapse of the gland of the third eyelid, idiopathic epilepsy and factor VII deficiency (Mustard *et al.* 2008).

## Behavioural problems

It has been recognised for many years that dogs housed in restricted environments tend to develop behavioural abnormalities (stereotypies) generally considered indicative of poor welfare (Luescher *et al.* 1991). Such environments may be restricted either in the overall space available, or equally in the lack of stimulating features.

Hubrecht *et al.* (1992) studied various different types of housing in which dogs were spending substantial proportions of their time in stereotypic behaviour including repeti-

tive jumping so the hindlegs leave the ground, circling around the pen, pacing usually along a fence, and social pacing in parallel with another dog on the other side of the fence. Whilst barking may be normal for the dog, in a colony situation some dogs develop a repetitive staccato barking which appears to have no communicative purpose and is often linked with other stereotypic behaviours.

Single housing of dogs is associated with passive and non-social repetitive behaviour probably due to the dog's efforts to offset boredom. Housing dogs in groups tends to be associated with non-repetitive social behaviour, high activity and investigation, together with low levels of aberrant repetitive behaviour. This is considered to be due to 'social buffering' associated with factors such as the complexity of the environment (Kikusui *et al.* 2006).

Provision of human contact may be of even greater social value than canine contact (Wolfe 1990) although it may only require a relatively small amount of time. Hubrecht (1995) tested the effect on young puppies of human socialisation and environmental enrichment with toys on ultimate adult behaviour. He found that human socialisation and even simple toys were enjoyed by puppies with benefits in adulthood. Means of managing behavioural problems in dogs are described by Horwitz *et al.* (2002).

### Further reading

The range of manuals published by the British Small Animal Veterinary Association (BSAVA) provides excellent background information and clinical details for the dog including haematology (Day *et al.* 2000), urology (Elliott & Graver 2007), endocrinology (Mooney & Peterson 2004) and neurology (Platt & Olby 2004).

# 31 The domestic cat

Sandra McCune

## Biological overview

### General biology

The domestic cat *Felis silvestris catus* used in laboratories is the same species that is commonly kept as a companion animal and which exists in substantial numbers in a feral state. Cats are intelligent, highly specialised mammals that have evolved a range of morphological adaptations and sensory abilities to suit their exclusively carnivorous life-style (reviewed by Bradshaw 1992). A cat's perception of the world is therefore different from ours. Hunting by sight at night means they see in lower light intensities than we can and are particularly sensitive to rapid movement. They are not, however, able to see in fine detail or to discriminate clearly between shades of colour (Bradshaw 1992). They also hunt by sound and are very sensitive to the ultrasonic frequencies that rodents use to communicate. Their sensitive sense of smell helps them to locate prey although, in the final stages of a kill, touch is the dominant sense. Smell is also used to select food while a second olfactory system (the vomeronasal organ) is used in social communication. Sebaceous glands are located throughout the body, especially on the head and the peri-anal area, and between the digits. Scratching, which deposits scent from the interdigital glands, is a marking behaviour which leaves visual and olfactory signals, and helps to maintain the claws in good shape (Rochlitz 2005). The deposition of urine and faeces, and rubbing of the body against objects, may also be used in olfactory signalling. Allo-rubbing, where cats rub their face and body against each other and intertwine their tails, serves to exchange scent profiles between cats.

Standard biological data are listed in Table 31.1.

### Size range and lifespan

Average domestic cats weigh between 2 and 5 kg. Males are significantly heavier than females. There are breed differences; American Ragdolls or Maine Coons can be three times heavier than the average, whilst the small Singapura weighs a mere 2–3 kg. Well cared for domestic cats can, on average, expect to live for about 12 years and many cats live into their twenties.

## Social organisation of free-ranging cats

Cats can adapt to a wide range of population densities. Feral cat populations range from densities of 1–2000/km<sup>2</sup> (Izawa *et al.* 1982; Izawa 1984; Kerby & Macdonald 1988). The social system feral cats adopt depends upon the distribution and availability of resources. The home ranges of breeding males are usually much larger than those of females. The sizes of their home ranges are determined by both food supply and social considerations (including availability of breeding females, whether females are solitary or social and the degree of competition for females). Male home ranges encompass the territories of several breeding females. The home ranges of females are determined by the needs for shelter and food both for themselves and for any dependent young. Where cats have to support themselves solely by hunting, they are often solitary as their prey is unlikely to be sufficiently abundant to sustain a social group. If food is more common but patchily distributed, then the home ranges of cats may overlap though they would rarely hunt in the same area at the same time.

Social groups exist where food is locally concentrated; usually as a result of human activities (Kerby & Macdonald 1988). These groups are basically matrilineal, consisting of females, usually related, and their offspring (including immature males). The size of the groups is very variable and seems to be determined largely by food availability, mortality amongst kittens from a range of infectious diseases and extermination by humans. Females are tolerant of other members in the group but defend their communal core area (containing their den and major source of food) aggressively against intruders. Their aggression intensifies if there are young kittens in the group. This exclusion of outsiders makes it difficult for females to move between groups. Males tend to disperse away from their mother's home range when they are 2 or 3 years old. Initially they avoid contact with all other cats but as they mature and get stronger they will challenge other males for access to females. Mature males are only loosely associated with any group but in areas where most females are group-living, a particular male may concentrate his mating efforts within a single group. Further information on cat behaviour can be found in Thorne (1992); Beaver (2003) and in the American

**Table 31.1** Standard biological data for the cat (after Hurni & Rossbach 1987).

Parameter	Value
Age of replacement of deciduous dentition (months)	3.5–6
Life expectancy (years)	9–14 (over 20 has been recorded)
Body weight:	
Female (non-breeding) (kg)	3–4
Male (kg)	3–7
Birth (g)	110 ± 20
Respiration rate (/min)	16–40
Volume (ml)	12–15 (0.3–0.4l/min)
Arterial blood pressure (mmHg)	120/75
pH	7.35
Blood volume:	
Total (ml/kg body weight)	75
Maximum single sample (ml/kg body weight)	7
Pulse rate (/min)	150–200 (range 120–220)
Body temperature (°C)	38–39.5
Dental formulae:

## Reproduction

Under optimum conditions, females become sexually mature at around 9 months (range 4–18 months). Males (toms) are sexually mature by 8 months though some may be fertile earlier. Cats are normally seasonal breeders in temperate climates. Toms are most sexually active in spring though they can sire kittens at any time of the year. Females will breed all year round if they are kept indoors with no exposure to sunlight and with a 12:12 hour light–dark regime. Most oestrous cycles last between 18 and 24 days. Oestrus lasts about 4 days if mating occurs but otherwise between 5 and 10 days. Cats are induced ovulators (although see Lawler *et al.* 1991), with foreplay and coitus stimulating ovulation. Sterile copulation may result in pseudopregnancy which lasts about 36 days. Successful pregnancies last about 63 days (range 58–72 days). Females are capable of coming into oestrus 3–4 weeks after a litter is weaned.

The average litter size is 4 (typical range 3–10), with 104 males born to every 100 females. Maximum litter size is

usually reached by the third litter. Females are optimally fertile between the ages of 1 and 8; subsequently their oestrous cycles may become irregular and litters are fewer and smaller. Although sperm quality declines with age, males can remain fertile into their twenties.

## Breeds, strains and genetics

A recent genetic assessment of 979 domestic cats and their wild progenitors – *Felis silvestris silvestris* (European wildcat), *F. s. lybica* (Near Eastern/north African wildcat), *F. s. ornata* (central Asian wildcat), *F. s. cafra* (southern African wildcat) and *F. s. bieti* (Chinese desert cat) – indicates that each wild group represents a distinctive subspecies of *Felis silvestris* (Driscoll *et al.* 2007). As *F. s. lybica* and domestic cats fall into the same genetic clade (a group of species with the same ancestor), it is likely that the *lybica* subspecies gave rise to the genetic lineage that eventually produced all domesticated cats. Cats were domesticated in the Fertile Crescent of the Near East and north Africa, probably coincident with the development of agricultural villages where cats fed on the rodents that infested the grain stores of the first farmers. The first evidence of cat remains buried together with human remains was found in Cyprus, and determined to be 9500 years old (Vigne *et al.* 2004). The earliest evidence for domestication comes from Egypt in the third millennium BC (Linseele *et al.* 2007).

Cats have not been subject to intensive selective breeding programmes with most breeds originating in single gene mutations or a few combinations. The concept of cat breeds dates from the nineteenth century. Breeds are classified into British (European or American) and Foreign on the basis of head shape, body conformation and coat quality. British types are stocky with a heavier coat. Foreign types are slender and smooth coated. Breeds are also classified by hair length; Short-hairs and Long-hairs. The difference is due to a single gene, the allele for long coat being recessive. A more recent hair mutation has resulted in three new breeds; the Cornish Rex, the Devon Rex and the American Wire-hair. Colour varieties are caused by less than a dozen mutations. Most seem to affect only pigmentation but that producing blue-eyed white cats is linked with timidity, deafness, elevated mortality and poor mothering ability. Breeders are now producing breeds in several colours; blurring the distinction between breeds and varieties (a full account of breeds and varieties is provided by Vella *et al.* 1999).

## Sources of supply

It is good practice, and a legal requirement in some countries (eg, in the European Union), for cats to be bred and obtained from approved establishments. Many laboratories use specific pathogen free (SPF) cats which will need to come from recognised SPF sources. These cats should be free from viral and chlamydial upper respiratory disease, FeLV (feline leukaemia virus), FIV (feline immunodeficiency virus), coronavirus and both ectoparasites and endoparasites. Cats should be quarantined for at least 3 weeks before joining the colony. Cats from random sources would need a 6 week quarantine

<sup>1</sup>[http://www.aafponline.org/resources/guidelines/Feline\\_Behavior\\_Guidelines.pdf](http://www.aafponline.org/resources/guidelines/Feline_Behavior_Guidelines.pdf)

as their disease status would be unknown. They might also have behavioural and handling problems.

## Management and breeding

### General husbandry

Husbandry systems should use best health care practices, which emphasise good welfare and meet the animals' behavioural needs. Systems should provide safe, comfortable, animal-friendly conditions, environmental choice for the animal, sensory stimulation, physical and mental exercise and should minimise disease. Detailed recommendations for cat housing exist (eg, Home Office 1989; European Commission 2007) and provide guidelines on the design, construction and security of animal facilities; and on the environmental conditions within the facility, encompassing guidelines for temperature, relative humidity, ventilation and lighting). There are examples of innovative design incorporating elements intended to meet cats' behavioural needs (Loveridge 1994; Loveridge *et al.* 1995).

### Housing

Cats can be kept outdoors or indoors. Considerations of environmental control, costs and disease transmission mean most colonies are kept in closed indoor accommodation. Housing needs to be easy to clean and maintain, and compatible with the requirements of laboratory studies. Using several individual buildings reduces the potential for disease to spread throughout a colony (Hawthorne *et al.* 1995).

### Group housing

Groupings should take account of density recommendations. In the UK for group-housed cats, recommended minimum floor area per cat is 3300 cm<sup>2</sup> for cats weighing up to 3 kg and 5000 cm<sup>2</sup> for cats weighing over 3 kg (Home Office 1989). This rises to 5000 cm<sup>2</sup> and 7500 cm<sup>2</sup> respectively when cats are housed singly. The revised guidelines of the European Convention for the Protection of Vertebrate Animals used for Experimental and Other Scientific Purposes (ETS 123), Appendix A (Council of Europe 2006), and the revised Annex II to the European Directive 86/609 (European Commission 2007) require a minimum floor area of 1.5 m<sup>2</sup> and shelving of 0.5 m<sup>2</sup>, with another 0.75 m<sup>2</sup> of floor space and 0.25 m<sup>2</sup> of shelf space for every additional cat; and that the cage should be 2 m high.

A critical minimum cage size has not been established for cats. Some cats will show behaviour problems when confined in cages with the dimensions given above. Indeed, some free-ranging cats will show behaviour problems. However, cats with restricted access to outdoors are more commonly presented with behaviour problems than free-ranging cats so it appears that space is limiting to some individuals even in relatively enriched home settings. The response of the individual to confinement varies widely and is based on many factors. The most important of these is likely to be quality of the confined space and the cat's previous experience. Investing in the quality of the space rather

than the quantity may often result in a better outcome for the cat.

The cat, having originated from a largely solitary-living species, has not developed the complex visual signalling that is typical of species that have had a long evolutionary history of social living, such as the domestic dog. As a result, lacking or having limited signals for avoiding conflict such as appeasement (Casey 2007b), and post-conflict mechanisms such as reconciliation (van den Bos 1998), they do not form distinct dominance hierarchies. Usually, cats will avoid physical confrontation by using behaviours to maintain distance, such as olfactory marking, posturing and vocalisation. Alternatively, they may try to evade threats from other cats by hiding or fleeing to elevated locations. If housing conditions in the laboratory do not provide for these responses, cats may end up in aggressive encounters with each other.

The maintenance of groups is influenced by factors that include familiarity, stability, socialisation to other cats and availability of resources. Sibling pairs of cats have more amicable relationships than unrelated cats living together (Bradshaw & Hall 1999), and close social bonds may also develop between unrelated kittens that are raised together. Attention to the socialisation of cats with other cats at a young age will make them more tolerant of others in adulthood. Optimal socialisation to humans occurs if kittens are handled between the second and seventh week of life (Karsh & Turner 1988), and it is generally accepted that the period of socialisation of kittens to other cats also occurs during this time (Rochlitz 2005).

Housing cats at high densities increases the likelihood of their being stressed. While housing in groups provides opportunities for complex social interactions and so increases mental and physical stimulation (Figure 31.1), group composition should be kept fairly constant to avoid disrupting established group dynamics. Social cohesion is maintained through behaviours such as allo-rubbing, which involves tactile communication and the mixing and exchange of scent, such that all individuals in the group have a shared scent profile. The frequent addition of new cats into a group disrupts relationships and introduces new olfactory profiles that interfere with social cohesion.

When cats are housed in groups, attention should be paid to the availability of resources (food, toileting sites, resting and hiding areas). Resources should be distributed in a number of places to prevent certain animals from monopolising one area, and to enable them to avoid conflict with others when accessing these resources. Cats which fail to adapt to a particular social group, for example those which avoid contact with all other group members, should be rehoused, either with a smaller group or singly.

### Individual housing

Sometimes cats need to be housed individually. For instance; post-/pre-parturition females; mature males; sick, injured or quarantined individuals; or as a necessary part of a specific research programme. The most specialised or extreme form of single housing is probably the metabolism cage which is used, for example, to facilitate the reliable collection and assessment of faeces. These cages are usually made of metal

**Figure 31.1** Enriched housing provides opportunities for play, social contact and privacy.

(often stainless steel) with mesh floors. They can be stressful to the cats confined in them in many ways. The accommodation may be unfamiliar to the animal if it is normally group-housed. The cages are usually small and so lack space for normal movement. They provide only a barren environment; devoid of comfort and facilities providing physical and mental stimulation. The enforced social isolation may also cause stress to cats that are used to social contact with others. These cages should be made as appealing as possible with the addition of resting boards with covers, toys and visual observation of other cats and should be used for as short a time as possible.

In response to the need to improve upon such cages, Loveridge and co-workers (1995) developed a system of two-roomed lodges which provide individually housed cats with an enriched environment, freedom of choice, mental and physical stimulation and conditions as similar as possible to those in the main colony (Figure 31.2). Extensive use of glass throughout the building allows the individually housed animals to be visually stimulated by those on either side, by human and cat activity within the colony, and by activity in the grounds outside the colony building. Individually housed cats should have access to a larger exercise area space and be given some personal attention every day (Figure 31.3). Even more recently, an organisation has developed a mechanical litter tray system that allows urine and faeces to be collected from specific cats housed in their normal group housing. Users should explore the possibilities of these techniques before resorting to metabolism cages.

### Environmental provisions

An important objective of good housing is to improve welfare by giving the animal a degree of control over its environment and the opportunity to make choices (Broom & Johnson 1993). Good laboratory housing for cats should include a range of shelving at different heights, and a choice of resting and hiding places. Timid cats and those less well integrated into the social group will occupy the higher shelves (Rochlitz *et al.* 1995), particularly those in corners as

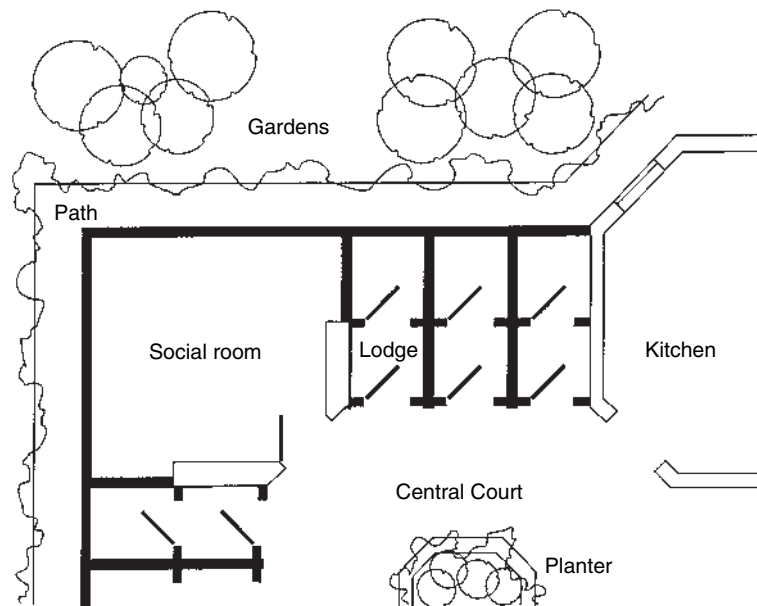

**Figure 31.2** Lodges for singly housed cats (in the background) can be built around central areas of activity to provide visual stimulation.

they provide the best vantage points and protect the cat from being approached from behind. Cats spend a large portion of their day either resting or sleeping, so it is important that there are plenty of rest areas with comfortable surfaces.

Hiding is a coping behaviour that cats often show in response to stimuli or changes in their environment (Rochlitz 2005). It is commonly seen when cats want to avoid interactions with other cats or people, and in response to other potentially stressful situations. A recent study investigated the effect of hiding enrichment on stress and behaviour of kennelled cats (Kry & Casey 2007). The hiding enrichment

**Figure 31.3** Section through a facility providing single and group housing for cats (from Loveridge *et al.* 1995). Reproduced with kind permission of Waltham Centre for Pet Nutrition.

consisted of a cardboard box (Hide, Perch and Go® box, British Columbia SPCA), whilst control animals were provided with an open bed. A significant reduction in stress was noted in the enriched group: these cats were more likely to approach humans and displayed relaxed behaviours much more frequently.

Visual barriers can be useful, to enable cats to get out of sight of others and also to break up the three-dimensional space into sections or compartments, making it more complex and giving the cat more choice about where it wants to be (Rochlitz 2005). Housing should incorporate features to provide opportunities for stimulation, and for environmental and social choice. For example: provision of internal windows to enable cats to watch other cats and human activity; internal arrangement of pens incorporating different levels to increase usable space and give opportunities for climbing, for example by imaginative use of shelving, climbing poles and ropes; semi-hidden spaces to explore or to withdraw from the group, for example, plastic hollow cubes, large children's toys etc which can be moved from group to group; experience of the natural environment either by direct access (which may not be possible in a minimal disease system) or through glass.

Olfactory enrichment is relatively underused in animal housing, perhaps because of the relatively poor sense of smell of humans compared with many other species. Surfaces for the deposition of olfactory and visual signals and for claw abrasion, such as scratch posts, rush matting, pieces of carpet and wood, should be provided.

#### Presentation of food and water

Fresh water should always be available and, ideally, replenished constantly from a chlorinated mains supply. Some cats prefer to drink from a water fountain. Food should be kept fresh. Removing food for a period each day seems to renew the cats' interest.

#### Identification and sexing

In small colonies cats can be identified by their markings and other characteristics. Microchip implants provide a secure, safe and permanent method of identifying individuals. Insertion of the microchips is less painful than tattooing. Collars can be used but their fit needs to be checked regularly and they are unsuitable for very young kittens. Cats can be sexed at birth from the ano-genital distance (about 6 mm in females and 13 mm in males).

#### Physical environment and hygiene

The physical environment should be monitored, and ambient temperature and humidity adjusted for comfort (15–24°C and 55% ± 10% relative humidity are recommended by the UK Home Office (1989)). Rather than having a homogeneous environment, creating a range of micro-environments is preferable as this provides a cat with some choice, for example: heated beds; sun-warmed ledges; and shaded lying areas. Even in single metabolism cages, a single shelf at least provides some choice of location for the individual. Good ventilation is important to dilute and remove air-borne pathogens and to disperse heat produced by animals and equipment. Cats need protection from extremes of heat and housing will need extractor fans, blinds or solar-absorbing glass and reflective film.

The combination of good design and an effective cleaning regimen will minimise disease transmission. All rooms and litter trays, 'furniture' and other surfaces within, need daily cleaning with detergent and disinfectant. Cleaning materials need to be chosen carefully as cats are particularly sensitive to phenolic compounds. Aerosolisation of phenolics can result in corneal lesions if the cats remain in the room during cleaning. Chlorhexidine appears to be a safe and effective disinfectant for cat rooms (suggestions in Hawthorne *et al.* 1995). Bedding should be disposable or washable. Only

small quantities of food should be stored within the buildings to avoid attracting vermin and this should be kept in vermin-proof containers. Every care should be taken to avoid any wild, stray or pet animals entering the animal facility. Particular care needs to be taken with drains and other services that penetrate the fabric of the building and so allow a potential route into the animal rooms.

### Health monitoring, quarantine and barrier systems

Cats should be handled frequently and checked daily; handling and restraint techniques were reviewed by Wills, J. (1993). Every week they should have a specific health check (ears, eyes, nose, genitalia and general body condition), be groomed and weighed (Figure 31.4). Twice a year they should have a dental examination and a haematology and biochemistry screen. Colonies should be screened for viruses, bacteria and parasites. Viral screening should occur on an epidemiological basis. Assuming a low incidence of disease a large number of cats may need to be screened to find a problem. Any unexpected death should be thoroughly investigated.

The probability of cats contracting an infectious disease depends on a number of factors, including: age; genetic predisposition; nutritional status; levels of stress; concurrent illness; level of infectious disease challenge and virulence of the infectious organism.

Separate facilities should be provided for the isolation of suspected infected cats and for those in quarantine. Isolation facilities should be completely self-contained and, ideally, in a separate building from the main colony. Disease transmission can be limited further by housing all cats according to their susceptibility. Preferably each susceptibility group should be handled by different personnel, otherwise the sequence in which they are handled should be on a susceptibility basis from most to least susceptible, eg: early-weaned kittens; queens with kittens; older cats; quarantine cats; and

finally sick cats. Further details are given by Hawthorne *et al.* (1995).

### Transport

Cats are not good travellers. Travel causes stress in many individuals and therefore should be kept to a minimum (McCune 1994). Journeys of over 10h duration appear to be especially stressful (Bradshaw & Holloran 2005). Preferably cats should be accompanied to ensure their safety and welfare. If cats are to travel unaccompanied, across borders, or by air, sea or rail then special regulations will probably apply. Each country and carrier will have its own regulations regarding animal transport. Cats appreciate being able to look out of their carrier. SPF cats will need to be protected from infection during transit. Cats travelling by air will require containers approved by the *International Air Transport Association (IATA)* who revise their regulations annually (see also Chapter 13 and Laboratory Animal Science Association (LASA) 2005).

### Breeding

For general advice see Wills, M.B. (1993).

### Condition of adults

Cats are sexually mature at 8–9 months of age. Cats that begin to cycle and are not bred are likely to develop uterine pathology that decreases reproductive performance. Therefore, if the colony has reproduction as a goal, queens should be placed into a harem in their first year. At the Waltham Centre for Pet Nutrition queens are retired at 8 years and toms are retired at 10 years, but other breeders may continue to use their breeding animals for longer than this if they remain in good health.

**Figure 31.4** Regular health checks and grooming are essential to ensure the well-being of individuals.

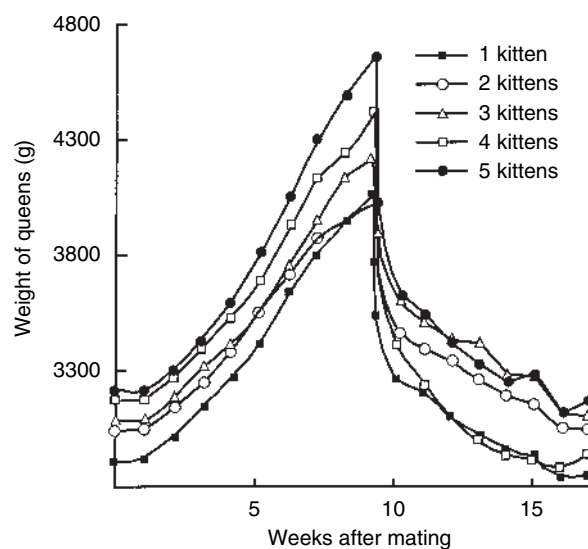

### Identifying the fertile state

Anoestrous females will respond aggressively to any sexual approach by a male. Females in pro-oestrus show subtle changes in their behaviour; they tend to be rather restless and rub up against objects. They allow males to approach but prolonged contact is not tolerated. Over the next 24 h the females rub their head and flank against objects with increasing intensity, they roll on the floor, stretch, purr and rhythmically open and close their paws, flexing their claws. At this stage they will tolerate grooming by the male but not mounting. Full sexual receptivity is indicated by females adopting the lordosis position; the female crouches with her head close to the ground, her hindlegs treading and partly extended, and her tail laterally displaced to expose the perineum (UK Cat Behaviour Working Group 1995).

### Mating systems

In the harem or group mating system, ideally one male cat is kept in a group of females. The dominant male will usually mate with more than 80% of the females. A potential difficulty with this system is that the exact date of mating is not known and pregnancy is determined by the female gaining weight (Figure 31.5). The female should be moved to kitting accommodation 10–14 days before birth is due to allow her to habituate to the new surroundings.

A second, but perhaps less welfare friendly, system is to house females together in groups and to accommodate the males in individual housing. When signs of oestrus are observed, the female is taken to the chosen male and mated a number of times. Males need to be replaced regularly to avoid inbreeding. The advantage of this system is that parentage and date of mating are known. The disadvantage for the singly housed males is they have relatively little social contact with other cats.

**Figure 31.5** Weight changes during gestation and lactation in queens with different litter sizes (group size = 15) (from Loveridge & Rivers 1989). Reproduced with kind permission of Waltham Centre for Pet Nutrition.

### Conception and pregnancy

Ovulation is triggered by mating, possibly from the stimulation of the tom withdrawing his barbed penis. After copulation both cats wash their urinogenital area, the female continues to roll for about 30 minutes before they mate again. Multiple copulations are normally required to trigger ovulation. Females may mate many times and with different males. Pregnancy can be reliably diagnosed by palpation at 21–28 days, by ultrasound after 21 days and by radiography after 40–45 days. Pregnancy can be assessed by monitoring weight gain, and weight gain also gives some indication of the size of the litter (Loveridge 1986).

### Nesting

Cats do not usually build nests but make use of whatever protective shelter is available; they will usually make use of boxes, newspaper, cardboard or other forms of bedding if provided. They like to choose where to give birth, and may visit suitable sites several times before coming to a decision. Some cats prefer dark, quiet places; a box provided in the breeding area will generally be used. Occasionally cats will transfer their kittens to a new nest site.

### Parturition

Group-housed pregnant cats are moved to separate accommodation about 10 days before parturition to protect the newborn kittens from attack. Feral queens living in social groups do use communal dens and collaborate to nurse each other's offspring; in large groups it tends to be mothers and daughters co-operating but in small groups all adult females may nurse each other's offspring, (Bradshaw 1992). Confined females have been known to kill newborn kittens. Infanticide by tomcats has also been recorded.

Before giving birth the queen cleans herself thoroughly, particularly her ventrum around the nipples, and her anogenital area. Parturition is usually uneventful. The kittens are born at 2–30-minute intervals. After the birth the queen removes the amniotic sac from around the kitten, severs the umbilical cord, eats the placenta and licks the kitten clean which stimulates its breathing. After delivery of the last kitten, the queen then encircles her litter and encourages them to suckle by nuzzling and licking them. Kittens find the nipple and suckle spontaneously using innate reflexes. Suckling must be established promptly as neonatal kittens cannot withstand even short periods without food and need to acquire maternal antibodies from the milk. The mother will remain in contact with the kittens for at least the first 24 h. For the first month the queen spends about 70% of her time in the nest caring for her kittens; initiating feeding bouts, grooming, and stimulating their perineal area to encourage urination and defecation (this must be done until they are about 7 weeks old).

### Development of the young

#### Sensory development

Sensory systems are not fully operational in the newborn kitten. They are born blind, virtually deaf and completely

dependent. They have a fully developed sense of touch, and can detect and respond to temperature gradients. Olfaction is fully developed by 3 weeks and hearing by 4 weeks. Kittens' eyes open at about 6 days. They can follow visual cues by 3–4 weeks. Thereafter their visual acuity improves and is fully developed by about 16 weeks. Internal control of body temperature is not fully developed until 7 weeks.

### Physical development

Motor skills develop in parallel with sensory abilities. Newborn kittens can only move by wriggling against a substrate but by the third week they can stand, though their balance is poor, and by 5 weeks they are attempting complex movements. Motor control is fully developed by 11 weeks. Predatory behaviour is observed in cats with no experience of prey but they require experience to become efficient hunters. Feral kittens learn by interacting with prey brought to the nest by their mothers. Pet kittens learn by interacting with toys, litter mates and their mothers.

Kittens' milk teeth begin to appear about 14 days after birth. Initially they are not very interested in solid food but by week 5 are consuming substantial quantities. Kittens can be weaned at 8 weeks. Sensory and physical development are reviewed in Robinson (1992a).

### Behavioural development

In the first 2 weeks, kittens mainly sleep and eat. The sensitive period for socialisation to people lies between the end of the second and seventh weeks. This is the period when contact with people has the greatest influence on a kitten's development of friendliness to people. Kittens should be given plenty of opportunity to socialise with other cats and humans, to play and experience colony routines. Older kittens should continue to be given a wide range of experiences as this will help them to accept novel events as adults. Cats that are handled from birth show more rapid physical development and, as adults, are more responsive to humans and to novel events (McCune 1992). Their friendliness to people is affected by the quality and quantity of handling they receive (reviewed in McCune *et al.* 1995) but is also dependent on their parent's temperament (McCune 1995a). Kittens from confident fathers are more confident themselves and cope better when faced with unfamiliar situations such as being handled by strangers or being caged (McCune 1992). Consequently, it is important to consider temperament when selecting individuals for a breeding programme.

### Weaning and rearing

The queen begins weaning by spending more time away from her kittens and by adopting postures which make her nipples inaccessible. Weaning can be encouraged by providing shelving to which queens can retreat and by removing queens for increasingly longer periods. The kittens are encouraged to eat solid food from approximately 3 weeks of age, which helps to reduce their dependence on mothers' milk. Weaning is usually complete at 8 weeks of age.

In breeding colonies, weaned kittens are usually housed separately from their mothers. Housing kittens aged 8–18 weeks together widens their social experience and increases their sociability to other cats. Young toms can be allowed supervised socialisation with groups of kittens. This provides stimulation and activity for the tom and teaches kittens how to interact with adults. Older kittens are usually grouped with others of a similar age.

### Selection of breeding stock

Cats used for breeding should be free from detectable abnormalities, have a good temperament, and be fastidiously clean. Breeding females should be good mothers and have produced good-sized litters with an even sex ratio and good-sized offspring. Immunodeficiencies may occur in inbred lines.

### Special systems – barrier colonies

A successful barrier colony can be established using simple and straightforward procedures (Loveridge 1984). The colony is set up using SPF cats and accommodated away from existing non-SPF catteries. Access is limited, and personnel shower and dress in a separate set of clean clothing before entering and only handle the barrier colony cats. Goods and equipment are disinfected by immersion in a tank containing aldehyde-based disinfectant, delicate items are wiped with disinfectant.

### Feeding

Cats are solitary hunters and tend to take prey that is considerably smaller than themselves. Although their natural feeding behaviour is to eat small meals through the 24 h day, cats are opportunistic feeders and will adjust their patterns of activity to suit the frequency with which food becomes available. Adult cats at maintenance can adapt to being fed once or twice a day but growing kittens and lactating queens require more frequent feeds. Confined cats are generally given food *ad libitum* and eat small quantities at frequent intervals. Cats are highly selective feeders and require their food to be highly palatable and fresh. Odour and texture play an important part in diet selection by cats. Careful observation is required to establish individual preferences and the correct level of feeding. Most cats seem to be able to monitor, and therefore adjust, their own calorie intake to match their energy requirements quite accurately. Good nutrition during pregnancy and lactation will give kittens the best start in life.

### Natural and prepared diets

Cats are obligate carnivores: they must eat meat products. Free-living cats eat most parts of their prey (small vertebrates and insects) including skin, bones and viscera. Most confined cats are fed solely on commercially prepared canned or complete dry cat foods. These diets have been designed to supply all the key nutrients and energy needed

and have been tested for digestibility and palatability. Many come in a range of types and flavours since cats are known to appreciate variety in their diet (Bradshaw 1992). Canned food is a heat-sterilised moist food and, as such, is a safe product with a very long storage life and so requires no special storage conditions. Good-quality complete dry food made specifically for cats can also be used as the sole source of nutrition. Dry food can be kept for many months providing it is stored in dry cool conditions. Offering some dry food maintains oral hygiene in cats. Its natural abrasive action helps to prevent build-up of plaque and reduces gum disease. Another advantage is that it can be left out longer than canned food, which allows the cats to adopt a more natural feeding pattern of many small meals throughout both the day and night. However, in general, most cats find dry foods less palatable than moist foods like meat or canned foods.

Diets can be made directly from raw ingredients. The National Research Council (NRC) (2006) gives dietary guidelines for cats, both minimum requirements and maximum tolerable levels, and lists the composition of a wide range of ingredients from which diets can be formulated to meet the cat's nutritional requirements. Further information can be found in Burger (1993) and Markwell (1994).

### Water

The requirement for fresh clean water is at least as important as that for other nutrients. The water content of the diet affects the amount of water cats drink.

### Dietary requirements

Dietary requirements are listed in Tables 31.2 and 31.3. These will change with life stage as does the way in which the food should be presented.

The NRC (2006) estimate energy requirements in normal adult cats using an exponential equation of  $100BW^{0.67}$  kcal per day (BW = bodyweight in kg), which is based on data from lean cats using indirect calorimetry (Nguyen *et al.* 2001). For overweight cats the suggested equation is  $130BW^{0.4}$  kcal per day (Table 31.2).

### Pregnant and lactating queens

Pregnant and lactating queens should be fed *ad libitum* on a balanced diet (Figure 31.6). Specially formulated diets are available and supplements should be avoided as they can result in nutritional imbalances (reviewed by Legrand-Defretin & Munday 1993). The NRC (2006) recommends the equation for energy requirements for gestation to be  $ME = 140BW^{0.67}$  kcal/day (Table 31.2).

Cats increase their food intake from the first day of pregnancy and, on average, gain about 39% of their pre-mating weight during pregnancy (reviewed in Loveridge & Rivers 1989). Weight gain varies with the size of the litter (according to the equation: weight gain (g) =  $888.9 + 106.5N$ , where N is the number of kittens in the litter) (Loveridge & Rivers 1989). Some of the weight queens accumulate is lost at parturition, the rest acts as an energy reserve for lactation (Loveridge 1986). In the first 4 weeks of lactation queens expend more energy than they can take in. They continue to

**Table 31.2** Energy requirements of growing cats (from the NRC Guidelines 2006).

Lifestage	Energy measurement	Notes
<b>Adult maintenance</b>		
Normal	100kcal/kg $BW^{0.67}$ /day	
Overweight/low activity	130kcal/kg $BW^{0.4}$ /day	
<b>Pregnancy</b>	ME 140 $BW^{0.67}$ kcal/day	
<b>Lactation</b>		
<3 kittens	ME kcal = maintenance + $18 \times BW \times L$	L = stage of lactation from week 1 to week 7 where Week 1 = 0.9 Week 2 = 0.9 Week 3 = 1.2 Week 4 = 1.2 Week 5 = 1.1 Week 6 = 1.0 Week 7 = 0.8
3–4 kittens	ME kcal = maintenance + $60 \times BW \times L$	As above
>4 kittens	ME kcal = maintenance + $70 \times BW \times L$	As above
<b>Growth<sup>†</sup></b>	$100 \times BW_a^{0.67} \times 6.7 \times (e^{(-0.189p)} - 0.66)$	where $p = BW_a/BW_m$ $BW_a$ = actual body weight (kg) $BW_m$ = expected mature bodyweight $E$ = base of natural log $\sim 2.718$

<sup>†</sup>The age at which a cat's energy requirement settles to the adult level is around 40 weeks, although actual bodily development may continue to 12 months – especially for a large male cat.

**Table 31.3** Nutrient requirements of cats (From the NRC Guidelines 2006). Nutrient requirements/1000kcal.

Nutrient	Units	Cat requirement
Protein	g	50.00

need extra energy whilst they suckle and rebuild body reserves. The amount of energy required depends on the number and age of the kittens. The NRC (2006) recommendation for ME in lactating cats is based on the maintenance requirement increased by a factor determined by the number of kittens in the litter and the stage of lactation (Table 31.2).

### Growing kittens

Nutrition is one of the major determinants of kittens' growth rate, along with freedom from disease, good husbandry, maternal weight and the kitten's sex (Loveridge 1987). During a kitten's first few weeks it is entirely dependent on its mother's milk to achieve the desired growth rate of nearly 100 g a week. If the queen's milk is insufficient, or kittens are being hand reared, specially manufactured milk replacers should be given at frequent intervals. Milk replacers mimic the composition of queen's milk, are highly digestible and may include a probiotic to help establish a healthy gut flora. NRC (2006) recommends a factorial equation to estimate the energy requirements for kittens (Table 31.2).

Although deciduous teeth appear about 14 days after birth, very young kittens are not very interested in solid food. From about 3–4 weeks, they become increasingly interested in the solid food that their mother is eating. By week 6, kittens are eating for 50 minutes a day (Robinson 1992a) and should be given finely chopped or moistened food. Commercial food specifically formulated for kittens is available; it has a higher concentration of energy and some nutrients than food formulated for adult cats. The amount of food kittens can ingest at one meal is limited and, ideally, they should be fed *ad libitum*. Weaned kittens do not need milk and become less able to digest lactose as their gut matures. At 6 months of age most kittens have gained 75% of their final adult weight and can be given food formulated for adult cats.

### Older cats

Most colony cats are retired when they are around 8 years old. If studies require geriatric cats some changes in feeding regimens may be required. Geriatric cats require small but regular feeds of a high-energy, highly palatable and digestible diet (feeding frequently rather than *ad libitum* allows food intake to be monitored). Recent research has shown that their ability to digest fat, protein and energy declines with

**Figure 31.6** Energy intakes of queens and kittens during lactation (mean of three kittens/litter).

age (Taylor *et al.* 1995), whilst energy requirements remain constant. It may be necessary to offer finely chopped or moistened food if they have poor dentition. It is particularly important that elderly cats have easy access to a supply of fresh clean drinking water. They are inclined to become dehydrated because they are less sensitive to thirst and are less efficient thermoregulators (Markham & Hodgkins 1989).

## Laboratory procedures

### Handling and training

Cats that have been handled and well socialised as kittens are much easier to handle and train as adults. Good handling techniques help cats feel comfortable and secure. Grown cats can be picked up with one hand under the chest, just behind the front paws, and the other under the hind-quarters (Wills, J. 1993). Once picked up, the cat will probably be most comfortable sitting in the crook of the handler's arm, with its forepaws either leaning against the handler's shoulder or held in the handler's other hand. Most of the cat's weight should be taken on the handler's arms. Young kittens should be picked up with one hand under the chest and the other under the hindlegs. A young kitten will be small enough to sit on a palm as long as the handler supports its head with the other hand.

### Manual restraint

The usual method of restraining a calm cat is to sit the cat on a surface and hold its front legs. The jaw can be gently but firmly held in the other hand to control its head. Alternatively, it can be wrapped securely in a blanket (reviewed by Wills, J. 1993). Further restraint may be necessary for agitated or nervous cats, for example the use of an extending collar on a rod or crush cages. Sedation is the preferred method of restraint for any cat with a history of being fractious. In the case of blood parameters, it greatly diminishes the effect of stimulating the fight or flight response on blood values.

A handling technique called 'clipnosis' or 'cliphnesia' has been described (Pozza *et al.* 2008), which is used to immobilise cats for nail clipping, blood sampling and other minor procedures. The application of spring paper clips or clothes pegs that gently grasp the skin along the dorsal midline of the neck and cranial thorax renders the cat immobile. Although the technique's effectiveness varies between individuals, it appears to be useful for providing gentle restraint in most cats (Pozza *et al.* 2008). Based on their behavioural responses, the application of the clips does not appear to be aversive to most cats.

### Training

Kittens will learn from their mother to use a litter tray. Hand-reared kittens need to be trained to use one by putting them on the tray frequently, particularly when they look ready to urinate or defecate. Consideration should be given to exposing kittens to minor procedures that will be part of

the routine in the future (eg, use of clippers and being gently restrained on an examination table).

## Physiological monitoring

To maximise welfare and data reliability, monitoring methods should be as non-invasive as possible. Procedures are easier with two experienced handlers; one restrains the cat while the other performs the procedure. The more relaxed the handlers and the cat are, the easier and less distressing the procedure.

### Recording body temperatures

Most cats can simply be held while their rectal temperature is taken. Cats that do object will need to be restrained.

### Collection of specimens

#### Blood

Samples of 1–2 ml are most easily obtained from the front leg: from the antebrachial cephalic vein. For smaller samples, blood can be collected directly by letting it drop out through the needle into the collection vessel rather than being drawn out by syringe. Larger samples are easier to obtain from the jugular veins. See Joint Working Group on Refinement (JWGR) (1993) for general guidance, and limits to blood volume that can be acceptably withdrawn.

#### Urine

Many of the methods used to collect urine (cystocentesis, catheterisation, manual transabdominal expression) are invasive and may be traumatic, particularly when testing is repeated or long-term. They also interfere with the cat's normal urination pattern (as can keeping cats on mesh floors through which urine drains). Most cats can be trained to urinate in a clean tray: cats accustomed to urinating and defecating in a litter tray can be trained to use decreasing amounts of litter until the tray is empty. The outlet of the tray can be connected to a collection vessel outside the pen, enabling urine to be collected separately from faeces. Markwell and Smith (1993) describe a non-invasive collection system whereby urine can be continuously monitored (Figure 31.7).

#### Milk

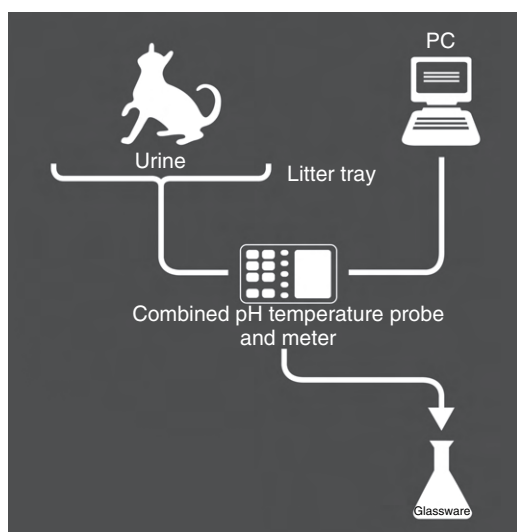

Milk can be manually expressed with some difficulty from lactating queens by gentle massaging of the teats after the administration of 5 IU of oxytocin (im) to stimulate milk flow (Keen *et al.* 1982).

## Administration of medicines

General advice on the administration of substances can be found in JWGR (2001). Most cats will detect drugs mixed in their food and will refuse to eat.

### Dosing and injection procedures

Oral dosing is best carried out with two handlers, one restrains the cat while the other gives the medicine. To give

**Figure 31.7** Non-invasive collection system for urine (after Markwell & Smith 1993). Reproduced with kind permission of Waltham Centre for Pet Nutrition.

a tablet grasp the cat's head from above, at the points where the jaws meet, with forefinger and thumb, tip the head back and press in with thumb and finger. Push on the lower jaw with the index finger of the other hand to open the animal's mouth and drop the tablet far back on the middle of the tongue. Push it quickly and gently so it moves over the back of the tongue. Close the mouth and gently stroke the throat to encourage swallowing. Large tablets have to be broken into smaller pieces. When giving liquid medicines let the liquid run down the tongue drop by drop, allowing the cat to swallow after every two to three drops or it may choke.

Cats need to be restrained for the application of eye and ear drops. To give ear drops hold the cat's head to one side and put the drops in, externally massaging the ear canal helps the drops to penetrate. Apply eye drops to the inner corner of the eye and keep the head back for a while to allow the drops to cover the eye's surface.

Injections are given when the cat is restrained. Subcutaneous injections are usually given into the scruff of the neck, intramuscular injections into the muscle (quadriceps) overlying the femur of the hindleg or, for small volumes, into the paralumbar (epaxial) muscles. Absorption can be accelerated by gentle massage. Cats which require routine subcutaneous injections (eg, diabetics) can be trained to accept injection without restraint by associating the procedure with a highly palatable food treat.

## Anaesthesia and analgesia

General advice can be found in Hall and Taylor (1994) and Flecknell (2009).

### Pre-anaesthesia

#### Preparation

Prior to administering an anaesthetic, food should be withheld for 12h (there is no need to withhold water). This will

reduce the risk of vomiting during induction or during the recovery period.

Cats object to aggressive restraint, particularly if they are not sedated. It is always better to give them the benefit of the doubt by first handling them with the minimum restraint. If stronger restraint is required, then premedication and anaesthesia may be used.

#### Premedication

Agents and dosages are given in Table 31.4. Premedication with a sedative is advisable, even in placid cats, as it reduces struggling during induction. A less stressful induction has several advantages: a reduced dose of induction agent and maintenance agent is required; recovery is smoother; and analgesia is more effective.

## Pain

Pain can be difficult to recognise in cats, as their behavioural responses may not be as overt as in other species such as the dog. Behaviours indicating pain can be subtle and easily overlooked, and there may be individual variation. Several studies have examined the behavioural indicators of post-operative pain; these indicators include the inhibition or loss of normal behaviour (such as decreased grooming or failure to eat), the expression of abnormal behaviours (such as altered posture or aggression) (Waran *et al.* 2007) and increased reaction or sensitivity to touch (Taylor & Robertson 2004). Chronic long-term pain, such as that caused by degenerative joint disease, is likely to have a more significant impact on the welfare of cats than is currently recognised. Typical signs of chronic pain include reduced activity, hiding, decreased interest and decreased response to surroundings; there may be inappetence leading to weight loss. Proper assessment of pain in cats will require the development and validation of behaviour-based, multidimensional pain measurement tools. These are available for dogs (Holton *et al.* 2001) but are in their infancy for cats. Guidelines on pain management in cats have recently been published (Hellyer *et al.* 2007).

## Analgesia

Safe and effective methods of analgesia are now available. Pain should be prevented whenever possible. Pain can be managed more effectively if analgesia is given before the pain occurs. It is particularly important to consider any requirements for analgesia in sedated cats as they may be unable to demonstrate in any observable way the true level of pain they are experiencing. If a procedure or a disease is known to cause pain in other species, or it seems probable that it might be painful, then analgesia should be given. Analgesics should not be given 'as needed', rather they should be administered on a fixed schedule which can be re-evaluated and changed as necessary. There should be a scale of assessment that all workers can use.

There are two approaches to analgesia:

1. Non-pharmaceutical (see Post anaesthesia section);
2. Pharmaceutical:
  - Opioids – morphine, oxymorphone, buprenorphine, fentanyl;

**Table 31.4** Sedatives, tranquilisers, analgesics, pre-anaesthetic and anaesthetic medication for use in cats (derived from BSAVA Small Animal Formulary 2005, National Office of Animal Health 2006, Flecknell 1996). See also Flecknell (2009). Data sheets should be consulted for the various drugs, combinations with other drugs and their dosages and route of administration.

Drug	Dosage	Route	Comments
Atropine sulphate	0.03–0.05 mg/kg	sc	
Acepromazine	0.03–0.125 mg/kg	sc, im	
Diazepam	0.1–0.3 mg/kg	iv	
	0.2–0.4 mg/kg	im	
<b>Opioids</b>			
Buprenorphine	0.01–0.02 mg/kg	sc, im. or sublingually	Lasts 6–8 h
Morphine	0.1–0.2 mg/kg	sc, im	Lasts 6–8 h
Oxymorphone	0.02–0.1 mg/kg	im, sc	Lasts 2–6 h
Fentanyl: skin patch	0.025 mg/h patch for cats weighing 3–5 kg; in smaller cats only half the protective liner should be removed	Applied to clipped and shaved chest wall, and covered with a light dressing	Replace every 2–3 days
<b>Non-steroidal anti-inflammatory drugs (NSAIDs)</b>			
Carprofen	4 mg/kg	sc or iv	Lasts 24 h, given as a single dose; one single further dose at 2 mg/kg may be given
Meloxicam	0.3 mg/kg	sc	Lasts 24 h, given as a single dose
	0.05 mg/kg	Orally	Once daily, following initial 0.1 mg/kg loading dose orally
Ketoprofen	2 mg/kg	iv, im, sc	Every 24 h for up to 3 days
	2 mg/kg	iv, im, sc	Given once, followed by 1 mg/kg orally every 24 h for 4 further days
	1 mg/kg	orally	Every 24 h for up to 5 days
<b>Local anaesthetics</b>			
Bupivacaine 0.5%	Up to 1 mg/kg	Perineural	Duration 2–6 h
Lidocaine 2%	Up to 4 mg/kg	Perineural	Duration 1–2 h
<b>Sedatives and anaesthetics</b>			
Ketamine	1–2 mg/kg	im	Analgesia
	11 mg/kg	im	Minor restraint (in lower doses and with fewer side effects if combined with other drugs)
	22–33 mg/kg	im	Minor surgery (in lower doses and with fewer side effects if combined with other drugs)
	2.2–4.4 mg/kg	iv	Sedation
Ketamine	5–10 mg/kg	im	Anaesthesia; xylazine and atropine are administered first, followed by ketamine 20 minutes later
Midazolam	0.2 mg/kg		Sedation or anaesthesia depending on dose
Ketamine	100 mg/kg	im	Anaesthesia
Xylazine	1.1 mg/kg		
Atropine	0.03 mg/kg		
Ketamine	5–20 mg/kg	im	
Medetomidine	40–100 µg/kg		
Ketamine	5 mg/kg	im	
Medetomidine	80 µg/kg		
Butorphanol	0.4 mg/kg		

- Local anaesthesia – lidocaine, bupivacaine;
- NSAIDs (non-steroidal anti-inflammatory drugs) – carprofen; meloxicam, ketoprofen.

Prolonged, effective analgesia is best achieved by using a combination of these drugs with non-pharmaceutical techniques. The effect of opioid analgesia can be optimised by sedatives.

### Anaesthesia

For procedures lasting 20 minutes or less, or for minor surgery (eg, suturing small skin wounds), cats are often given intravenous general anaesthetics or heavy sedation

with analgesia (xylazine, medetomidine or ketamine). For longer procedures or major surgery, general anaesthesia is usually induced with intravenous agents and then maintained with a gaseous anaesthetic. The preferred route for intravenous administration is into the cephalic vein in the foreleg (using a 0.6 mm or 0.5 mm (24–25 G), 16 mm needle). If this is not possible, the injection can be made into the medial vein of the hindleg or jugular veins.

For intubation, a selection of endotracheal tubes, from 3.0–5.5 mm, should be available. Cats have a very sensitive laryngeal reflex. To prevent laryngeal spasm, the larynx is sprayed with 2% lidocaine and the endotracheal tube is

lubricated with lidocaine gel. The formulation of some local anaesthetic sprays can cause laryngeal oedema in cats, and the spray should be checked before use to ensure it is safe for use in cats. A semi-rigid wire in the lumen of the endotracheal tube can facilitate tracheal intubation. The end of the tube should not pass further than the point of the shoulder.

#### *Intravenous agents and dosages*

Agents used routinely for intravenous induction of anaesthesia are: 2.5% thiopental (10 mg/kg iv) or propofol, 10 mg/ml emulsion (6 mg/kg iv for a premedicated cat).

#### *Gaseous agents*

Gaseous agents include isoflurane, sevoflurane and halothane. Isoflurane is considered to have several benefits over halothane. Sevoflurane is relatively new to the veterinary market, but appears to have benefits over halothane and to be similar to isoflurane (Hammond 2007).

#### *Muscle relaxants*

With modern anaesthetics, muscle relaxants are not usually necessary. Their use is not recommended unless the anaesthetist is very experienced with feline anaesthetics.

#### *Anaesthetic protocol – best practice*

A best practice protocol for routine surgery would be: acepromazine; buprenorphine; carprofen or meloxicam; intravenous propofol; isoflurane; and with application of local anaesthetic into the wound.

#### *Post anaesthesia*

A variety of non-pharmaceutical techniques can be used to create the optimum conditions in the cat's external and internal environments. Cats should be allowed to recover from anaesthesia in a quiet warm room. They should be nursed on soft bedding and kept clean and comfortable. A semi-enclosed box or high-sided soft bed where the cat can feel secure and still be monitored can be useful. Cats that are used to contact with humans can be given plenty of reassuring verbal and physical contact. Frightening noise and smells should be excluded from the recovery area. Any painful tissues should be immobilised using splints or bandages. The cat should be carefully monitored throughout the post-anaesthesia recovery period, as it is during this time that complications are most likely to occur.

## Euthanasia

Euthanasia should be performed in a dignified manner, minimising any mental or physical suffering to the cat, (see also Chapter 17). The method of choice is injection of an anaesthetic agent sufficient to cause rapid unconsciousness and a certain death. A common method is to give a high overdose (about 200 mg/kg) of pentobarbital by intravenous injection. This results in an immediate loss of consciousness, rapidly followed by deep narcosis and respiratory and cardiac arrest. The cat dies within a few seconds apparently without pain or distress. If a cat is difficult to handle, it may need to be sedated before being euthanased.

## Common welfare problems

### Disease

This section summarises the diseases that most commonly threaten laboratory cats. More detailed reviews are provided by Chandler *et al.* (2007) and Sherding (2008). See also King and Boag (2007).

### Prophylaxis

Cats are susceptible to a number of viral, bacterial and parasitic diseases. Colony cats should be vaccinated from the age of 9–12 weeks against feline viral rhinotracheitis, feline calicivirus and feline infectious enteritis. It is important to use a killed vaccine in an SPF-derived cat to minimise the risk of experiencing full-blown disease. Closed colonies are unlikely to be exposed to the feline leukaemia virus. Cats entering the colony should be treated to eliminate all parasites; in a closed colony reinfestation is unlikely.

### Signs of diseases

A cat's behaviour and appearance reflect its state of health. A healthy cat will have an alert bearing and move easily and confidently about its accommodation. It will be interested in its surroundings and its food, and groom frequently. It will have clean ears, eyes, mouth and skin. Animals that show any deviations from these signs should be observed and examined carefully to investigate the cause. Any cat exhibiting watery lacrimation, purulent discharges from eyes, nose, or ears, excessive salivation, vomiting or diarrhoea should be isolated immediately.

### Viral diseases

#### *Feline immunodeficiency virus (FIV)*

FIV is a lentivirus that shares many characteristics of other lentiviruses, such as human immunodeficiency virus. FIV is transmitted primarily by parenteral inoculation of virus present in saliva or blood, via bite and fight wounds. This accounts for the higher prevalence of the virus in adult male cats. Occasional transmission of virus *in utero* and post parturition via the milk may occur.

FIV infection progresses through several stages: an acute phase; a clinically asymptomatic phase of variable duration; and a terminal phase of infection often referred to as feline acquired immunodeficiency syndrome (Sellon & Hartmann 2006). The hallmark of FIV pathogenesis is progressive disruption of normal immune function. During the last stages of infection, clinical signs are often a reflection of opportunistic infections, neoplasia, myelosuppression and neurological disease. However, with proper care some FIV-infected cats can live for many years with a good quality of life, and may die in old age from causes unrelated to FIV infection.

Diagnosis of FIV infection is made most commonly by detection of FIV-specific antibodies in blood by either enzyme-linked immunosorbent assay (ELISA) or rapid immunomigration-type assays (Sellon & Hartmann 2006). An FIV vaccine is available commercially (Fel-O-Vax®, Fort Dodge); because the vaccine contains whole virus, cats

respond to vaccination by producing antibodies that are indistinguishable from those produced during natural infection.

#### *Feline leukaemia virus (FeLV)*

The prevalence and importance of FeLV as a pathogen in cats are decreasing, primarily because of testing and eradication programmes and the routine use of FeLV vaccines. FeLV, a retrovirus and member of the Oncornavirus sub-family, causes clinical illness related to the haemopoietic and immune systems and neoplasia. The three most important FeLV subgroups are FeLV-A, FeLV-B and FeLV-C; only FeLV-A is contagious and passed horizontally from cat to cat in nature. Subgroups FeLV-B and FeLV-C evolve *de novo* in an FeLV-A-infected cat by mutation and recombination between FeLV-A and cellular or endogenous retroviral sequences contained in normal feline DNA (Hartmann 2006).

FeLV spreads between susceptible cats primarily via saliva, where virus concentration is higher than in plasma. Vertical transmission can also occur: kittens can be infected transplacentally or when the queen licks and nurses them. Susceptibility to infection is highest in young kittens. The outcome of FeLV infection mainly depends on immune status and age of the cat, but is also affected by virus pathogenicity, infection pressure and virus concentration. Guidelines for testing cats for FeLV have been published (American Association of Feline Practitioners and Academy of Feline Medicine (AAFP/AFM) 2001). While persistently viraemic cats have a decreased life expectancy, treatments for the many clinical syndromes that accompany infection are available. A discussion of FeLV infection and outcome, testing and treatment can be found in Hartmann (2006).

FeLV vaccines are available but the relative efficacy of the vaccines is controversial. Vaccine efficacy testing protocols vary widely between studies and are complicated by the natural resistance of cats (especially older cats) to FeLV infection; none of the licensed vaccines are 100% effective.

An epidemiological association exists between FeLV (and rabies) vaccination and the later development of soft tissue sarcomas at the injection site, referred to as injection site sarcomas, vaccine-associated sarcomas and vaccine site-associated sarcomas (Hartmann 2006).

#### *Feline infectious peritonitis (FIP)*

FIP is an infrequent virus infection, which is almost invariably fatal. It is caused by feline infectious peritonitis virus (FIPV), which is generally accepted to be a mutation of feline enteric coronavirus (FECV) (Addie & Jarrett 2006). The latter is common in the domestic cat population, particularly in multicat households or where cats are kept in crowded conditions. Transmission is primarily indirect through contact with virus-containing faeces or fomites, for example contaminated litter trays.

The mutation enables FIPV to infect macrophages and monocytes, and spread throughout the body. The damage caused by the virus is due to the intense immune reaction, localised inflammatory response and vasculitis at the site of virus colonisation.

Two basic forms of FIP, effusive (wet) and non-effusive (dry) are recognised. Approximately half the cats with FIP

are less than 2 years of age, although all age groups can be affected (Addie & Jarrett 2006). The risk factors for FIP development are age and crowding, with young cats in crowded catteries being most at risk. Good husbandry is particularly important in controlling FIP. When establishing a colony a decision must be made on whether to focus on FIP or the coronavirus family. If it is the broader family, then the goal should be to maintain the cats free of antibodies to coronaviruses. This would require a different level of surveillance and then the use of vaccines.

An intranasal vaccine, given to cats over 16 weeks of age, has been developed but it is not effective if the cat has already been exposed to the virus. Definitive diagnosis of FIP is by *post-mortem* examination or by using DNA sequencing to detect FIP virus genes in blood, peritoneal fluid or tissue biopsy.

#### *Feline infectious enteritis or panleucopenia (FIE)*

Feline panleucopenia is a parvovirus; it is shed in all body secretions during acute stages of disease, but mainly in the vomitus and faeces. It has a short shedding period but long survival in the environment (Greene & Addie 2006), where it is resistant to heat and to many disinfectants. FIE is a highly infectious disease with a high mortality rate. The virus is usually transmitted by indirect contact of susceptible animals with contaminated premises; *in utero* transmission does occur, and may cause early foetal death and resorption or result in the birth of live kittens with varying degrees of neurological damage.

Subclinical cases of infection, more common in older cats, may go unrecognised, while severe clinical illness is the rule in young kittens; sudden death may occur. A presumptive diagnosis is usually made based on clinical signs and the presence of leucopenia. With appropriate symptomatic therapy and nursing care, cats may recover from infection. Immunisation has been very effective at reducing the incidence of this disease.

#### *Feline viral upper respiratory infection (cat 'flu)*

Between 85% and 90% of cases are caused by either feline herpesvirus (which causes feline viral rhinotracheitis) or feline calicivirus. Feline herpesvirus (FHV) generally causes more severe disease than feline calicivirus (FCV), but FCV appears to be relatively more common. The viruses are shed mainly in ocular, nasal and oral secretions, and transmission is largely by direct contact from infected to susceptible cat.

After FHV infection virtually all recovered cats become latently infected carriers, with intermittent episodes of virus shedding, particularly after periods of stress. FCV carriers shed virus more or less continuously; in some cats the carrier state appears to be lifelong, but most cats at some point spontaneously recover and appear to eliminate the virus.

*Bordetella bronchiseptica* is also recognised as a primary pathogen to the feline respiratory tract, although its precise contribution to disease in the field is not yet fully established (Gaskell *et al.* 2006).

Although immunisation cannot guarantee complete protection from upper respiratory infection nor from the development of latent infection, routine vaccination of kittens using a modified live or killed bivalent vaccine, and regular booster vaccination, is recommended.

Cats can carry zoonotic diseases that may be a risk to people (reviewed by Greene & Levy 2006).

### Reproductive problems

Major causes of infertility in both toms and queens include inbreeding, poor husbandry, disease, anatomical or reproductive defects and social stress. Investigation should first eliminate any non-reproductive disorders by a thorough physical, haematological and biochemical examination, followed by a thorough evaluation of the reproductive system and semen.

Prolonged anoestrus is usually a management problem. The cats' general health and nutrition should be optimised, and they should be exposed to 14–16h of light per day and to reproductively active cats. Some queens cycle but do not show any oestrous behaviour (silent heat). They may breed if housed with a male.

Failure to mate may be caused by inexperience. Virgins should be partnered with an amenable, experienced mate. Immature toms can lack libido, some may respond after visual exposure to breeding males, others may need more time to mature. Toms should mate in familiar surroundings otherwise they may concentrate on territory marking instead of mating. Mating may fail because the cats are incompatible; the cats may have definite mating preferences, or some physical incompatibility may prevent intromission.

Queens may not conceive after mating. Failure to conceive following breeding is occasionally caused by vaginal or, more commonly, by uterine disease. Ovulation may fail because of inadequate vaginal stimulation or hormonal insufficiencies. Toms may fail to inseminate; their fertility declines if they are mated too frequently. Failure to carry a pregnancy to term has been associated with environmental stress, dietary insufficiencies, or failure of extraovarian progesterone.

### Effects of neutering

Neutering eliminates sexual behaviour in males and females, and maternal behaviour in females. It reduces the incidence of behaviours such as urine marking in both sexes, and increases tolerance towards cats from outside the social group (Bradshaw 1992). However, neutering predisposes to obesity by causing a reduction in energy expenditure. While a cat may adapt its food intake in accordance with this, the adaptation may take 9–10 weeks, by which time its body weight would have increased. The risk of obesity is greatly increased if the cat is confined in a small enclosure and is inactive.

### Abnormal behaviour

Specific problems associated with confinement include boredom, aggression to people and cats, fearfulness, behavioural inhibition, withdrawal, escape behaviour, hiding, poor reproductive success, anorexia, weight loss, tail chasing, stereotypies, fabric eating and self-mutilation (reviewed in McCune 1995b). Introducing a new cat into a stable colony produces conflict in the group until both newcomer and residents habituate to the new social hierarchy.

Studies of stray cats housed communally at a shelter have shown that most overt aggression occurs within the first 4 days and that mutual toleration is established after 2 weeks (Bradshaw 1992). However, although many of these cats will appear to have behaviourally habituated to confinement at this stage, a recent study has shown that cats were still showing abnormally high urinary cortisol levels (indicative of increased stress) up to 5 weeks after entry to a quarantine cattery (Rochlitz *et al.* 1995). Behavioural inhibition is commonly the response of cats to confinement. Unlike the more overt forms of distress like vocalising, spitting, hissing and growling, behavioural inhibition is easy to miss unless detailed observation is made of the cat (McCune 1992).

### Preventing problems

Research animals without behavioural problems are likely to have better welfare and be better for research purposes. Many problems associated with confinement can be prevented by adequate early socialisation and careful selection of cats for suitable temperament (Robinson 1992b; McCune *et al.* 1995). Siegford *et al.* (2003) developed and validated a test to evaluate temperament in cats. These authors found that cats could be ranked, using an easily scored feline temperament profile (FTP), as being more or less sociable toward people, and that FTP scores were fairly consistent over time and circumstance and correlated positively with responses of cats to animal care staff and unfamiliar humans. Cats with timid temperament, extremes of age and restricted experience are more likely to have problems adjusting to confinement and responding to novelty.

There are three approaches to preventing stress in confined cats: (1) selective breeding of the most suitable individuals; (2) an investment of time and effort in the early development phase of kittens; and (3) maintaining a varied and stimulating environment which offers cats choices about what they do and where they do it.

All these approaches have been touched on earlier in this chapter. The benefits of breeding from healthy, confident, well socialised, unrelated parents will help preserve the quality of a cat colony. Early socialisation is a critical time in the development of kittens and, if handled sensitively, will produce cats that are more tractable and pleasant to work with. The quality of the environment is also critical to a cat's well-being. With a little imagination, there can be many opportunities for providing variety and reducing stress (reviewed in McCune 1997). Enriching the environment through the provision of social contact, toys and food presented in novel ways will help to ensure good welfare.

Keeping groups stable reduces conflict. Where cats cannot be group-housed they can be given visual, olfactory and auditory contact by using glass partitions with nose-height holes drilled between adjacent pens. They can be given access to a communal room on a rota basis, each cat leaving olfactory and sometimes visible messages for the next occupant. Likewise, scratch posts can be moved from one pen to another (these posts carry interesting olfactory information).

Although cats normally spend a large part of their day asleep or resting, they can become bored. They should be

given opportunities for play, exercise and predatory behaviour. Food is often used as an enrichment device. Dry food is particularly suitable for hiding in pens or for placing inside containers which the cat has to work at to extract individual pieces. Puzzle boxes are now commercially available and can extend the handling time of the food. Small pieces of dry food (or toys) can be pawed through irregular openings in the lid of the box (Figure 31.8).

Cats socialised to humans find human company stimulating and have been found to show signs of stress when the caretaking style becomes less interactive (Carlstead *et al.* 1993). A range of activities can be engaged in, from talking quietly to interactive play with a range of toys. Activities can be selected to suit the personality and response of the individual cat. Cats will play with toys. They show most interest in toys that mimic prey but toys need to be changed frequently and offered in randomised rotation to sustain long-term interest. Rods attached to toy fish that can be jiggled to stimulate play seem particularly popular with younger cats.

In addition to providing an enriched environment, fearfulness can be significantly reduced by consistent, positive handling (Gourkow & Fraser 2006). Animal care staff should handle the cats under their care daily, at times that are not part of routine caretaking procedures such as feeding or cleaning (Rochlitz 2000). Hoskins (1995) examined the effect of human contact on the reactions of cats in a rescue shelter: cats that received additional handling sessions, where they interacted closely with a familiar person, could subsequently be held for longer by an unfamiliar person than cats that did not receive additional handling sessions.

### Older cats

A range of medical and behavioural conditions is recognised in older cats. Common medical conditions associated with aging include renal disease, dental disease, hyperthy-

**Figure 31.8** Presenting part of the food ration in a puzzle can provide a rewarding challenge.

roidism, diabetes mellitus and osteoarthritis. Sensory loss, such as deafness, and signs of cognitive impairment may become evident (Bowen & Heath 2005). Signs of cognitive impairment may include disorientation, altered interaction with others, sleep problems (usually associated with vocalisation), house soiling and failure of appetite. A number of treatment approaches may be used. Environmental modification, by making the environment more accessible to the cat (for example, providing additional, lower resting and hiding places), exposure to play and increased social contact, will stimulate and maintain mental processes. Dietary supplementation with a range of antioxidants, essential fatty acids and other additives has been shown to improve neuronal metabolic function and boost central nervous system antioxidant reserve. While environmental enrichment and dietary modification should be the mainstay therapies to delay progression of cognitive decline, and where euthanasia is not indicated because of the nature of the research, some psychoactive drugs may also be useful (Bowen & Heath 2005).

### Feline facial pheromones

A range of pheromones has been isolated from feline facial secretions (Mills 2005), and two fractions are available commercially: F3 and F4. The F3 fraction can be used to have a calming effect on cats and facilitate their adaptation to new environments, such as new housing or hospitalisation for veterinary treatment (Griffith *et al.* 2000), or during transport. It is also used in the treatment of behavioural problems such as urine marking and spraying, and scratching of objects. It is available as a spray for application onto cages, tables and blankets and as a plug-in diffuser for rooms or treatment areas. The F4 fraction reduces the cat's wariness of unfamiliar people, and is used to reduce the risk of aggression due to handling in the veterinary hospital. It is available as a spray that is applied to the environment or to the person's hands prior to handling the cat.

### Monitoring welfare

The effect of changes made to relieve stress and enrich the captive environment can be assessed by looking for a decrease in abnormal behaviours associated with long-term stress (Bradshaw 1992) and for a behavioural repertoire which more closely resembles that of free-ranging cats (UK Cat Behaviour Working Group 1995; see also Chapter 6). Changes over time can be assessed quickly by using a scoring system. A composite behavioural scale for quantifying stress in confined cats was devised by McCune (1992) and had 10 levels, which were later reduced to seven (McCune 1994). This scale was refined by Kessler and Turner (1997) by adding more postural elements to form the cat stress score (CSS), still with seven levels. This behavioural score correlates well with many indicators of stress (McCune 1992), although there is not always agreement between it and some physiological measures of stress (McCobb *et al.* 2005). Casey (2007a) found a negative correlation between the rate of decline of the CSS and the rate of decline of

urinary cortisol to creatinine ratios for cats newly admitted to an animal shelter. This implies the presence of different 'coping styles' in cats, where some actively respond to stress and adapt to the unfamiliar surrounding physiologically, while others appear to be more passive but change little physiologically.

All workers in an establishment should ensure they are using the score in the same way and are being consistent over time in their scoring. Although such a score does require training, once learnt it is a powerful means of assessment as it summarises so much fine detail and can be quickly applied.

A combination of good innovative design and thoughtful husbandry enables confined cats to be kept in conditions where the demands on their welfare and the laboratory's work schedule can be harmoniously balanced.

## Quality of life

Quality of life is an abstract construct that has been formally recognised and widely used in human medicine. In recent years there has been much discussion about the concept of quality of life and its application to companion animals. While it is generally accepted that quality of life has to do with the animal's feelings, how it can be defined, measured and reported in animals is currently being explored (McMillan 2005; Scott *et al.* 2007). Approaches include the observation and interpretation of the animal's behaviour, and the use of questionnaires directed at the person most closely involved with the animal's care (see also Chapter 6).

## 32 Pigs and minipigs

Wolfgang Holtz

### Biological overview

#### General biology

Pigs are found in almost every part of the world. Within the order Artiodactyla (even-toed ungulates) the Suiformes, encompassing pigs, peccaries and hippopotamuses, form a suborder of animals with a single stomach. There are two families: Tayassuidae (Central and South American pigs) and Suidae (true pigs). Within the the Suidae are the genera: *Potamochoerus* (bush pigs), *Phacochoerus* (wart hogs), *Hylochoerus* (forest hogs), *Babirussa* (Celebes hogs) and *Sus* (European pigs).

All modern domestic pigs are varieties of the species *Sus scrofa* and have 38 (2N) chromosomes. They are omnivorous mammals with a high degree of adaptability and intelligence, a lively temperament and high fecundity. The anatomy and physiology of pigs is thoroughly covered in a range of veterinary textbooks, most comprehensively in Pond & Mersmann (2001). Most of the information is also applicable to miniature pigs (minipigs), which are often used in biomedical research as an alternative to larger breeds. Minipigs are smaller than large domestic pigs, but there is close resemblance with regard to proportions and functions. Texts covering various aspects of minipigs are Glodek & Oldigs (1981), Leucht *et al.* (1982) and Svendsen (1998).

#### Size range and lifespan

The typical body masses of farm and miniature pigs (Goettingen strain) at various ages is presented in Table 32.1. The growth curve of farm pigs follows the classical sigmoid pattern (Figure 32.1), whereas in minipigs it is more linear, with the point of inflection appearing at about 250–300 days of age (Brandt *et al.* 1997; Koehn *et al.* 2008). Farm pigs reach their adult body mass of 180–250 kg, or sometimes more, at an age of 3 years. According to information compiled by Swindle (2007), amongst the miniature pig breeds the Goettingen miniature pig is the lightest, approaching 35–45 kg at the age of 2 years. In order of increasing adult mass, other breeds are the Yucatan micro, Sinclair, Yucatan and Hanford. Adult pigs fed a high-energy diet while not breeding tend to grow excessively obese. The average life expectancy is 10–20 years.

### Social organisation

Wild pig social groups consist of small numbers of females and their offspring. Adult males tend to be solitary except during the mating season. In groups of domestic pigs, a social dominance order is quickly established. Generally, the level of aggression, mainly expressed by butting and biting the neck and ears, soon subsides. Rarely, fighting continues to the state of total exhaustion. Sexually mature males may fight fiercely, especially in the presence of females.

Within a litter of newborn piglets a social hierarchy is established within 3–4 days after birth. From then on each piglet suckles its individual teat, with dominant piglets usually gaining the more productive anterior teats. When piglets from different litters are mixed after weaning, they establish a new dominance hierarchy. Usually, ranking is established through aggressive interaction, but may take place without overt aggression. Dominant–subordinate relationships remain unchanged as long as a group stays together. Subordinates that have been separated from a group will be attacked after reintroduction, whereas reintroduction of dominant animals rarely results in aggression.

### Reproduction

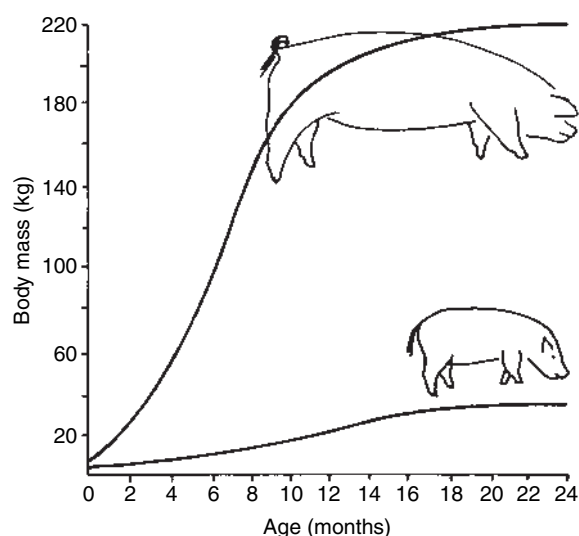

Domestic pigs are prolific and reproduce at all times of the year. They are polytocous and the uterus consists of two long convoluted horns. The oestrous cycle averages 21 (17–25) days. First signs of heat (pro-oestrus) make their appearance 2–3 days before the onset of oestrus. Oestrus, which is characterised by the standing reflex, lasts for 2.5 (1–5) days, and within another 2–3 days the symptoms gradually subside (post- or metoestrus). Ovulation occurs early in the second half of standing oestrus (Figure 32.2) and extends over 1–4 h. Signs of oestrus include swelling and reddening of the vulva, restlessness, increased interest in other animals, especially males, mounting of other animals, occasionally growling sounds and, eventually, display of the standing reflex in the presence of a male or if mounted by another female.

Mating is preceded by foreplay: the male circling, sniffing and nudging the female and attempting to mount. If the sow displays the standing reflex, intromission occurs and the corkscrew-shaped tip of the penis is locked into the cervix

**Table 32.1** Typical body masses (kg) of female breeding stock of farm pigs (ad libitum feeding, figures assembled from several sources) and Goettingen miniature pigs (restricted feeding, figures from the breeding herd at Dalmose/Denmark).

Age	Farm pigs	Miniature pigs
Newborn	1.3	0.45
4 weeks (weaning)	7.5	2.5
3 months	33	7
6 months	90	13
1 year	150	26
2 years	200	35
3 years	230	45

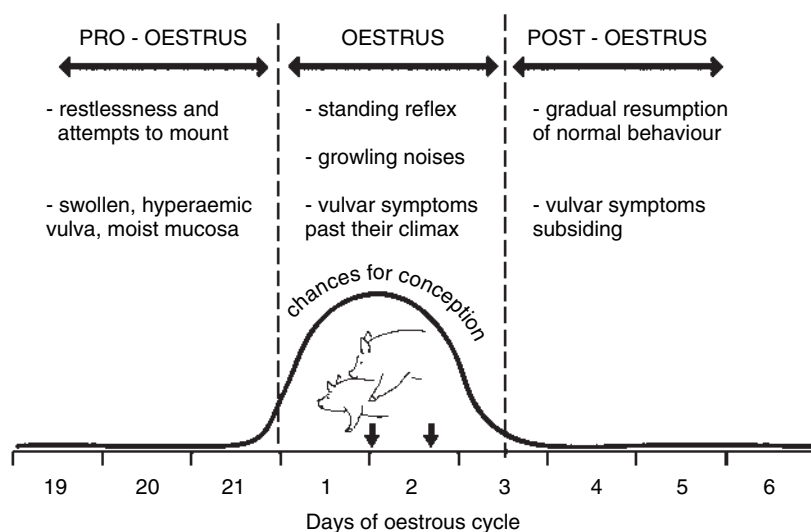

**Figure 32.1** Growth curves for farm pigs and Goettingen miniature pigs. Whereas the former shows the classical sigmoid pattern, the latter is almost linear.

of the sow. Copulation lasts 3–10 minutes and the semen is deposited in the uterus. Intrauterine sperm transport is rapid and fertilisation occurs in the ampullar segment of the oviduct. Embryos enter the uterus 2–3 days after fertilisation at the four-cell stage. Six days after fertilisation the blastocysts hatch from the zona pellucida, start migrating throughout both uterine horns and are eventually evenly distributed. Attachment to the endometrium begins 2 weeks after conception. There are no specialised areas of contact (*placenta diffusa*) and, compared with primates, attachment is rather superficial (epitheliochorial). The average length of the gestation period is 115 days in farm pigs and 114 days in minipigs, plus or minus 3 days. Small litters are carried a day or two longer than larger ones. The embryology of the pig is described in great detail in Patten (1948) and Marrable (1971). Corresponding information on minipigs may be found in Glodek & Oldigs (1981).

In most domestic farm breeds 11–16 ovulations are typical for primiparous and 14–18 for pluriparous females. Typically more than 90% of the ova are fertilised, but early embryonic mortality, occurring within the first 30 days of pregnancy, generally amounts to 30–40%. In well managed herds, typical pregnancy rates are 80–90% with litter sizes of 9–12 piglets born to primiparous and 11–14 to pluriparous females. In Goettingen, our experience with miniature pigs is that litter size for both primiparous and pluriparous females is much less (five to eight and six to eight, respectively). Typical reproductive parameters are summarised in Table 32.2.

Sows produce milk rich in dry matter, containing about 9% fat, 6% protein, 5% lactose and 0.7% minerals. Colostrum contains close to 20% protein, comprising mainly gamma-globulins that act as antibodies. These need to be imbibed by the piglets within the first few hours after parturition to cross the wall of the alimentary tract and provide passive immunity. Milk production of suckling sows increases up to the third week of lactation and declines gradually thereafter. The daily milk production of a sow suckling 10 piglets is about 8 l. Data on milk production in minipigs are not avail-

**Figure 32.2** Oestrous symptoms and the best time for having sows mated or inseminated (arrows). The oestrous cycle of approximately 21 days is divided up into 2–3 days of pro-oestrus, 2–3 days of 'standing' oestrus, 2–3 days of post-oestrus and the inter-oestrous period. In the absence of a boar the standing reflex will be elicited 12 h later than indicated in the diagram.

able. The natural suckling period may extend to 10 weeks, and in extreme cases up to 17 weeks. In commercial production units piglets are usually weaned at around 4 weeks, but sometimes at 5 or 6 weeks of age. While suckling, sows usually do not come into oestrus. The first post-partum oestrus, which is accompanied by ovulation, is usually recorded 4–8 days after weaning. In primiparous sows and under unfavourable environmental conditions the return to oestrus may be delayed. Heat symptoms that are observed about 3 days after parturition in many animals are not associated with ovarian function and ovulation.

### Standard biological data

Published information on biological parameters of the pig is inconsistent. Reference values for cardiovascular, respiratory, haematological and clinical chemical parameters vary within a wide range. Some variation may be explained by genetic differences; however, age, reproductive status and a variety of environmental factors such as husbandry system, microbiological status and conditions under which the information was obtained have a much greater impact.

**Table 32.2** Typical reproductive data for adult farm pigs (figures from various sources) and miniature pigs (Goettingen strain, figures from Goettingen, Germany and Dalmose, Denmark).

Parameter	Farm pig	Minipig (Goettingen strain)
Age at puberty (months)	7	4
Minimum breeding age (months)	8	5
Length of oestrous cycle (days)	21	19.5
Duration of oestrus (days)	2.5	2.9
Number of ovulations	20	11
Gestation period(days)	115	114
Litter size	11	6
Birth weight/piglet (g)	1300	450
Interval weaning-oestrus (days)	5	7
Ejaculate volume (ml)	250	90
Spermatozoa/ejaculate ( $10^9$ )	50	10
Spermatozoan motility (%)	75	75

Differences between various pig breeds and among farm pigs and miniature pigs at a comparable stage of development are comparatively minor. Differences between adult miniature pigs and weight-matched farm piglets, however, may be substantial because of the difference in the physiological state of maturity. Likewise, biological parameters originating from anaesthetised animals do not necessarily agree with those of conscious animals, depending on the anaesthetic used. Factors that may be responsible for variability include: immobilisation, transportation or fasting of the animals, sampling site and method (venepuncture or permanently indwelling catheter).

Table 32.3 provides some values for vital functions and Table 32.4 provides physiological means and ranges of relevant blood parameters typical for farm and miniature pigs.

### Breeds, strains and genetics

There are close to 100 known breeds of pigs mostly reared for pork and bacon production. Breeding stock have been selected with an emphasis on growth rate, feed conversion and lean content, as well as fecundity and mothering ability. The most common domestic breeds are Yorkshire and Landrace (white), Pietrain and Hampshire (spotted or belted) and Duroc (red). In commercial pork production, hybrid crosses of two, three or more breeds are common.

Miniature pig breeds were established for the purpose of biomedical research. They are smaller than farm pigs, but resemble them in proportion and physiology. Many of the present breeds of miniature pigs have their origin in the Minnesota (Hormel) minipig, which was developed in 1949 at the Hormel Institute in Austin, USA. Miniature pigs derived from this population are the Goettingen minipig, developed in 1961, the NIH (Beltsville) minipig and the Sinclair minipig. Others are the Pitman-Moore and the Hanford (derived from the Pitman-Moore). A Mexican feral pig was used in research in 1960 and later referred to as Yucatan mini- and micropig. In addition, breeds such as the Minisib minipig (Siberia), Ohmini and Clawn minipigs (Japan) and several other breeds have been established.

Colonies bred for biomedical research may be random-bred, outbred or (partially) inbred. In commercial pig farming, random breeding and crossing are typical. Purpose-bred pigs and minipigs for biomedical research typically originate from colonies with outbred genetics.

Pigs have 18 autosomal chromosome pairs plus the X and Y chromosomes. A map of the entire genome is close to being fully established (Swine Genome Sequencing

**Table 32.3** Typical resting values for some vital functions for farm and miniature pigs (figures assembled from several sources).

Age (weeks)	Heart rate (beats/min)	Mean arterial blood pressure (mmHg)	Respiratory rate (breaths/min)	Rectal. temperature (°C)
1	220	–	50	39.5
3	150	–	40	39.5
6	120	120	30	39.5
12	100	135	25	39.0
52	70	150	15	38.9

Consortium (SGSC) 2009), which will facilitate research on locating genes associated with traits of economic or disease importance. The similarity of the human and porcine genome maps suggests that there will be further development of the pig as a model for human diseases and in xenotransplantation research.

### Sources of supply

Pigs from random-bred sources are typically of farmed strains, whose breeding has been focused on production rather than family genetics. In these populations individual genetic and phenotypic variation is high, and such animals may not be suited for certain experiments. Purpose-bred pigs and minipigs for biomedical research typically originate from a closed colony with outbred genetics. These populations require genetic management to ensure contin-

ued genetic variability. Monitoring may involve biomedical, immunologic or DNA markers or quantitative genetic analysis of physiological variables. Some minipigs are partially inbred as a result of selection for a specific phenotype, such as expression for major histocompatibility complex (MHC) homozygosity (eg, the NIH minipig).

Pigs and minipigs may be sourced from breeders with different health status, such as conventional, minimal disease (MD), specific pathogen free (SPF) and microbiologically defined. Whereas MD, SPF and biologically defined pigs are produced under barrier protection with increasing security (Table 32.5), conventional pigs are kept in a less rigidly controlled environment with a regular health monitoring schedule and thus have a largely unknown microbiological status.

### Uses in the laboratory

Pigs and minipigs are valuable models in various areas of biomedical research, including: physiology, pharmacology, toxicology, radiology, surgery and organ transplantation, traumatology, pathology, embryology and paediatrics. Characteristics that make them particularly suitable for research include:

1. a convenient body size for most clinical and surgical experiments or trials involving repeated collection of blood samples, biopsies, etc;
2. many similarities with the human, in particular, skin, skeleton and joints, teeth, gastrointestinal tract, pancreas, liver and kidney, cardiovascular system, lung, immune system and physiological state of the newborn;
3. the ease and safety of handling and housing under confined conditions;
4. the relatively low price of acquisition and maintenance;
5. a vast literature extending from embryonic development to modern genomics as well as the expertise of highly specialised commercial farmers and veterinarians;
6. the availability of reproductive technologies, including collection, storage and manipulation of gametes, well in advance of what is available for most other laboratory species.

**Table 32.4** Physiological values of some haematological and clinical chemical parameters for adult farm and miniature pigs (values assembled from various sources).

Parameter	Mean	Range
Blood volume (ml/kg)	65	55–75
Erythrocyte count ( $10^9$ /ml)	7	5–9
Haematocrit (%)	33	30–50
Haemoglobin (mg/ml)	125	90–180
Leucocyte count ( $10^6$ /ml)	13	12–17
Neutrophils (%)	48	40–55
Eosinophils (%)	1.5	0–4
Basophils (%)	0.5	0–1
Monocytes (%)	3.5	1–7
Lymphocytes (%)	50	35–60
Thrombocytes ( $10^6$ /ml)	450	200–500
Total protein (g/dl)	7	6–9
Albumin (g/dl)	4	3–5
Aspartate aminotransferase (AST) (U/l)	38	20–200
Creatine kinase (CK) (U/l)	450	100–3000
Alkaline phosphatase (AP) (U/l)	60	30–130

## Laboratory management and breeding

### General husbandry

#### Housing

Wild pigs roam in forests with no permanent retreat except when they build a nest to raise a litter. Their domesticated descendants are less hardy and, in cold climates, are kept indoors during the winter months. All year round indoor housing is also a common practice to protect the herd from parasites and epidemics. This, however, can conflict with the pig's natural qualities of alertness and curiosity and restricts activity. In regions with mild climatic conditions (eg, UK and France), the use of huts or kennels on pasture for breeding sows has gained some popularity.

Detailed information on the housing of farm pigs may be found in husbandry texts (see Further reading section). In a typical commercial piggery, separate quarters are provided for:

1. young stock from weaning to breeding age (growing quarters);
2. weaned sows and gilts that are to be mated and are, therefore, kept in close proximity to a boar (mating quarters);
3. pregnant sows (gestation quarters);
4. parturient and nursing sows (farrowing quarters).

Young gilts and pregnant sows are usually housed in groups. During the first 4 weeks and at an advanced stage of gestation sows should be able to enter a protected area, especially when feeding, otherwise fighting and crushing against rails can lead to abortion. When farrowing, sows have traditionally been caged in special farrowing crates (Figure 32.3). The crates are equipped with rails to prevent the sows from the lying on and crushing their young. They also provide hygienic conditions and protect the stock person from sow aggression while managing the litter. Farrowing crates, however, seriously compromise sow welfare by restricting nest building behaviour and other periparturient behavioural patterns and are, therefore, much disputed and banned in some countries. Loose farrowing and other pen systems under investigation have, under most practical farming conditions, failed to provide viable alternatives as far as piglet losses (Cronin & Smith 1992; Kamphues *et al.* 2003) and other economic considerations such as barn space and labour requirements are concerned. If crates are to be abandoned, pen systems must be devised that provide most of the benefits of farrowing crates. From a welfare point of view ideally the sow should have enough space to turn around and the floor should be, at least in part, solid and covered with shavings or chaff. Anti-crushing rails and a separate heated creep area for the protection of the piglets and provision for temporary fixation of the sow are necessary. Ideally, the sow should be able to leave her nest to move to a separate dunging area as was possible with early farrowing crates when the sows were group-fed twice daily outside the farrowing area. Until more suitable systems have been devised the period of confinement in a farrowing crate should be limited to the period of 3–4 days from the onset of parturition (when the urge for nest building has

**Figure 32.3** Top view of a traditional farrowing crate. Confinement of the sow should preferably be restricted to the 3–4 days following commencement of parturition. Loose housing farrowing systems favour the well-being of the sow, though usually at the price of increased piglet losses.

subsided) until the danger of crushing is over. Various farrowing and nursing pen types are dealt with in a report by European Food Safety Authority (EFSA 2007).

For experimental purposes pigs are occasionally housed in special crates or cages. Up to a body mass of 30kg they may be kept on perforated or wire mesh floors for limited periods (at the most for a few weeks), provided the cages are located in a room with perfectly controlled climate and ventilation. However, since pigs lack an insulating coat, cage-rearing is a vulnerable system requiring constant care. Several manufacturers supply special miniature-pig cages, including metabolism cages that permit collection of urine and faeces. Dog facilities can usually be modified to house young pigs or minipigs. Partitions between cages should be 1.00–1.10m high. Individually penned pigs must be in visual or olfactory contact with other pigs. Cages should be large enough for the confined animal to turn around and should have separate sleeping and dunging areas. Minimum floor space recommended by various sources varies considerably. The most recent proposal of the Commission of the European Community in the Directive of the European Parliament and of the Council on the Protection of Animals Used for Scientific Purposes<sup>1</sup>, to take effect in 2017, calls for a minimum pen size of 2m<sup>2</sup>. Guidelines for minimum floor space per animal are provided in Table 32.6. They represent a reasonable compromise between the requirements of the animals and practical and economic considerations of space limitation. More confined enclosures may be justified for limited periods to serve special experimental conditions, for example, when monitoring individual feed consumption, or

<sup>1</sup><http://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=CELEX:52008PC0543:EN:NOT>

**Table 32.6** Recommended minimum enclosure dimensions and space allowances for the accommodation of farm and miniature pigs. Figures were assembled from various sources, in particular the commission recommendations of the European Convention (2007) ([http://eurlex.europa.eu/LexUriServ/site/en/oj/2007/l\\_197/l\\_19720070730en00010089.pdf](http://eurlex.europa.eu/LexUriServ/site/en/oj/2007/l_197/l_19720070730en00010089.pdf)) and the Council of Europe (2006) Multilateral Consultation of Parties to the European Convention for the Protection of Vertebrate Animals used for Experimental and other Scientific Purposes (ETS 123) Appendix A. Cons 123 (2006) 3 ([http://www.coe.int/t/e/legal\\_affairs/legal\\_cooperation/biological\\_safety,\\_use\\_of\\_animals/laboratory\\_animals/2006/Cons123\(2006\)3AppendixAen.pdf](http://www.coe.int/t/e/legal_affairs/legal_cooperation/biological_safety,_use_of_animals/laboratory_animals/2006/Cons123(2006)3AppendixAen.pdf)).

Body mass (kg)	Pen length (m)	Enclosure size (m <sup>2</sup> )	Floor area (m <sup>2</sup> /animal)	Lying space** (m <sup>2</sup> /animal)
≤10	1.0	2.0	0.25	0.11
11–20	1.4	2.0	0.35	0.18
21–30	1.6	2.0	0.50	0.24
31–50	1.8	2.0	0.70	0.33
51–70	2.0	3.0	0.80	0.41

\* Miniature pig boars require half the space at the most

\*\* Thermoneutral conditions

taking serial samples. As a rule of thumb, adult miniature pigs require about half the space of adult farm pigs.

### Physical environment and hygiene

With their scanty hair covering and lack of sweat glands, pigs are sensitive to temperature extremes. A particularly efficient heating and ventilation system is required when they are kept on perforated floors. Optimum environmental temperatures for pigs vary with age. Newborns thrive best at temperatures of 30–32°C. The temperature may be lowered by 1°C for every day of the first week and by 1°C each week for the second, third and fourth weeks of age. Adult animals housed singly and without bedding feel comfortable at 20°C or more. With an insulated floor and abundant bedding, they will tolerate temperatures as low as 10°C without ill effect, especially in a group-housing system where they are able to huddle. In order to satisfy the special temperature needs of the young without exposing the mother to heat stress, farrowing pens should be provided with a heated creep area (Figure 32.3). In hot climates, the lack of shade and of wallows or sprinklers may lead to sunburn or heat stroke.

The favourite relative humidity for pigs is around 60–70%. It should not range beyond extremes of 50% or 90%. Ventilation is critical to keep the concentration of potentially harmful gases low, especially in densely stocked quarters. Concentrations of 10 ppm for ammonia, 0.15 vol% for carbon dioxide and 5 ppm for hydrogen sulphide should not be

exceeded. Air speed must not exceed 0.2–0.3 m/s for adult animals and 0.1 m/s for piglets.

Pens should be cleaned out frequently, and on concrete floors dry bedding is most desirable. The daily excretions of an adult farm pig amount to 0.5–3.0 kg faeces (water content 55–75%) and up to 6 l of urine. Once a month, pens should be emptied for thorough cleaning and disinfection. Floors, walls and caging utensils should be soaked and scrubbed or washed down with a high-velocity water jet and treated with a disinfectant. The animals should be returned to the pens once they are dry.

### Environmental provisions

Like their wild ancestors, domestic pigs and minipigs are sociable, lively and exploratory animals. They spend 70–80% of their time lying or sleeping; during the remaining time they like to romp, wallow and root in soil or bedding. When given the opportunity, pigs are clean, choosing specific sites for defecation and urination, and keeping their sleeping area dry. In modern pig farming, however, animals are commonly kept in less welfare-friendly conditions such as single stalls or crowded pens, on slatted floors with no bedding. Moreover these environments are often deficient in external stimuli and objects to keep them occupied. Tethering of sows used to be common but is now banned. Pigs, being curious and agile animals, will suffer from boredom if not given the opportunity to perform a range of activities (Wemelsfelder 2005). Common enrichment items include the provision of hanging chains or objects in the pens. Straw provides comfortable bedding, keeps the animals occupied with rooting and chewing activities, and serves as low-calorie fodder, providing a feeling of satiation without leading to obesity. Therefore, clean, dry straw may contribute substantially to the well-being of pigs. Unless experimental conditions require otherwise, the best way of accommodating pigs or minipigs is by housing them in groups of up to 10 or 15 in spacious pens with straw-covered floors. In a number of countries, rules and regulations are laid down to improve husbandry conditions for pigs (eg, European Council 1991; European Commission 1997; New Zealand National Animal Welfare Advisory Committee 2005; EFSA 2007).

### Social grouping

Socialisation within groups and the establishment of a social hierarchy are behavioural traits typical of free-ranging pigs. These behavioural patterns should be taken into account when housing pigs in pens. Isolated housing of individuals should be avoided, with the exception of adult males and farrowing sows. When animals are grouped, they should be of similar size and, if feed is restricted, trough space should be sufficient to permit all animals to feed at the same time. Ideally, partitions should be provided, enabling weaker animals to evade aggression from others. If group size exceeds 10–15, agonistic behaviour tends to be increased because no lasting hierarchy is established. This is not always the case, however, because in addition to the amount of space, the quality of space is also important (pen divisions, availability of substrates, feeding places etc). If possible,

stable groups should remain together. When animals are mixed from different pens, fighting can be minimised by grouping them just before feeding or sleeping time, preferably in an unfamiliar pen. The animals' individual scent may be camouflaged by sprinkling the animals with anything from cresol to eau-de-cologne. In critical cases, the injection of a tranquillising agent may be necessary.

Adult boars tend to live a solitary life when given the opportunity. Therefore, for them, individual housing is appropriate. Nonetheless, it is possible to group-house boars, with the exception of particularly aggressive individuals, provided they have been reared together or given the opportunity to get accustomed to each other under unconfined conditions, such as on pasture or in a yard. The level of aggressiveness in males is reduced to that of females if they are castrated at an early age (barrows).

### Presentation of food and water

Pigs are generally fed once or twice a day. Dry pelleted rations may be presented on the bare, clean concrete floor as long as there is a sufficient distance from the dunging area. More commonly, the feed is presented in a trough or bowl of non-corrosive material installed at or close to ground level. Trough space per animal should be 20–40 cm depending on body size. The feed may be dry or mixed with water or whey to make a gruel or soup. Self-feed hoppers for concentrates, sometimes equipped with a built-in spray nipple for moisturising the feed, are also common. When dry feed is not provided, troughs need to be cleaned daily. Stale feed may lead to digestive disorders. As adult pigs tend to put on excessive fat, transponder systems with computer-controlled feeding stations have been designed. One of these stations will serve 40–50 animals. A hayrack with freshly cut green fodder, hay or straw is valuable from a nutritional and behavioural point of view.

Clean drinking water should be available at all times, so automatic drinkers (nipple or bowl type) are recommended. Nipples should be installed at an adjustable height of 15–50 cm, depending on the size of the animals, preferably above the trough or, otherwise, in the pen area where the animals are expected to defecate and urinate. If automatic drinkers are not available, the usual practice is to mix water with the feed and refill the trough with water after the pigs have finished eating (see Feeding section). Farrowing pens should be equipped with an extra easy-to-operate automatic drinker for the piglets (Figure 32.3).

### Health monitoring, quarantine and barrier systems

Existing systems for disease control in pigs are generally aimed at improving the economy of farming operations. Specific pathogen free (SPF) or minimal disease (MD) animals may be infected with pathogens which, although of little economic relevance, could interfere with experiments by changing physiological responses through: immunosuppression, contamination of biological products, anaesthetic death, etc. Therefore, pigs bred for biomedical research

should ideally originate from a caesarean-derived colony, be kept in a protected environment (see Sources of supply) and have a regular health-monitoring programme; as is common practice in laboratory rodent colonies (Table 32.5). Staff should not have contact with other pigs, and all materials, including feed, bedding and equipment, needs to be sterilised (autoclaved, fumigated or otherwise). Embryo transfer is an important technique for introducing genetic material into a closed unit.

The Scandinavian Federation for Laboratory Animal Science (Scand-LAS) has published guidelines for health monitoring of pigs (Hem *et al.* 1994), and the Federation of European Laboratory Animal Science Associations (FELASA) has a working group on animal health establishing similar guidelines (Rehbinder *et al.* 1998).

### Transport

Transportation is stressful for pigs. To reduce physical strain the animals should be deprived of feed for at least 12 h beforehand. Hot, humid conditions should be avoided, as should extremely low temperatures and draught.

Large pigs are generally transported by truck or trailer. A space of 0.5 m<sup>2</sup>/100 kg body mass should be allowed. Floors must not be slippery and should be fitted with battens or covered with a deep layer of sand. Large loading surfaces should be subdivided by partitions. When driving or loading animals, it is important to understand that they are bewildered and anxious, rather than stubborn. Therefore, be patient, determined and firm, but never rough. Pigs are apprehensive of sloping surfaces, especially if these are unstable or slippery, and do not like entering dark or brightly lit areas.

Miniature pigs and young farm pigs may be transported in portable dog kennels or custom-made durable crates. The floor and bottom part of the sides must be closely boarded to avoid spillage of excreta. Ample straw or shavings must be provided to furnish soft bedding and absorb moisture. There should be openings for fresh air and sufficient space for all animals to lie down comfortably. Feed should be made available at least once, and water at least twice daily. Under certain conditions, the use of a tranquillising agent may be useful. Additional information may be obtained from the latest issue of Live Animals Regulations by the International Air Transport Association (IATA)<sup>2</sup>.

Microbiologically defined or SPF pigs or minipigs should preferably be transported in air-conditioned vans equipped with filtered ventilation to prevent infection.

Within the laboratory, animals may either be walked from one place to another, or transported in a trolley; the sides of which should be high enough to prevent the animals from jumping out, but not too high to make it impractical to lift them in and out. When driving pigs, a group always handles better than single individuals. Training the animals by rewarding them with tasty morsels will make operations easier and faster.

<sup>2</sup><http://www.iata.org>.

## Identification and sexing

Ear tattoos are the most common method of permanently identifying pigs. With pigmented breeds or those with small, cartilaginous ears, such as certain minipig breeds, it may be necessary to resort to notching or ear tagging (Figure 32.4). However, where possible the least invasive method of marking should always be used. Nowadays, electronic identification systems are available, consisting of transponders that are attached to the ear or injected into the tissue at the base of the ear. Recently, injectable microchips have been successfully implanted into unborn piglets (Birck *et al.* 2008). Stationary or portable readers can be used to read the transponders. For temporary marking, special colour markers or sprayers with water-soluble dye are available. Pigs with a light complexion may be given lasting body tattoos applied with a slap marker or an electric tattooing device.

Sexing of pigs presents no problem as they have clearly discernible sex organs from birth.

## Breeding

### Condition of adults

In contrast to their feral ancestors, reproductive activity in the domestic pig is not seasonal. Normally sows ovulate

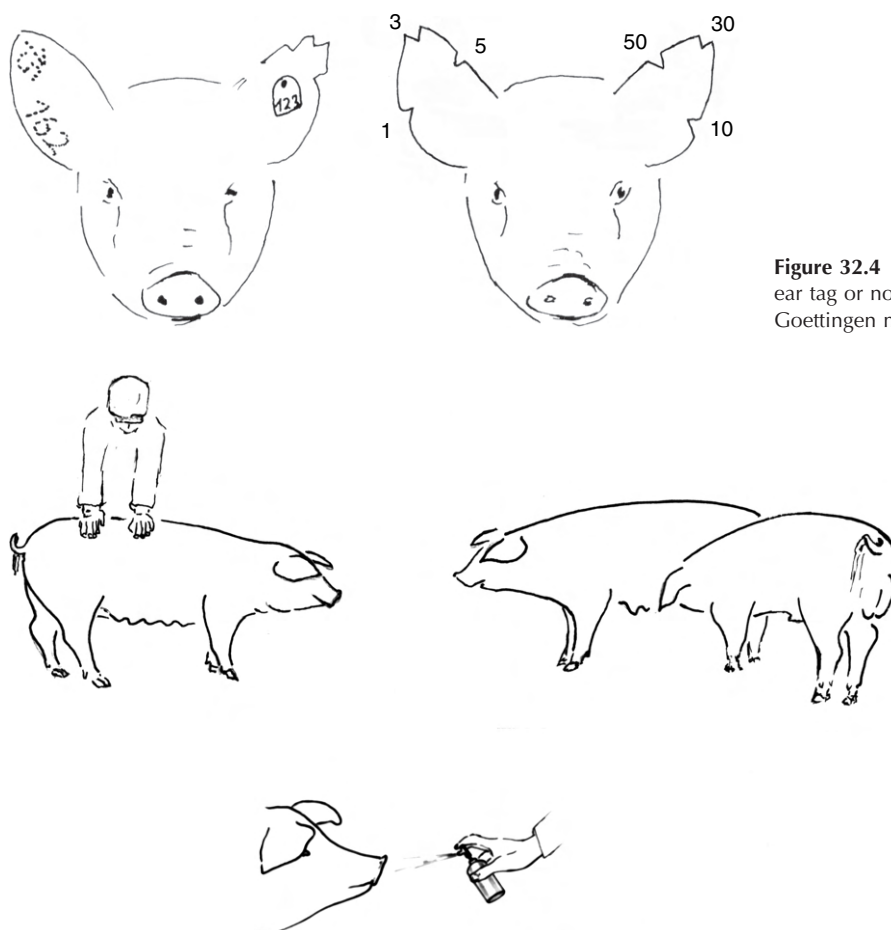

every 21 days. Males are always ready to mate. Ovulation is accompanied by characteristic oestrous symptoms climaxing in the standing reflex.

Heat checks should be performed at least once daily at a time when animals are not occupied by feeding or the like. Vulvar and behavioural signs are used for testing for oestrus. When there is no teaser boar available, tactile and olfactory stimuli can be imitated by applying manual pressure to the sow's back and by spraying synthetic boar taint (Figure 32.5). Standing heat lasts longer when the boar is present.

The optimal time to have a sow mated or inseminated is about 24h after the onset of standing oestrus if oestrus is detected with the aid of a boar and about 12h after the onset of oestrus in the absence of a boar. Additional matings at about 16h intervals should be allowed as long as sexual receptivity persists.

It is possible to avoid having to detect oestrus by controlling the oestrous cycle and conducting fixed-time insemination. In prepubertal gilts and freshly weaned sows this is done by injecting equine and human chorionic gonadotropins (eCG and hCG), in cycling females, by oral administration of the progestagenic compound altrenogest, followed by withdrawal and an eCG injection (Wallenhorst *et al.* 2000).

As previously mentioned, well managed pig herds achieve farrowing rates of 80–90%. The average gestation period in pigs and Goettingen miniature pigs is 114–115 days (see Reproduction).

**Figure 32.4** Pigs are commonly identified by ear tattoo, ear tag or notches in the ears (notching key used for Goettingen miniature pigs worldwide on the right).

**Figure 32.5** Oestrus detection in pigs with the aid of a teaser boar or by manual back pressure and commercially available boar taint.

Artificial insemination has become standard in modern pig farming, and can also be used with minipigs. Semen collection and insemination are easy to conduct, and, with experienced personnel, success rates are comparable with natural mating. Semen can be stored in a commercially available diluent at 15–18°C for 3–4 days. Conception rate and litter size after insemination with cryopreserved semen is usually unsatisfactory.

There are reasonable success rates for transfer of pre-implantatory embryos, usually flushed from superovulated donors around day 7 after conception (Bruessow *et al.* 2000). Existing techniques for cryopreservation of embryos are unsatisfactory and, at present, embryo transfer must be looked upon as a technique for special situations and experimental purposes.

The traditional method of pregnancy detection is to carefully observe the sows for oestrous signs around the 3rd and 6th week (one and two cycles) after insemination. In modern farming operations ultrasonic equipment is available: the A-mode pulse echo system produces reliable results between 28 and 85 days of pregnancy; the more elaborate and time-consuming Doppler system can be used to detect pregnancy as early as day 16; and real-time echography enables visualisation of foetuses by day 23 of pregnancy. The latter system requires specially trained operators. Rectal palpation, serum progesterone, urinary oestrogens or histological examination of vaginal biopsies are feasible alternatives, but are rarely applied.

Approximately 1 week before they are due to farrow, sows should be moved to the farrowing quarters where they are kept in farrowing crates (Figure 32.3). Under conventional (non-barrier) housing conditions, they should be wormed, scrubbed down with soap and water and treated with a parasiticide. The crates are equipped with rails controlling the movement of the sow to protect the piglets from being crushed and with a heat pad and/or creep area with overhead heat lamp to provide them with a suitable microclimate. If no heat source is available, ample straw bedding must be provided to enable the piglets to burrow into it, huddling together for warmth.

During the 2–3 days prior to farrowing, feed supply to the sow should be reduced to half. Components rich in crude fibre, such as bran, are increased, water is supplied *ad libitum* and sometimes 1 or 2 tablespoons of Epsom or Glauber's salt are added. These measures help to reduce the incidence of constipation and parturient infection of uterus and mammary glands, commonly termed metritis–mastitis–agalactia (MMA) or post-partum dysgalactia (PPD) syndrome.

About 1 day before parturition, sows will display nest-building behaviour when given the opportunity. They will carry grass and other nesting material in their mouth to a shallow pit and with snout and forelimbs arrange it in a cup-shaped nest of more than 2 m<sup>2</sup>. The young are born into the nest. Sows penned in a conventional farrowing crate will start getting restless, repeatedly change their posture, paw and root the floor, gnaw and tear on the confining rails or boards and defecate frequently. This behaviour may be interpreted as displacement nest-building behaviour, or as symptomatic of frustration.

Signs of approaching parturition are enlargement of the vulva and swelling of the mammary glands with the pres-

ence of colostrum, restlessness and nest-building behaviour. Eventually the sow lies down on her side and the piglets are delivered at intervals of 10–30 minutes, the fetal membrane being expelled between births or within 2–3 h after the birth of the last piglet. Although birth is usually trouble free, supervising parturition can minimise piglet losses. It may be necessary to free newborn pigs from the enveloping membranes, remove mucus from mouth and nose to help them start breathing, help weaker ones to reach the udder or the heated creep area, and rescue them from being crushed by overlying, trampling or savaging by the sow. With weak and underweight piglets, stomach tube feeding of colostrum substitute will improve survival. As a general rule, intervention should be limited to a minimum. Occasionally, savaging of piglets becomes a problem. In these cases piglets should be removed from the sow and placed back as soon as she has finished farrowing. If the sow does not quieten down, a small dose of tranquilliser will usually help.

If labour lasts for more than 45 minutes without visible progress, assistance should be given by inserting a clean, preferably gloved, and lubricated hand into the vagina, gently correcting the condition preventing delivery. In nulliparous gilts and minipigs where the vagina is too narrow, the use of gynaecological forceps is necessary. If inertia of the uterus is the problem, one or several injections of 1–2 IU oxytocin and infusion of 30–40 ml of a 50% calcium gluconate solution are indicated. Large doses of oxytocin tend to cause spasm and even rupture of the uterus. As a last resort a caesarean section should be performed without unnecessary delay, because more than 24 h after the onset of labour the piglets are usually dead.

Parturition may be induced prematurely to facilitate supervision and cross-fostering of piglets ('batch-farrowing'). Induction can be achieved by injecting prostaglandin F<sub>2α</sub> or one of its analogues. Normally, delivery commences 24–30 h after prostaglandin injection. Parturition should never be induced before 111–112 days after the last mating, otherwise premature piglets will be born that have reduced chances of survival. Individual variation in response to the prostaglandin treatment can be further reduced by following the prostaglandin injection, about 20 h later, with a long-acting oxytocin preparation.

### The young

Pigs produce precocial offspring born with all sense organs functioning. The newborn immediately start seeking the udder and generally achieve their first successful suckle within about 45 minutes. Baby pigs need antibody-containing colostrum within the first few hours. The energy reserves of newborn piglets are limited and they rely heavily on a warm, protected environment and frequent milk feeds. Young piglets suckle at less than 1 h intervals; later the frequency declines. Soon after birth, piglets fight fiercely until a teat order is established. The teat order arrived at about 4 days after parturition is adhered to until weaning.

When nursing, the sow lies down on her side calling her litter with a series of grunts. The piglets start nosing the udder vigorously until the milk let-down reflex is elicited. After 15–20 seconds, during which the sow gives a series of

low grunts in quick succession, the milk flow ceases. Young piglets fall asleep at the udder; as they grow older they move back to the creep area. Neonatal mortality averages 10–15%, 80% of which occurs within the first week. Most losses occur during the first 24h after birth, especially if the birth mass is low and litter size exceeds the number of functional teats. The primary causes of death are crushing by the mother (almost half of the losses), chilling and starvation.

Fostering piglets from one sow to another (eg, in the case of extranumerary piglets, agalactia or loss of a sow) is not a major problem and works best within the first 2 days after birth among sows that have farrowed within a day or so of each other. Unsuckled mammary glands dry up after about 3 days. When adjusting unequally sized litters, a measure facilitated by batch farrowing, the most vigorous members of a litter should be fostered, especially if the offspring of the host are older and stronger. When cross-fostering older piglets, it is important to camouflage their individual scent and mix the foster piglets with the original litter for 2–3h before presenting them to the new mother. The piglets to be fostered may be rubbed, particularly in the perineal region, with dung from the sow's own litter.

During the suckling period it is important to consider the following issues relating to health and well-being of sow and litter:

1. Parturient infection of uterus and mammary glands, often accompanied by agalactia, may pose a major problem in some herds. Therefore, it is advisable to monitor body temperature of the sow for the first 3 days after parturition, to immediately take action in terms of suitable antibiotic treatment and support of the piglets.
2. Newborn piglets can injure the sow's teats with their needle-sharp canines. This is commonly an indication of a deficiency in the amount of milk produced by the sow. The piglets' teeth may be blunted with the aid of an electric tooth grinder. Care should be taken not to expose the pulp and clippers are not recommended as their use may lead to pulp infection.
3. In commercial breeding units where the intestinal threadworm *Strongyloides ransomi* may occur, piglets have to be wormed within the first 3–4 days after birth.
4. Within 1 week after birth, piglets having no access to soil or another source of iron must be given an intramuscular injection or oral medication of an iron preparation because they are born with a very limited store of iron and the iron content of the sow's milk is low. After 2–3 weeks the treatment should be repeated.
5. Where males are neutered, this has to be done in the period between birth and 8 weeks. Within the first week bleeding and pain are thought to be less than in older animals. The testes are removed via two incisions in the ventral scrotum. The incisions should remain unsutured to facilitate drainage. Strict hygiene must be observed to prevent infection, especially since at age 3–6 weeks piglets have low antibody titre. Anaesthesia, as well as administration of a long-acting analgesic, is recommended.
6. For older animals, and where tail-biting is a problem, amputation of the caudal third of the tail within 3 days after birth may be necessary. The remaining part of the

tail is more sensitive to pain, so the animal will not tolerate others to gnaw on it. Once they sense blood, other piglets will mercilessly pursue the victim and may inflict potentially fatal injuries. Tail-biting commonly is a consequence of suboptimal husbandry conditions. Reducing light intensity may attenuate this behaviour. Keeping pigs in permanent darkness, however, is prohibited by law.

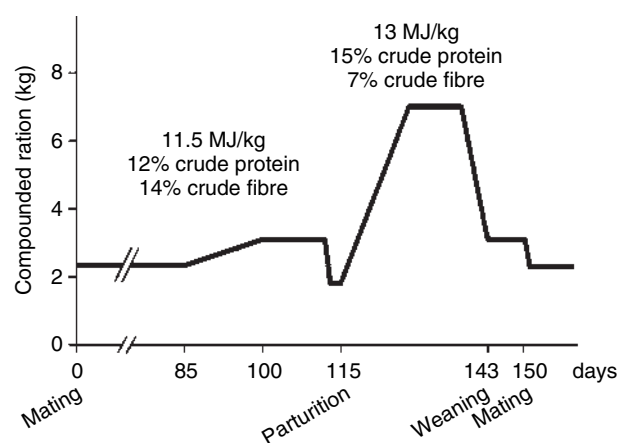

7. After parturition, the amount of feed provided to the sow must be gradually increased to reach *ad libitum* levels within 1 week (Table 32.7, Figure 32.6).

**Table 32.7** Basic nutrient requirements of farm pigs (NRC, 1998 and other sources) and miniature pigs (GV-SOLAS, 1999b) at various ages and reproductive states.

Category	Metabolisable energy (MJ/day)	Crude protein (%)	Maximum crude fibre (%)
Piglet			
3–5 kg	2–5	25	2
6–10 kg	6–8	22	6
11–20 kg	10–13	20	6
21–50 kg	18–24	18	6
51–120 kg	25–40	14	7
Pregnant sow			
<12 weeks	28	12	14
>12 weeks	35	16	7
Lactating sow (10 piglets @ 5 kg)	80*	16	7
Breeding boar	33	16	7
Adult maintenance	16–28**	12	14
Minipig (20–40 kg)			
Breeding	12–19	12–15	6–8
Maintenance	4–6	12	14

\* 17 MJ for maintenance of sow + 5.8 MJ per piglet

\*\*  $0.44 \times \text{BM}^{0.75}$

**Figure 32.6** Average daily amount of a complete compounded ration fed to a sow of 200 kg at various reproductive states (litter size: 10; suckling period: 4 weeks).

In conventional production units, piglets are usually weaned at about 4 weeks of age. At that stage they weigh 7–8 kg and are strong enough, and are able from an immunological point of view, to cope with the harsh environment of modern rearing units (eg, flat-deck cages). Moreover, by that time the reproductive tract of the sow has recovered to the extent that normal fertility has been regained. This system of early weaning was originally adopted to yield more piglets per sow and year. The younger the piglets are at weaning, the more vulnerable they are, consequently more attention must be given to environmental control. When post-weaning rearing conditions are suboptimal, piglets should be weaned at an age of 6–8 weeks. As long as the weaners are accustomed to creep feed, they will readily take to solid food and water. The average daily weight gain in pigs increases from 150 g after weaning to 700–800 g or more for body weights between 40 and 80 kg.

When a mother dies or suffers from agalactia, or if more young are born than there are functional teats, piglets have to be either fostered onto another sow or reared artificially. The latter is labour-intensive and time-consuming, and the following provisions must be made.

The accommodation must supply protection from draught; temperatures should be around 30°C at the beginning and may be gradually reduced to 20–22°C at 3 weeks of age; relative humidity should not exceed 60–70%. A suitable substitute for sows' milk has to be provided. This may consist of a commercially available substitute, cow colostrum, condensed cows' milk fortified with minerals and vitamins or slurry made up of 20% starter creep in water. Each feeding must be freshly and hygienically prepared and provided in portions small enough to be consumed at once. During the first few days the feed must be warm; after this, a gradual decline to room temperature is acceptable. For hand feeding, there should be four to six feeds of about 100 ml each, preferably offered in a shallow bowl. Today reliable automatic feeders are available that may be programmed or sensor-run.

If possible, piglets should obtain colostrum (sow or cow) during the first 6–12 h of their life to provide them with protection from infection. In the event of scouring, feed intake should be reduced drastically for at least 24 h, and fluid intake should be encouraged and a suitable therapy, if necessary, with antimicrobial agents (oral or parenteral), should be put into effect. Transfer to solid feed (initially milk-based, later cereal-based) should take place at 2–3 weeks of age (about 3 kg body mass).

### Breeding programmes

The selection of breeding stock has to comply with the breeding goal in question, and this may differ for farm and research pigs. Miniature pigs have been selected for low body mass (Koehn *et al.* 2008). The original breeding policy of the Goettingen miniature pig has been described in Glodek & Oldigs (1981) and Glodek *et al.* (1977). Special breeding programmes, such as selection for larger ear veins (to enable better access to the blood system) are used at Dalmoose, Denmark, where Goettingen miniature pigs are being bred. Attempts to select strains for hereditary diseases, such as diabetes mellitus, arteriosclerosis, cutaneous

melanoma and congenital ventricular septum defect, to generate genetic models of human disease, tend to fail because most defects have a multifactorial genetic background (Hand *et al.* 1987).

## Feeding

### Natural and laboratory diets

Wild and domesticated pigs are truly omnivorous, consuming and digesting anything from grass to highly concentrated food of plant or animal origin. Their ability to break down and utilise raw fibre, however, is limited. Although a large proportion of the nutrient requirements can be provided by good pasture, it is more common to keep domestic pigs indoors throughout the year and feed them on concentrates. These usually consist of ground cereals supplemented with protein (fish meal, soybean meal, milk by-products), essential amino acids (mostly L-lysine, D-methionine, L-threonine, L-tryptophan), vitamins (A, D<sub>2</sub>, D<sub>3</sub>, E, several B vitamins) and minerals. Standard diets may be obtained from commercial producers as meal or in pelleted form. They may be fed as complete rations, or in combination with several kinds of roughage or by-products such as brewers' grains or whey. If roughage is supplied, it may consist of grass, lucerne, clover, hay, silage or root and tuber crops.

Meal or pelleted feed may be offered dry or mixed with water or whey to make a mash. For young stock and animals kept on a maintenance diet, a single feed per day suffices; lactating animals should be fed more than once. Where computer-controlled feed dispensers are available, transponders, usually attached to the ear, make sure each individual receives the appropriate amount.

Laboratory diets for pigs and minipigs are based on natural ingredients, and are usually fixed-formula diets. They are available from specialised commercial producers as diets for growth or maintenance. Some producers offer expanded diets that have been heat-treated with steam. This process is claimed to give a better availability of nutrients, a low microbial count and good acceptability by the animals. Laboratory diets should be batch controlled for nutrient content and contaminants as variation in nutrients may produce unexpected experimental results. Contaminants such as heavy metals, fungal toxins or pesticides may also seriously impair the health status of animals and interact with drugs.

Before introduction into an SPF environment, diets may be sterilised by autoclaving or irradiation. In general, expanded diets have a low microbial count, and may be introduced into a barrier after decontamination of the feed containers.

### Water

Since most diets are offered in a dry form, clean drinking water must be constantly available, even though pigs drink mainly after eating. The average daily water demand of adult pigs varies between 10 l and 30 l (nursing sows). The individual demand is quite variable as for lactating sows between 10 and 78 l have been recorded. Under high tem-

perature conditions the demand may be substantially increased. Therefore, functioning automatic drinkers are the best solution. Usually, but not always, water from the public supply is of good quality. If necessary, water may be decontaminated with chlorine or ultraviolet light.

### Dietary requirements

Nutrient requirements for animals of different ages and reproductive status differ, especially with regard to protein, energy and crude fibre content. Under farming conditions, generally three types of rations are supplied: (1) creep feed for suckling and newly weaned piglets (at least 20% crude protein, not more than 7–8% crude fibre); (2) production rations for growing, late pregnant or nursing animals (16–18% crude protein, not more than 7–8% crude fibre); (3) maintenance rations for mature animals (12% crude protein, 14% crude fibre). The lipid content (ether extract) of most rations is in the range 3–3.5%. Changes from one type of ration to another should occur gradually. Dietary requirements for pigs are given in detail by the National Research Council (NRC 1998) and *DLG-Futterwerttabellen Schweine* (DLG 1991). Despite the fact that these are minimum requirements to prevent deficiencies, the National Research Council guidelines are based on maximum growth and, when keeping mature animals on a maintenance ration, may lead to obesity. Table 32.7 lists lower energy requirements for pigs of 21–120 kg. Since sows that are hungry tend to be restless and aggressive, it is advisable to feed rations with high crude fibre content or include good-quality hay or straw with the ration. Note that a high level of crude fibre will impair feed efficiency.

Figure 32.6 summarises a typical feeding strategy for sows fed exclusively on a commercially available complete compounded ration. As obesity predisposes to birth difficulties, postpartum metabolic disorders and low milk yield, the feed supply for dry sows has to be strictly limited. Only during the last third of pregnancy should the ration be gradually increased. By reducing the feed supply 2 or 3 days before expected parturition, commonly encountered problems with constipation and postpartum complications may be averted. After farrowing, the level of feeding is gradually stepped up at a rate of 400 g per day to the maximum amount of wholesome feed the sow will consume. As a rule of thumb, suckling sows should be provided with 1% of their body mass plus 0.5 kg per piglet of a concentrated ration each day. Three or four days before weaning, the feed supply is gradually cut back to pre-parturient level, and is further reduced as soon as the sow has been re-mated. After mating, the original system of restricted feeding is resumed.

This highly controlled feeding regimen necessitates individual feeding facilities; otherwise slow eaters and weaker animals will not get their share, while others grow fat. By monitoring the appetite and condition of the animals, individual requirements must be recognised and met by adjusting the amount of feed accordingly.

The growth rate of suckling piglets is such that, with large litters, after about 2 weeks the mother's milk will not satisfy their nutritional demand. Thus, piglets should have free access to palatable creep feed of high digestibility and protein, vitamin and mineral content from 1 week after par-

turition onward. After weaning, farm pigs are fed *ad libitum* until reaching a body mass of 80–90 kg. Thereafter feed intake has to be restricted; in the case of concentrates to about 80% of the unrestricted intake. More detailed information on the nutrition of domestic pigs is provided in standard texts (NRC 1998; Lewis & Southern 2000; Lindberg & Ogle 2001; Kirchgessner *et al.* 2008; Jeroch *et al.* 2008).

The nutritional requirements of miniature pigs closely resemble those of farm pigs. The daily energy requirement for maintenance is about 0.4 MJ/kg body weight<sup>0.75</sup>; during the growth phase it approaches 1.2 MJ/kg body weight<sup>0.75</sup>. A major problem in feeding adult miniature pigs is the avoidance of obesity, particularly in females not producing offspring. Restricted feeding imposes a perpetual feeling of hunger, with obvious animal welfare implications. Therefore, it is better to provide a voluminous, low energy density, maintenance ration with high fibre content (14% or more) with an adequate vitamin and mineral content. The ration should contain components such as bran, sugar beet pulp, green fodder, hay or straw. At Dalmoose, Denmark, Goettingen miniature pigs beyond 6 months of age receive their daily ration in just one feeding. This way they remain sedate throughout the day. The German Society for Laboratory Animal Science (GV-SOLAS 1999b) has published the dietary requirements for miniature pigs. Although the recommendations are based on empirical results, they will lead to satisfactory growth, good fertility and the avoidance of obesity.

## Laboratory procedures

### Handling and training

Pigs that are not used to being handled are shy and excitable. When anxious or confined they tend to panic. They scream, struggle and may even succumb to circulatory collapse. Force or subjugation will aggravate the situation, where patience, a handful of feed, a chip of apple or a lump of sugar will render a pig tame and co-operative. When handled gently and patiently, pigs become affectionate and usually relish a back scratch or stroking behind their ears or on their bellies. Vietnamese potbellied pigs are more reluctant to overcome their fear of humans. Adult boars should be approached with due respect as they can inflict serious injury with their tusks. But they, too, will grow tame and easy to handle, provided the person working with them always remains calm, though firm. To avoid injury it is advisable, under anaesthesia, to cut the tusks of adult males close to the gums with a wire saw. Sows rearing litters will sometimes be aggressive if they deem their young in danger.

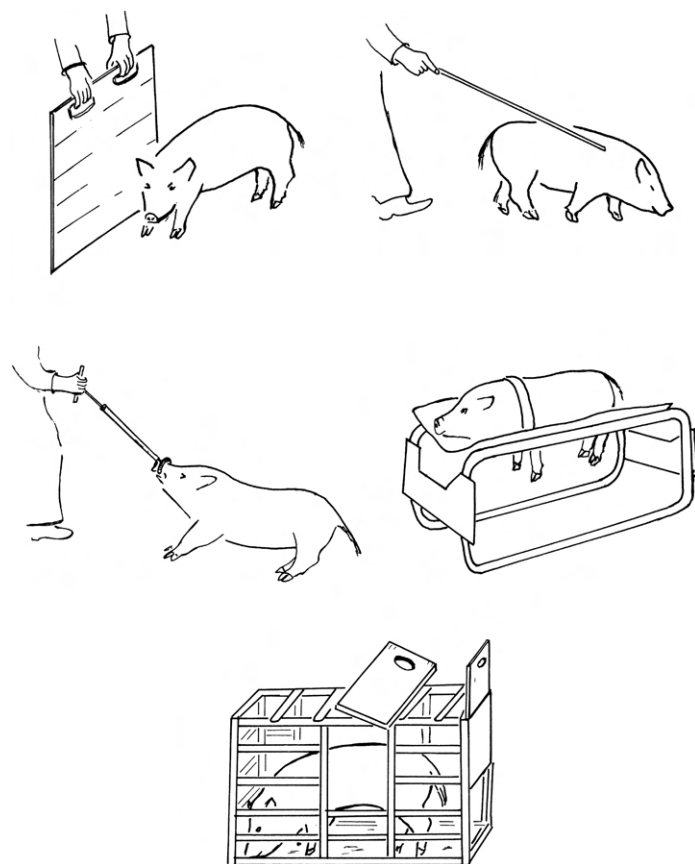

Up to 5 kg, piglets can be picked up by the hindlegs, but a better method, resulting in less stress, is to lift them on the arm, as with a small dog. Heavier animals up to 20 kg can be held tucked under the arm. For certain procedures, such as taking faecal samples or blood from the jugular vein, smaller animals may be held on the lap or placed legs up in a V-trough (Figure 32.7). Another method of immobilisation is to move them into a special restraint box or place them in a hammock-like sling with holes for the legs. Animals too

**Figure 32.7** Handling and restraining of light farm pigs or miniature pigs. Piglets may be picked up by the hindlegs but should only be held like that for short periods.

heavy to be held can be restrained using the agricultural practice of slipping a wire snare over their upper jaw and positioning it behind the canines. In this situation the reaction of the pig is to pull back (Figure 32.8). If this is executed skilfully, the floor is not slippery and the animal is able to rest its rear against a wall, then not much force needs to be exerted and the animals are not overly stressed. Whereas a wire snare has to be held continuously, a rope noose may be tied to a pole or fence. This means of restraint is commonly applied for brief manipulations on conscious animals such as administration of an injection or collection of blood or a faecal sample. Miniature pigs sometimes behave differently: jumping and turning around instead of pulling back. A more gentle approach would be to train the animal to walk into a large sling with some method of elevating it. The best alternative, though time consuming, is for the handler to establish a relationship with the animal that will enable him or her to train the pig to accept regular routine procedures such as injections or blood sampling, using appropriate positive reinforcement.

When moving individual pigs or groups of pigs, light boards or hurdles are useful. Single animals may also be driven by walking behind them, directing them with a cane or paddle (Figure 32.8). Pigs are quick to learn and easy to train. They will perform routine acts such as entering a restraint box or keeping to a certain order. Tasty rewards are a sure way to success, whereas the use of force or punishment is counterproductive.

**Figure 32.8** For moving pigs or miniature pigs about, light boards or a cane are useful. For immobilising them, an upper jaw snare, a sling with holes for the legs or a restraint box are expedient.

## Physiological monitoring

**Recording body temperature, cardiac and pulmonary functions**

Body temperature in pigs is measured by inserting a thermometer 5–6 cm deep into the rectum or vagina. The pulse may be taken by placing the palm of the hand (or a stethoscope) against the thoracic wall under the left elbow or on the inside of the thigh where the femoral artery is close to the skin. Alternatively an artery on the rostral rim of the ear or the coccygeal artery on the underside of the tail may be palpated (Figure 32.9). Careful auscultation of heart and lung has to be carried out with a stethoscope as described in Straw *et al.* (2006). Percussion is described in Jaksch and Glawischnik (1990). Blood pressure may be approximated by palpation of the pulse on the underside of the tail. A more accurate estimate may be obtained by applying the inflatable cuff method after Riva-Rocci in the coccygeal artery at the base of the tail. Direct measurement of arterial and venous pressures requires introduction of catheters or probes into blood vessels (Marshall *et al.* 1972; Neundorf & Seidel 1977). To obtain an electrocardiogram, the electrodes of the recording unit may be attached to the trunk of the animal to approximate an Einthoven's triangle with the heart in its centre (Neundorf & Seidel 1977), referred to as the Nehb-Spoerri method, or to the extremities (Hoeller 1959). The latter approach provides poorer wave amplitudes. The animals must be kept off the ground and should, therefore, be placed in a sling (Figure 32.8). A long-term electrocardiogram recording system for miniature pigs has been described by Suzuki *et al.* (1998) and a range of electrophysiological and other recording procedures may be found in Swindle (2007).

Procedural information on a range of electrophysiological, haemodynamic and other procedures can be found in Heinritzi *et al.* (2006) and Swindle (2007).

## Collection of specimens

**Blood**

General advice on blood collection can be found in Joint Working Group on Refinement (JWGR) (1993). In the pig there are not many easily accessible blood vessels. Depending on the quantity desired, several approaches may be taken. To obtain just a few drops or up to 1 ml of blood it is easiest to nick an ear vein with the tip of a scalpel blade. Up to 5 ml may be collected by puncturing the distended marginal ear vein with a hypodermic needle. The procedure resembles an intravenous injection. Larger volumes are drawn from the cranial vena cava, the brachiocephalic or the external jugular vein. The cranial vena cava extends from the heart to the cranial tip of the sternum, where it branches into the brachiocephalics, which branch again to form the external and internal jugular veins running toward the head on both sides of the trachea. To draw blood from the vena cava or the brachiocephalic veins of animals weighing up to 30 kg, the animals are held in a supine position, preferably in a V-trough, head and neck straightened out and front limbs drawn backwards (Figure 32.7). In farm and minipigs up to 25 kg, a 20 G hypodermic needle (0.9 × 40 mm), in adult miniature and farm pigs a larger cannula (1.5 × 100 and 1.5 × 150 mm, respectively) is inserted cranial to the sternum slightly lateral to the midline. While advancing the needle in a caudal-dorso-medial direction, a vacuum is maintained in the syringe so blood starts streaming in as soon as the vessel is punctured. The use of vacutainers or monovettes facilitates the operation. In minipigs the cannula should be inserted on the midline just cranial to the sternum, at an angle of 60°. To find the external jugular vein further up the neck, the jugular fossa may be used for orientation. In heavier animals, the same procedure is followed while they are standing up with the head pulled forward and slightly upward by an upper jaw snare (Figure 32.8). A way of col-

**Figure 32.9** Pulse rate may be monitored by placing the palm of the hand under the left elbow or by palpating auricular, femoral or coccygeal vessels.

lecting venous blood from the sinus ophthalmicus is described in Huhn *et al.* (1969) and Leucht *et al.* (1982) and from the tail vein by Muirhead (1981). Arterial blood may be collected from the brachiocephalic artery (Neundorf & Seidel 1977).

Excitement before or during the collection of blood can induce contraction of the spleen, resulting in an increase in packed cell volume of more than 10%. It is also likely to result in a neuro-endocrine response. Therefore, permanently indwelling catheters may be used for repeated blood collection. Adult domestic pigs, that have big enough ear veins, may be fitted with ear vein catheters. The animal is immobilised by an upper jaw snare and, after thorough cleaning of the ear, a tourniquet is placed around its base. A sharp, thin-walled 14G hypodermic needle is inserted into the marginal (*V. auricularis lateralis*) or central (*V. auricularis intermedia*) ear vein. After releasing the tourniquet, approximately 60cm of tubing (PE 100, 0.86 and 1.52mm internal and external diameters) is threaded through the needle which then is removed. Occasionally some resistance is met at the ear base. A small zippered purse, sutured to the ear with two stitches or a pocket of adhesive tape enveloping the ear, contains the curled-up free end of the stoppered catheter.

In young farm pigs and minipigs, with small ear veins, it is best to resort to jugular catheters. These may be fitted by non-surgical means as described by Carroll *et al.* (1999) for young pigs and Damm *et al.* (2000) for adult animals. For long-term catheterisation a surgical approach is preferable because the catheter may be secured by a retention cuff to prevent it from being pulled out. A thick-walled silicone catheter (1.0mm internal diameter, 2.4mm external diameter) with a retention cuff, 10–15mm in diameter consisting of 1mm thick extra firm grade silicone rubber sheeting attached with silicone adhesive 8–14cm from the tip, is fitted as follows. Under anaesthesia the external jugular is exposed caudal to the larynx via a small skin incision lateral to the *musculus sternomastoideus*, followed by blunt dissection. The vessel is liberated from surrounding tissue for a length of 3–4cm and the blood flow is blocked at both ends with the aid of suture material. A puncture hole is inflicted with a sharp lancet and spread with two loops of fine thumb forceps to permit insertion of the non-bevelled catheter which is filled with sterile physiological saline. The catheter is advanced 6–12cm (depending on the size of the animal) so the tip gets located close to the junction of cranial and caudal *vena cava*. Only on occasion a purse string suture is required to prevent haemorrhage. With the aid of a long stainless steel probe the free end of the catheter is routed to the back of the neck subcutaneously and brought out through a stab wound in the dorsal neck region. About 10cm protruding from the neck is left unrestrained and stoppered with a tight fitting plug. Before suturing the ventral incision, the wound is thoroughly rinsed with sterile saline containing a few drops of iodine, which helps to avoid local infection.

Catheterised animals have to be kept in a clean environment and the catheter exteriorisation site should be dressed with antibiotic powder or ointment on a daily basis. Between samplings, catheters must be filled with sterile saline containing an anticoagulant (100IU/ml heparin) and be tightly stoppered to prevent blood from entering and occluding it.

Daily replacement of the saline is advisable. Provided strict hygienic principles are followed, both ear vein and jugular catheters may remain functional for many weeks. Bilateral jugular catheterisation, even if resulting in complete occlusion of both veins, is well tolerated by the animals. Instead of the jugular, the cephalic vein may be used by making an incision halfway between shoulder joint and *manubrium sterni*.

Arterial catheters may be inserted in the carotid artery, which is easily localised dorsal to the jugular vein by digital palpation of the pulse.

Serial blood sampling in conscious pigs may also be accomplished by implanting a vascular access port (VAP) consisting of a reservoir with self-sealing rubber septum and a silicone catheter. The catheter is introduced into a vein and its free end is attached to the VAP reservoir located in a subcutaneous pocket made, for example, in the dorsolateral neck region. The port can be accessed through the skin with a needle for withdrawal or infusion. VAPs are easy to implant (Baille *et al.* 1986; Palmisano *et al.* 1989) and allow for group housing, which is not possible with animals with a protruding catheter.

Porcine erythrocytes are fragile and excessive turbulence and agitation during blood collecting and processing will bring about haemolysis. Coagulation of porcine blood is rapid, and to avoid clotting, the collecting vials must contain an anti-coagulant (Straw *et al.* 2006).

### Urine

The easiest way to obtain urine from a pig is to keep it in a metabolism cage, however this is a restricted environment for the pig. Collecting urine during spontaneous micturition is best done after making the animals get up from a resting position, as they will usually urinate soon afterwards. Collection directly from the urinary bladder may be carried out in the female by introducing a catheter of no more than 2mm external diameter into the urethral orifice with the aid of a vaginal speculum. In the male, the urethral approach is not feasible and urine specimens can only be obtained by turning the animal on its back and piercing the abdominal wall cranial to the pubic arch with a long cannula. For repeated collection a flexible catheter is introduced via an incision in the pubic area. This technique has been described by Marshall *et al.* (1972).

### Faeces

Specimens may be collected by introducing one or two gloved fingers into the rectum. The faecal sample is grasped with one hand, while the other hand pulls down the plastic glove, everts it and ties the top of the glove to a knot, thus sealing the sample. The use of positive reinforcement techniques might be an option in some studies. If large amounts of faeces are to be collected, animals must be placed in a metabolism cage.

### Milk

Milk may be stripped from the teat of a lactating sow. If the sows are trained they will readily present their udder for

manual massage and stripping. In some cases oxytocin has to be administered intravenously. For experimental purposes special milking machines have been designed. These are operated in conjunction with oxytocin treatment.

### Biopsies

Biopsies have been taken from the testes, skin and other organs, usually under full anaesthesia or after tranquillisation and local anaesthesia. Special equipment has been developed for the taking of back fat and muscle biopsies from pigs without anaesthesia causing neither distress nor pain (Lahucky *et al.* 1982).

### Other specimens

To obtain information on the collection of specimens not covered in this chapter, such as lymph, bile, bone marrow, stomach or intestinal contents, skin scrapings, biopsies or entire organs, the following sources may be consulted: Mount & Ingram (1971); Marshall *et al.* (1972); Neundorff & Seidel (1977); Glodek & Oldigs (1981); Leucht *et al.* (1982); Heinritzi *et al.* (2006); Swindle (2007). A system for continual perfusion or dialysis of internal organs in freely moving miniature pigs has been described by Jarry *et al.* (1990) and van Kleef (1996).

### Administration of substances

General advice on the administration of substances is provided in JWGR (2001).

### Tablets, pills and capsules

Administration of drugs often involves restraint of the animals. Tablets, pills or capsules may be deposited deep in the buccal cavity with the aid of a balling gun. When offered concealed in a morsel of tasty feed, they may be taken voluntarily. In order to circumvent hepatic passage, rectal suppositories may be inserted.

### Liquids

Small amounts of liquids may be squirted into the back of the mouth with the aid of a syringe. For large amounts, animals have to be restrained and a mouth gag made of wood or non-toxic hard plastic, with a hole in the centre, is wedged between the jaws. A lubricated stomach tube (0.8–1.7 cm outside diameter) with rounded tip is introduced through the hole into the oesophagus. It will meet elastic resistance, especially when passing the cardiac notch. The pig will vocalise strongly. A smell of acid is indicative of arrival in the gastric lumen. If the tube does not meet resistance, the animal does not scream and breathing is detected, it will have been inserted into the trachea.

In young piglets the tip of a syringe may be introduced into a nostril and pressed firmly against it. If fluid is gradually introduced, it will be swallowed.

### Injections

The most common routes of injection (Fig. 32.10) are:

- Intradermal (id, intracutaneous). These injections usually involve very small volumes (2–4 µl) and are administered to the corium layer of the skin on the ear or the back of the animal with a fine (0.6 mm) hypodermic needle.
- Subcutaneous (sc). In animals up to 25 kg such injections are most conveniently administered by lifting them up by the hindlegs, gripping the skin fold between flank and hind leg and introducing the needle (0.9 mm) between the two layers of skin. In animals too heavy to be picked up the needle is introduced caudal to the base of the ear in a perpendicular direction. Dziuk (1991) reports that '*with a little patience and some dexterity*' it is possible, even in unrestrained pigs, to place an injection under the thin, loose and relatively insensitive skin area of the chest just behind the elbow.
- Intramuscular (im). Usually, these injections are administered by inserting the needle (0.9 mm) 1 or 2 cm caudal to the base of the ear in a ventromedial direction. Alternatively, the musculature of the dorsal neck or the thigh may be used. The volume administered should be small, though large enough that there is not a risk of depositing the drug in a fat layer where absorption is poor. Peak blood and tissue levels for most drugs will be reached within about 2 h.
- Intraperitoneal (ip). Usually intraperitoneal (abdominal) injections are applied to animals light enough to be picked up. When held head-down by the hindlegs, an injection caudal to the navel will not cause injury to inner organs. Distribution of the drug throughout the body is faster than with im injections.
- Intravenous (iv) These injections are usually given into an ear vein. For that purpose, the head of the animal has to be fixed, usually with the aid of an upper jaw snare, and the veins are raised by rubbing or slapping the ear and tying a string or rubber band around its base. After the needle (0.7–0.9 mm) has been inserted, the tourniquet is released and infusion can commence. Most minipigs have small, sometimes pigmented ears, with the consequence that the veins can only be identified with the aid of a torch. Other reasonably accessible superficial vessels are the cephalic vein near the forearm, and the femoral and caudal epigastric veins on the inside of the hindlimb. In conscious animals, however, it is very difficult to introduce a needle into these; therefore most people prefer to use the jugular or the cranial vena cava. The procedure resembles that of blood collection (Figure 32.10).

Injection volumes considered to be good practice and maximum acceptable doses are summarised in Table 32.8. The figures refer to aqueous solutions, not to solvents such as dimethyl sulfoxide (DMSO), carboxymethylcellulose (CMC) or oily suspensions. If the administration of larger volumes is unavoidable, multiple injection sites may be indicated. It should be kept in mind that injections might cause pain and tissue damage and should, where possible, be replaced by other routes of administra-

**Figure 32.10** Typical injection sites: intramuscular (top), intravenous (middle), intraperitoneal (bottom left) and subcutaneous (top left and bottom right).

**Table 32.8** Good practice dose volumes for injecting miniature pigs of 25–40 kg body mass (GV-SOLAS, 1999a; Dorsch, 1999). For lighter pigs smaller volumes are recommended; however, for heavier pigs approximately similar volumes are appropriate.

Dose volumes	ml/injection site			ml/kg body weight		
	id	sc	im	ip		iv
				Bolus	Slow injection	
Recommended	0.2	10	5	1	1	2
Maximum	0.4	20	10	20	2	5

tion. In the case of antibiotics administration *per os* is usually possible.

For continuous drug administration, permanently indwelling catheters or ambulatory infusion pumps positioned, for example, in a pocket of a specially tailored vest, might be employed. An alternative approach is to implant an osmotic pump.

## Anaesthesia and analgesia

### Sedation

Pigs that are to be anaesthetised should be deprived of feed, but not water, for at least 12 h. To minimise stress, it is advis-

able to sedate them by administering an intramuscular injection of a tranquillising agent in familiar surroundings. The needle can be prevented from being pulled out, if the animal moves, if the hypodermic needle and syringe are connected with flexible tubing. The most commonly applied tranquillising drug is azaperone (1–4 mg/kg) sometimes combined with midazolam (0.5–1 mg/kg) or ketamine (5–20 mg/kg). Azaperone has a wide tolerance range and few side effects and produces sedation, indifference and drowsiness, but not analgesia. Atropine (0.05 mg/kg im or sc, 0.02 mg/kg iv) should generally be included as it cuts down on profuse salivation and bronchial secretion and stabilises the heart action. Animals should be left alone for 5–15 minutes, preferably in dark surroundings, for the sedative to take full action. The animals will remain sensitive to acoustic stimuli and body temperature will drop.

### Surgical anaesthesia

No anaesthetic satisfies all possible requirements (ie, sedation, hypnosis, analgesia and muscular relaxation). Therefore, depending on the type and duration of the surgical intervention intended, combinations of various agents may be indicated. Minor surgery may be performed by combining sedation with local anaesthesia using, for example, procaine or lidocaine. For longer interventions it is recommended to place an indwelling catheter in the lateral ear vein for intravenous injection and intubation of the animal.

### Injectable anaesthesia

Ketamine is commonly used as a replacement for metomidate, which is no longer available. As ketamine tends to increase muscle tone and exerts little visceral analgesia, it is usually combined with other agents such as azaperone, droperidol, acepromazine, diazepam, midazolam, fentanyl, telazol or xylazine. According to Green and Benson (2002) the group of tranquillisers that is most effective in pigs is the butyrophenone class. Azaperone is a member of this group that is specifically approved for use in pigs by the Center for Veterinary Medicine (CVM) of the Food and Drug Administration (FDA). Phenothiazine tranquillisers are less effective but are also commonly used when butyrophenone tranquillisers are not available. Alpha-2-agonist sedatives are useful, especially in combination with other agents, but relatively high doses must be used (eg, 2.2 mg/kg xylazine). Various laboratories have established protocols of their own depending on the purpose of study. A protocol found to be effective, safe and both clinically and economically sound (Erhardt *et al.* 2004) consists of an intramuscular injection of a mixture of azaperone (2 mg/kg), ketamine (15 mg/kg) and atropine (0.02 mg/kg) followed, 10 minutes later, by an intravenous injection of either the barbiturate thiamylal (5–15 mg/kg) or propofol (4 mg/kg). Propofol is metabolised rapidly, whereas thiamylal, as it is redistributed in the body, will remain present somewhat longer. For extension of anaesthesia, additional amounts of barbiturate or propofol may be infused and an analgesic has to be administered. The amount required may vary considerably.

### Inhalation anaesthesia

Anaesthesia may be accomplished with the aid of an inhalation drug, but surgical interventions should not be carried

out under inhalation anaesthesia alone. An analgesic such as metamizole or fentanyl should be used in combination. For inhalation anaesthesia halothane or another flurane (sevoflurane, isoflurane) is recommended. Sedated animals rapidly pass into deep anaesthesia without excitation if they inhale 4% halothane in oxygen at a flow rate of 6–8 l/min via a face mask or via an endotracheal tube. Once surgical anaesthesia has been reached, the halothane concentration may be reduced to 1.5 or 2%. In a closed circuit, requiring a tracheal cannula or nose tubes (Bolin *et al.* 1992), surgical anaesthesia will be maintained at concentrations as low as 0.5–1.5%. A further reduction in halothane concentration to 0.4–1.0% may be accomplished by replacing pure oxygen with a mixture of one-half to two-thirds nitrous oxide (laughing gas). An asset of halothane is the quick recovery of the animals and the lack of adverse after effects, even after several hours of anaesthesia. Other fluranes are more expensive than halothane but, according to Smith *et al.* (1997), safer for the personnel. With some susceptible breeds (Pietrain, Poland China and their crossbred offspring) the use of fluranes is not advised as they can induce malignant hyperthermia syndrome; this is characterised by a rapid increase in body temperature, hyperventilation, muscle rigidity and sudden death. The heritable condition is transmitted by a single dominant gene and it is associated with general susceptibility to stress. Breeding programmes are conducted aimed at eliminating the trait from the population. In miniature pigs the condition is unknown.

Finding face masks for pigs that fit snugly and have little dead space is a problem. Shape and size of the pigs' heads varies depending on breed and age. Sometimes commercially available dog masks, consisting of a plexiglas dome fitted with a rubber diaphragm with a central opening for the snout, may be suitable. Improvised masks can also be used, for example, a deflated punch ball, with the bottom cut off, which can be drawn over the pig's snout with the gas supply provided via the blow-tube. Small-animal endotracheal tubes of 5–12 mm outer diameter may be used for nose tubes. They are lubricated and inserted about 4–5 cm into the nares. A broad rubber band tied around the upper jaw just behind the tip of the snout secures the tube in position (Bolin *et al.* 1992).

Endotracheal intubation requires experience. Pigs need to be sedated and anaesthetised (usually via a mask) and treated with atropine. They are placed in lateral or ventral recumbency, the neck is extended and the jaws are opened as wide as possible so the larynx can be seen with the aid of a laryngoscope. The tongue is pulled forward and a long spatula, the first 5–15 cm of which is slightly bent, is inserted between the vocal cords to serve as a guide for the endotracheal tube. The tube should ideally be lubricated with gel containing a local anaesthetic. It must be carefully inserted into the trachea during an inspiratory movement, and is held in position by an inflatable cuff. The tube may be fixed to the upper jaw with adhesive tape or a gauze bandage. Depending on the body weight, the outer diameter of the tube should be between 9 and 12 mm. For miniature pigs, normal oral paediatric endotracheal tubes of 6–8 mm outer diameter without a cuff proved to be suitable. According to Becker & Stauffer (1974) these can be introduced without the

use of a spatula. Detailed descriptions of the procedure may be found in Svendsen & Rasmussen (1998); Erhardt *et al.* (2004) and Swindle (2007).

As an alternative to endotracheal intubation a laryngeal mask airway (LMA), designed for use in humans, may be inserted into the hypopharynx of a pig. Once inflated, it will provide an airtight seal around the laryngeal inlet and proved to be efficient in both spontaneously breathing (Wemyss-Holden *et al.* 1999) and mechanically ventilated pigs (Goldmann *et al.* 2005). The system proved to be convenient and efficient even when applied by relatively inexperienced personnel.

#### *Epidural anaesthesia*

If surgery is to be performed caudal to the umbilicus, epidural anaesthesia may be applied. Animals are tranquillised and procaine or lidocaine is infused into the spinal canal by inserting a long 20–22 G hypodermic needle through the lumbosacral aperture as described by Neundorf & Seidel (1977), Bolin *et al.* (1992), Heinritzi *et al.* (2006) and Swindle (2007).

#### **Peri- and post-operative care**

Most precautions taken to maintain anaesthetised animals in a state of near homeostasis are the same for most mammals. Pigs, lacking a dense hair coat, are particularly prone to hypothermia. To aid in body heat retention it helps to drape them and/or place them on a heating pad both during anaesthesia and the recovery phase. Recuperating pigs should at least be bedded on a thick straw mattress and covered with an armful or two of clean dry straw. During extended interventions additional care might be warranted, including administration of parenteral fluids for maintenance of water and electrolyte balance, analgesics and other drugs. Depending on the situation it may be indicated to monitor respiration, heart rate, body temperature, blood pressure, blood gases or EEC. Appropriate ways of accomplishing this are to be found in Swindle (2007).

Intra- and post-operative analgesia may be provided by using non-steroidal anti-inflammatory drugs (NSAIDs) such as carprofen or meloxicam, metamizole and/or an opiate like fentanyl, remifentanyl or buprenorphine (Preissel, personal communication). The effect of analgesics lasts between a few hours and a whole day depending on the substance used (e.g. the NSAIDs carprofen or flunixin provide analgesia for 24 h whereas the pyrazole derivative, metamizole, needs to be administered every 6 h). The combination of an anti-inflammatory NSAID and the spasmolytic agent metamizole appears suitable (Steffen *et al.* 2002). Carprofen has the advantage that it can be administered as a tasty chewable tablet instead of having to be injected. The use of opiates for bolus administration or continuous infusion during surgery requires intubation because of the opiate's respiratory depressive action. For post-operative analgesia buprenorphine is to be administered at 8–12 h intervals. The use of a fentanyl (an opiate) patch, attached to the shaven skin behind the ear, has been found to be useful (Malavasi *et al.* 2005; Stubhan *et al.* 2008).

## Emergencies

The mild respiratory depression caused by barbiturates is easily controlled. If respiration fails, animals that are intubated must be connected to a respirator. It may be necessary to intubate them at this point. Usually it suffices, however, to place them in lateral recumbency, and compress the thorax rhythmically with both hands 10–20 times per minute. Oxygen may be offered, if available. As long as the heart is beating, artificial respiration should be maintained, as the animal has a good chance of recovery. Artificial respiration should be interrupted, from time to time, to reactivate the respiratory centre. In severe cases, especially when working with barbiturates, an intravenous application of a heart stabilising agent, such as lidocaine or, as a last resort, adrenalin may be indicated.

Detailed treatises covering anaesthesia in the pig are to be found in Riebold (1995); Thurmon & Benson (1996); Svendsen & Rasmussen (1998); Erhardt *et al.* (2004) and Swindle (2007). See also Flecknell (2009).

## Euthanasia

Euthanasia should be accomplished by methods that induce rapid unconsciousness and death of the animal without pain or distress (see Chapter 17). Generally, inhalant or non-inhalant chemical agents (such as barbiturates, inhalant anaesthetics and carbon dioxide) are preferable to physical methods such as a penetrating captive bolt. However, there might be reasons against using chemical agents. Pigs destined for consumption and slaughter are killed by stunning them with electric current, captive bolts or carbon dioxide, and then bleeding them to death by stabbing with a long knife cranial to the sternum to sever the great blood vessels at the base of the heart. In exceptional cases a free bullet may be used instead of a captive bolt. Very young animals may be killed with a strong blow on the head, but generally an overdose of anaesthetic is preferable. Pigs that are not to be consumed may be killed by intravenous or intraperitoneal injection of a large overdose of an anaesthetic or toxic substance (eg, more than 150 mg/kg pentobarbital). In anaesthetised animals, intravenous infusion of 2 mmol/kg potassium chloride or terminal exsanguination are acceptable.

## Common welfare problems

### Disease

#### Prophylaxis

Pathogenic microbes travel with airborne particles or droplets, but more commonly they are transmitted via animal vectors. The most important of these are infected pigs. Other vectors include domestic animals such as cats and dogs, vermin, such as rats and mice, birds, insects and, most frequently, humans. Therefore, good barrier systems should ideally be employed. Principles and procedures of such systems are described in the section on health monitoring, quarantine and barrier systems. When the establishment of a barrier system is not feasible, precautions must be taken

to minimise the risk of infectious disease. A few basic principles to be considered are the provision of appropriate housing, husbandry and feeding conditions, a good sanitation programme and, as far as possible, prevention of the introduction of infectious agents.

Before moving animals into quarters formerly occupied by others, the rooms must be thoroughly cleaned and scrubbed with antiseptic solution, preferably with a high pressure jet and hot water or steam. Complete units should be evacuated, cleaned and restocked (all-in, all-out). Animals should be treated for internal and external parasites before being introduced to sanitised housing especially when they had been run on pastures or dirt lots. Animal traffic and visits by people who have been in contact with other pigs within the last 48 h should not be permitted. Foot dips and changing of clothes should be mandatory. Health control specialists advocate a shower to be taken before entering a unit. The origin and quality of biological material (feed, bedding, experimental materials) and equipment should be controlled to prevent the introduction of infectious agents. A rodent and insect barrier should be part of the disease-control programme.

Depending on the source of the pigs and the diseases prevalent in the area, vaccination protocols have to be established. It should be kept in mind that vaccination will protect against disease, but will not usually prevent the transmission of pathogens. Furthermore, vaccinated pigs will be seropositive, which may interfere with health monitoring. Prophylactic antibiotic treatment may control bacterial propagation and enable the host to develop immunity, but will not eliminate the pathogen. Animals to be introduced into the herd should originate from suppliers providing a high standard of hygiene (preferably with SPF or MD status) and a defined disease-control system. It is good practice to quarantine new arrivals for at least 3, preferably 6, weeks before integrating them into the herd. The first 3 weeks are a period of isolation, the animals being monitored, wormed, vaccinated etc; during the following 3 weeks animals from the herd they are to be integrated in are introduced so they may adapt immunologically.

#### Signs of poor health

General symptoms indicating poor health in adult pigs are emaciation; listlessness and lack of appetite; increased body temperature; discoloration (cyanosis) of skin areas; stiffness of limbs; diarrhoea; snuffling and coughing; in certain conditions hyperactivity, excitability, frequent change of posture and convulsions. Typical symptoms of diseased young piglets are: wasting; listlessness; rough coat; abnormal posture and behaviour; diarrhoea; sneezing, coughing and laboured breathing ('pumping'); swollen joints; increased body temperature and skin conditions.

In addition, there will generally be specific symptoms indicative of the particular ailment involved.

#### Common diseases

In commercial pig husbandry usually large numbers of animals are kept under confined conditions, facilitating rapid spreading of infectious diseases.

The most important viral diseases affecting pigs are foot and mouth disease, hog cholera (swine fever), porcine influenza, porcine rotavirus, porcine parvovirus, porcine reproductive and respiratory syndrome (PRRS), transmissible gastroenteritis (TGE)/porcine endemic diarrhoea, pseudorabies (Aujeszky's disease) and circovirus. As some are brought under control (eg, pseudorabies) new ones are cropping up (eg, circovirus).

Bacterial and fungal infections may cause enteric (*Escherichia coli*, *Isospora suis*, *Clostridium perfringens*, *Brachyspira hyodysenteriae*, *Salmonella* spp., *Campylobacter* spp., *Yersinia enterocolitica*), or respiratory diseases (*Mycoplasma hyopneumoniae*, *Pasteurella* spp., *Actinobacillus pleuropneumoniae*, *Streptococcus pneumoniae*, *Bordetella bronchiseptica*) or diseases affecting the skin (*Microsporium* spp., *Trichophyton* spp.), renal system (*Actinobaculum suis*) or a range of other organ systems (*Haemophilus parasuis*, *Erysipelothrix rhusiopathiae*, *Staphylococcus hyicus* and *aureus*, *Streptococcus suis*).

Endoparasites that might give reason for concern even under well managed indoor husbandry conditions are the nematodes *Ascaris suum*, *Strongyloides ransomi* and *Trichuris suis* as well as the protozoan parasites *Isospora suis*, *Eimeria* spp. and – where cats are permitted – *Toxoplasma gondii*, a zoonosis.

Useful handbooks covering diseases in pigs are Taylor (1999), Prange (2004), Waldmann & Wendt (2004), Heinritz *et al.* (2006) and Straw *et al.* (2006).

## Abnormal behaviour

Prevailing husbandry conditions for many farmed pigs are notoriously deficient in providing a complex enriched environment (see Environmental provisions) and high-quality individual attention (see Handling). Under farming conditions breeding stock is usually slightly better off than fattening animals, though, with increasing herd size and growing economic pressures, even these are increasingly reduced to anonymous production units. Unfortunately more acceptable production systems have usually turned out to be less economically viable.

These unfavourable conditions facilitate behavioural aberrations, the most commonly observed of which being:

1. Bar biting. The animals take horizontal bars in their mouth and either bite on it with a chewing motion or just hold it in their mouth for extended periods. This behaviour is commonly observed in sows kept in single crates on concrete floors without litter, and is an expression of boredom and frustration.
2. Vacuum chewing. Animals chew with an empty mouth, froth dripping from the lips and the corners of the mouth. Sometimes the chewing motion is interrupted by gaping. As in the case of bar biting, this behaviour is associated with isolation and boredom.
3. Dog-sitting (German: trauern). Animals spend extended periods in a dog-sitting posture with a sad and distracted look on their faces. This behaviour is usually associated with stimulus-poor situations under conditions of single housing and cold floors.

4. Cannibalism. This usually begins with a non-injurious sucking and nibbling of the ears, legs and, most commonly, the tail of another animal. Typically the tail is taken into the mouth crosswise and bitten playfully; first gently, then harder until blood is drawn. Now all other animals join in and the injured animal becomes the object of a hunt. Once the tail is bitten off, the ears and other parts of the body are mutilated. Eventually the victim becomes apathetic and will usually succumb to bacterial infection. Another variation on the theme is the continued forceful massage of the anal region with the snout. This, too, may lead to injury, inflammation and eventually death.
5. Piglet savaging. This abnormality is usually limited to sows giving birth for the first time. Sometimes the newborn are killed immediately after birth. This might be related to pain and anxiety associated with parturition. Occasionally a sow savages her young after initially accepting them. In some cases this occurs following severe disturbance and turmoil. The occasional consumption of dead piglets by the mother is not directly associated with killing.

With the possible exception of piglet savaging, all the abnormal behaviours mentioned are related to environmental deficiencies such as lack of space, exercise and distraction (see section on environmental provisions), unsuitable floor construction, microclimate or ventilation, insufficient access to feed and water, no means of social interaction, large group size, high stocking density and lack of ability to evade aggressive pen members.

## Reproductive problems

Reproductive problems are not common in pigs and minipigs. If they occur, it is usually due to shortcomings in housing, feeding, health status or management. Pigs may produce more than two litters per year and have been selected for centuries to have a high rate of reproduction. Oestrus detection may pose a problem when applying artificial insemination, especially in the absence of a teaser boar. Newly mated sows are sensitive to environmental changes around the time of implantation. During that time shipping or changes in diet should be avoided, otherwise embryo survival is impaired and sows will return to oestrus. In some herds, puerperal infection is an issue and may assume epidemic dimensions. The so-called MMA syndrome is a combination of metritis, mastitis and, as a sequel of the latter, agalactia. Rigorous hygiene programmes and antibiotic therapy may help to alleviate the problem. Abortion and stillbirths may occur and are usually caused by infections such as parvovirus.

## Further reading

Further information of relevance for pig experimenters are to be found in specialised texts covering the fields of porcine anatomy (Sack 1982), physiology (Pond & Mersmann 2001; McGlone & Pond 2002), nutrition (Kyriazakis & Whittemore

2006), husbandry and breeding (Glodek 1992; EFSA 2007), behaviour and welfare (Report of the Scientific Veterinary Committee 1997; Kaliste, 2004; Broom & Fraser 2007) and experimentation (Stanton & Mersman 1986; Tumbleson 1986; Tumbleson & Schook 1996; Bollen *et al.* 2000; Swindle 2007). Texts focusing specifically on miniature pigs are Glodek and Oldigs (1981), Leucht *et al.* (1982) and Fisher (1993). In addition, attention should be given to websites such as those offered by breeders on handling of miniature pigs, anaesthesia and surgical techniques and to the RETHINK project on the use of minipigs in toxicity testing<sup>3</sup>.

# 33 Cattle

Roger Ewbank

## Introduction

Although there are many papers, books and reports on the husbandry, management and agricultural use of cattle, there has been relatively little published on their care and use in biomedical research. Publications that do exist include: a series of chapters in the various editions since 1967 of this volume; Doyle *et al.* (1968) produced a review article on the use of domestic farm animals in medical research; the guidelines published by the US National Academy of Sciences (1974); the 1st edition of The Canadian Council on Animal Care *Guide to the Care and Use of Experimental Animals* contained a short section on the specific environmental needs of cattle (Canadian Council on Animal Care 1980)<sup>1</sup>; a chapter by Brooks *et al.* (1984) on ungulates as laboratory animals; in 1988 a USA Consortium of universities, land grant colleges and concerned professional organisations (now the Federation of Animal Science Societies) produced the first edition of their full and detailed *Guide for the Care and Use of Agricultural Animals in Agricultural Research and Teaching* (Consortium 1988); recommended pen sizes for the accommodation of cattle are provided by the Home Office (1989) and Institute of Laboratory Animal Resources (1996); Swanson (1998) discussed the place of farm animals in biomedical research and (Barnett 2007) provided a relatively short but up-to-date care and husbandry chapter.

The proceedings of two conferences on the general theme of farm animals and their use in the biomedical and agricultural sciences have been issued (Mench *et al.* 1992; Baker *et al.* 1996); and a substantial book on cattle welfare has recently been published (Rushen *et al.* 2008).

Much of the material contained in these proceedings, articles and books is relevant to the humane, efficient and wise employment of cattle as experimental animals.

## Biological overview

### General biology

Most breeds of cattle are large and horned, although a few small and/or naturally polled breeds do occur. Cattle are,

even-toed, hoofed, ruminant mammals (ungulates) possessing a four-chambered stomach, and with upper incisor teeth replaced by a thickened layer of the hard palate, the dental pad. They belong to the genus *Bos* within the family Bovidae (suborder Ruminantia, order Artiodactyla). They were domesticated some 8000–10000 years ago, and they are now used for the production of milk and meat and, in certain areas, for draught purposes. Their current world population is put at some 1370 million (Food and Agricultural Organization 2004).

The care and management of domesticated cattle should present few problems. Due to their extensive commercial use, farmers, agriculturalists and stockmen are well versed in the practicalities of their care. Veterinarians are familiar with their diseases and know how to treat and/or prevent them, while nutritionists understand their dietary requirements. Buildings, fittings, equipment, feed etc are commercially available and realistically priced.

### Social organisation

Cattle are a group-living species. Farmers tend to limit the number of males which are allowed to grow to sexual maturity, and the traditional domesticated cattle breeding herd is (or was) a group of females with one attendant bull. Due to the ease and efficiency of artificial insemination in bovines, commercial dairy cattle groups are sometimes totally female. The behavioural organisation of cattle groups is based on a number of co-existing social hierarchies of which the dominance hierarchy (bunt order) seems the most important. Large (older) animals tend to occupy the top places in the hierarchies while smaller (younger) animals fill the lower positions. The well known entry-order of cows into the milking parlour is not strongly related to social hierarchy – high-yielding cows tend to enter first and, during grazing, it is not necessarily the most dominant animals that lead the herd (Hall 2002). For full accounts of the behaviour of cattle see Albright & Arave (1997), Hall (2002) and Phillips (2002).

### Breeds and types

Cattle are classified into numerous breeds and types: some have been developed for the production of milk, some primarily as producers of meat, whilst others are essentially

<sup>1</sup>The CCAC 1993 Guide is available at: [http://www.ccac.ca/en/CCAC\\_Programs/Guidelines\\_Policies/GUIDES/ENGLISH/V1\\_93/CHAP/CHIV.HTM#4B1](http://www.ccac.ca/en/CCAC_Programs/Guidelines_Policies/GUIDES/ENGLISH/V1_93/CHAP/CHIV.HTM#4B1)

**Table 33.1** Biological data for cattle. For further information see Allen (1991), Feldman *et al.* (2000), Kerr (2002) and Reece (2004).

Parameter	Normal value
Age adult weight attained (years)	3–4
Adult weights (kg) (depends on breed)	
Males	600–1000
Females	400–800
Total lifespan (years)	15–20
Body temperature (°C)	38.5 ± 1.0
Pulse rate (beats/minute)	50–70
Respiration rate (breaths/minute)	15–30
Blood volume (ml/kg body weight)	57–62

draught animals. Not all breeds are as specialised, and dual-purpose and even triple-purpose breeds and types are recognised. From the biological point of view, however, most breeds of cattle can be placed into one of two groups: those mainly derived from Asiatic stock, the humped (Zebu) (*Bos indicus*) type animals, and those developed mainly from European stock, the non-humped (*Bos taurus*) cattle (Epstein & Mason 1984). Interbreeding between the groups results in fully fertile offspring. There are some anatomical, physiological and behavioural differences between the two groups, such as the presence or absence of humps or pronounced dewlaps, the smaller digestive tract capacity in Asiatic derived cattle, differing water needs, differing behavioural reactions to environmental heat and differences in disease susceptibility. Although for most practical purposes both species can be considered as one kind of animal, there are differences. Therefore, the following account is mainly directed towards European cattle – for details of the husbandry of Asiatic group animals see Payne and Wilson (1999) and Fielding & Matthewman (2004).

Standard biological data for cattle, including size range and life-span, are shown in Table 33.1.

### Sources of supply

Cattle required for experimental purposes can be obtained as follows:

- (1) by purchase, at any age, from a public market;
- (2) by purchase, at any age, direct from an established breeder, rearer or contract supplier who has genetically defined animals which are known to be healthy and disease free and who allows his premises to be inspected and, where appropriate, selected animals to be blood tested and/or vaccinated or treated prior to transport to the research establishment;
- (3) by breeding at the research establishment.

Cattle bred at a research establishment have the advantages that they are of known health and rearing history and have usually been handled from an early age. Unfortunately, this ideal approach demands substantial resources of land, buildings and staff, and is often only practical at the larger institutes.

Most research establishments purchase their animals from an established breeder, rearer or contract supplier. Depending on the nature of the scientific investigation, the cattle may be examined/sampled on the farm of origin to assess suitability and, if necessary, vaccinated against respiratory disease (particularly if they are going to be mixed with other cattle). After transportation to the research establishment they will probably be placed in quarantine for further tests, etc, if necessary. In other cases the animals may be transported directly into quarantine and all the tests/treatments etc, carried out there.

Whatever the source, the overall strategy should be to ensure that the biosecurity of the institute is maintained, and that the condition/health status of the cattle is suitable for the management system in which they will be kept and the experiments to which they will be subjected.

### Uses in the laboratory

Because of their great economic importance, cattle have been the subjects of scientific study in many agricultural and veterinary research institutes. Most investigations have been in the fields of bovine nutritional, environmental, reproductive and lactation physiology, or on cattle diseases. They are not often used as a model for human conditions although Leathers (1990) has listed some 18 human diseases for which cattle have been useful biological models. Kues & Niemann (2004) have also reviewed the contribution of farm animals to human health following recent developments in transgenic technology. There has also been research into zoonoses such as tuberculosis and brucellosis and in conditions such as bovine spongiform encephalopathy (BSE), which are of considerable interest with respect to public health.

### Use of cattle twins in scientific work

It is possible, using like-sex twin cattle, to considerably reduce the numbers of animals used in studies which seem to involve a high environment/treatment/genetic interaction, without lowering the statistical significance of the results (Rowan 1989). Identical (one-egg) twins are best for this purpose, but like-sex non-identical (two-egg) twins can be of value.

The logistical problems of locating, identifying and collecting naturally occurring identical twin calves has largely resulted in the abandonment of this somewhat novel approach to reducing the size – and thus the cost – of certain kinds of cattle experiments.

Relatively recently hormonal methods have been developed to produce multiple ova and embryos, and these can result in the birth of multiple viable offspring. Live embryos can be surgically harvested and transferred to recipient cows; and harvesting micromanipulation and subsequent implantation of fertile zygotes can result in the birth of monozygotic twins. These techniques may result in a further look into the use of genetically similar cattle in experimental work. For details of these various twin producing techniques see Gordon (2003, 2004) and Ball & Peters (2004).

## Laboratory management and breeding

### General husbandry

#### Environmental conditions and housing

If healthy and well fed, cattle can cope with wide extremes of climatic conditions, and can be kept outside all the year round in most parts of the temperate and sub-tropical parts of the world. It is widely held – without much in the way of quoted scientific evidence – that there is breed and/type variation in adaptability; beef cattle seem to stand cold better than dairy cows and Asiatic (Zebu) type cattle tolerate high temperatures more readily than European type animals. Whatever the breed, all animals must be protected against extremes of weather, shade or windbreaks must be provided as appropriate, and the animals should always have access to food and water.

Cattle used for scientific purposes should be kept in comfortable quarters (Reinhardt & Reinhardt 2002). The type of housing used is dictated by the type of investigatory work to be undertaken; the need to monitor the welfare of the cattle and the disease security required. Sometimes no

housing is provided and the animals are kept outside on pasture or even under extensive range conditions but it is more likely that cattle kept for experimental purposes will be accommodated in one of the following:

1. Small paddocks close to the laboratories.
2. Open-sided buildings with strawed (deep litter) or slatted-floors or containing lines of cubicles.
3. Enclosed buildings, for example, loose boxes or enclosed sheds. For study of infectious diseases these may include barriered buildings with bird proofing, and for contagious diseases sophisticated buildings with negative pressure air regimes and waste containment equipment.
4. Special facilities within a building, such as metabolism or feeding trial crates (Figure 33.1) or individual tie-up standings (Figure 33.2).

Indoor facilities and even some outdoor paddocks can be equipped with closed-circuit television to record animal behaviour.

Within open-sided buildings, loose boxes and enclosed sheds there should, as a general rule, be at least sufficient

**Figure 33.1** Young cattle confined in feeding trial crates.

**Figure 33.2** Individual tie-up standings contained within a building.

space for each animal to readily stand up, lie down, turn round, stretch its limbs and groom itself (Table 33.2). The animals should, if appropriate to the experiment, have continuous access to individual cow cubicles or to a communal dry bedded-down lying area and to a water supply (trough or water bowls). They should, wherever possible, be housed in sight of each other – as cattle are herd animals, visual contact is important and is a major component of environmental enrichment. There are tables giving the recommended minimum pen sizes for the accommodation of laboratory cattle in the UK *Code of Practice for the Housing and Care of Animals in Scientific Procedures* (Home Office 1989) and in the American *Guide for the Care and Use of Laboratory Animals* (Institute of Laboratory Animal Resources 1996) and the figures in Table 33.2 are based on them. The European Commission has recently adopted minimum enclosure dimensions (European Commission 2007).

Accommodation for dairy cattle must provide facilities where they can be milked. The development of the portable milking machine means that animals kept in isolated places can be milked mechanically, reducing the demand for time-consuming hand milking. To milk larger numbers of cattle a special milking parlour can be used but, of course, the cows have to be moved to the parlour and then returned to their living quarters. A vacuum pump system capable of maintaining a negative pressure of about half an atmosphere (approximately 35 cmHg) must be provided, as must equipment for cooling the milk for storage; for details of milking techniques etc see McNitt (1983) and Leaver (1999). For further information on cattle housing see Blowey (1994) and Lawrence (1994).

Much experimental animal accommodation has solid concrete flooring for ease of disinfection. This is usually easy to keep clean, but if it is too smooth, the cattle may slip and injure themselves; if too rough, it may be uncomfortable and can damage the udder, legs and feet of the animals. Concrete floors should, wherever possible, be covered with either a deep layer of straw over a thin scattering of sand, or ample shredded newspaper. In most bedding systems the soiled bedding must be removed and fresh bedding added each day.

One of the best types of bedding for cattle is deep litter (thick straw and /or shavings and/or sawdust). This is usually used in cattle yards or loose boxes. It must be kept dry and there must be no real contact, in the case of dairy

animals, between udders and dung (faeces). If well managed, this bedding provides some warmth (from bacterial action occurring deep in the bed) and much comfort.

The choice of bedding will depend on the design of the building, the availability of suitable material and the nature of the experiment. Typical considerations affecting the choice may be experimental restrictions on cattle eating it or contamination on its disposal due to disease or toxin. Whenever possible, preference should be given to bedding that offers comfort, as indicated by maximum lying time.

Exercise helps to maintain the health and welfare of cattle. Animals accommodated outside in grassed paddocks or kept together with others in yards will usually take sufficient exercise of their own volition. The space allocated for group-housed cattle is generally sufficient for them to exercise. However cattle held singly for lengthy periods of time in loose boxes or other restrictions should, wherever possible, be exercised daily. This can be done by either releasing them for set periods into exercise yards or paddocks (small groups work best); or by walking them out individually on hand-held halters on dry, firm ground or non-stony soft-surface roadways (purpose-built cow tracks are even better); or by attaching them by halter to a mechanically operated horizontally rotating 'bull-walker'.

#### Presentation of food and water

Food is usually presented to cattle in raised troughs. The troughs ideally should be designed, constructed and sited so that:

- they are not readily contaminated with faeces;
- they are easily cleaned;
- they are not likely to injure the animals in any way;
- they do not allow the cattle to waste their food.

Water can be piped to bowls which are automatically kept at a constant water level or which are operated by the cow when it pushes its muzzle against a shaped flange (tongue) in the bowl. Water meters can readily be fitted to piped supplies to monitor consumption. Water can also be offered in buckets (generally within fittings to stop them being knocked over) but this is labour intensive and tends to be used for calves or loose-box housed animals but does allow water consumption to be measured. Water sources should be positioned so as to minimise contamination by faeces, food or

**Table 33.2** Minimum space requirements for loose housed cattle. Adapted from Home Office (1989), Institute of Laboratory Resources (1996) and Council of Europe (2006).

Weight of animal (kg)	Min. enclosure (ie, single housing) size (m <sup>2</sup> )	Min. floor area/animal (m <sup>2</sup> /animal)	Trough space (or feed rack length) for ad libitum feeding of polled cattle (m/animal)	Trough space (or feed rack length) for restricted feeding of polled cattle (m/animal)
Up to 100	2.50	2.30	0.10	0.30
100–200	4.25	4.00	0.15	0.50
200–400	7.00	4.80	0.18	0.60
400–600	8.00	7.50	0.21	0.70
600–800	11.0	8.75	0.24	0.80
Over 800	16.0	10.0	0.30	1.00

bedding and, ideally, the water should be placed near a floor drain so that spilt water does not lie about and/or wet the bedding.

### Identification

Cattle which are kept in small numbers and which are frequently handled will be individually recognised by care staff. However, many countries have statutory requirement that all cattle should be permanently, individually and uniquely marked. They can be permanently marked by having tattooed numbers or 'tamper-proof' numbered tags placed in their ears. (It should be noted that 'tamper-proof' tags, once correctly placed fully into position, cannot be removed without either mutilating the ear and/or damaging the tag.)

If it is important that animals should be identifiable from a distance, for example where groups of cattle are kept at grass or housed in yards, then they should have one of the following:

- large coloured and/or numbered plastic tags placed in their ears;
- coloured and numbered plastic collars placed round their necks;
- large numbers or letters freeze-branded on to a pigmented area of their skin (the intense cold of the freeze-branding process permanently damages the pigment-forming cells and white hairs grow in the treated areas);
- large numbers or letters marked on non-pigmented areas of their skin by application of hair dyes; these marks have to be renewed as the hairs grow and are replaced.

There is increasing use of implanted microchips and bar codes on eartags – both these methods of identification require the use of an electronic reading device. Some commercial systems have microchips placed in neck collars for ration management (they may, for example, control access to a feeding station). Microchips may also be placed in eartags or foot bands to assist with recording the production performance of dairy cows.

The marking system chosen should be the least invasive method, consistent with the husbandry system and the aims of the research. No matter what type of individual identification is used, it is good practice to have a database containing information on individual animals. The data retained should trace key life events and list any interventions that the animal has been subjected to.

### Physical environment

Ideally, the environment inside buildings should be kept at about 17–18°C (range 10–24°C) and a relative humidity of about 50% (range 25–75%). Enclosed buildings should have a ventilating capacity of at least 5 air changes per hour in winter and up to 25 air changes per hour in the summer, in the hotter parts of the world. Background lighting of 200 lux or above should be provided for not less than 12h each day. The light:dark ratio should be about 1:1 and additional artificial light of not less than 500 lux must always be avail-

able, so that animals can be closely inspected at any time of the day or night.

### Health monitoring, quarantine and biosecurity

A health plan should be drawn up by the institute veterinary surgeon in consultation with the stock managers for all the cattle held and used on the experimental station. The plan will vary with the type of cattle involved, the environment and the experimental design.

As for all animals used in experiments that may impact on their health and welfare, clinical signs should be regularly monitored and clear guidelines provided regarding actions to be taken. Records should be kept of all veterinary treatments and operations. All animals that die should be examined post mortem, and the reasons for their deaths determined and recorded. There should be health and welfare meetings between all staff involved in a particular experiment prior to starting as well as review meetings at the end. There also should be regular and, if necessary, frequent meetings during the span of an experiment, to review the on-going health and well-being of the animals. This is especially important for long drawn-out investigations.

### Quarantine and biosecurity

One of the major health risks is the introduction of new animals into an establishment or even, at times, between different groups within the same establishment.

Animals arriving at the experimental farm should be placed into rodent-, and wild bird-free, easily disinfected quarantine premises. The quarantine facility should be separate from the main animal buildings and should have its own food and bedding stores and its own handling facilities. It should be surrounded by its own double, stock-proof fence. The manure from the quarantined cattle should be kept adjacent to the quarantine quarters. The quarantine area should have its own separate drainage and waste product disposal system.

The whole experimental farm should be surrounded by a stock-proof and, ideally, vermin-proof ring fence to prevent contact with ground-dwelling animals living outside the unit. This is best if it is double: the two fences should be at least 1m and preferably 3m apart, particularly if there are cattle in adjacent properties. It is important to control visitors and deliveries to the unit. The entrance should be gated and provided with a shallow drive-through disinfection bath for vehicles – for use should the need (local disease situation) dictate.

The road to the reception area should be concreted, short in length and not in close proximity to the animal accommodation or grazing paddocks and the parking area for visitors' cars and delivery lorries should be of concrete and easily washed down. Goods should be received into a secure, clean 'bonded' store and only issued after due inspection and verification that they are indeed what was ordered and do not pose a risk of introducing disease into the unit. All visitors should report to reception and be pro-

vided with institute-owned rubber boots and protective clothing before they are allowed access to other parts of the establishment. Isolation and other 'sensitive' areas may require special visitor access procedures and facilities. All persons entering or working in quarantine or isolation areas should wear colour-coded overalls etc, unique to the particular area.

All material moved within the unit as well as waste material leaving the unit should be risk assessed regarding potential release of infectious organisms or toxins. It may be necessary to arrange sterilisation and/or safe disposal.

For further details on farm animal biosecurity etc, see Gibson and Andrews (2000); Belk *et al.* (2007).

## Transport

For long-distance movements, cattle should be carried in specially designed animal transport lorries. Stock trailers towed behind a van or tractor can be used for short local journeys and within the institute. These trailers and trucks should be designed, constructed and maintained so that they are easily cleaned and disinfected, and do not injure the animals transported within them. Care must be taken in loading and unloading animals from these transport vehicles; non-slip loading and unloading ramps must be used.

For further details of cattle transportation see Grandin & Gallo (2007) and Grandin (2009).

## Breeding

### The adults

Cows, which are on heat (oestrus), tend to show characteristic behaviour such as head rubbing, mounting, standing to be mounted, vocalisation (bellowing) and more general activity (restlessness) than is usual. Signs that cows have been mounted include soiling of the flanks and tail/head rubbing. A clear, viscous (the latter may be more definitive) discharge may be seen issuing from the vulva. Swollen vulval lips tend not to be a feature of cattle in oestrus. Groups of cows must be observed several times a day if all the heat periods are to be detected.

Cows, under normal conditions, are capable of producing, on average, one calf per year (see Table 33.3 for reproductive data) and most management systems are based on this. The simplest way of producing a calf crop is to run a known fertile bull with a group of cows and/or heifers. A crayon marker, which can have its colour changed at 14-day intervals, can be placed on the sternal region (brisket) of the bull. Daily observation of the cows will then indicate which ones have mated and which, if any, have to be returned to service (ie, have been mated but have not conceived). From this information the approximate date of parturition of each cow can be calculated.

Alternative artificial insemination (AI) is generally used for dairy cattle. The cows should be served by AI approximately 12h after the heat is first detected. The insemination is usually done by inserting a long sterile plastic pipette into the vagina and depositing semen either on to the cervix, or

**Table 33.3** Reproductive data for cattle.

Parameter	Normal value
Onset of puberty (months)	12–15
Length of reproductive life (years)	12–15
Type of oestrus cycle	Polyoestrus
Duration of oestrus (heat)(h)	12–14 (shorter duration in the winter)
Frequency	Every 20–21 days
Seasonality	Oestrus occurs all the year round but most strongly in the summer; herds running all the year with a bull tend to calve in the spring
Length of gestation (days)	c 280 (about 7 less for twins)
Number of calves born	1–2; occasionally 3 or more; twinning rate in cattle about 2–3%
Average weight of calf at birth (kg)	23–45; much breed variation; males tend to be slightly heavier than females of the same breed/type
Post-partum oestrus	30–60 days after parturition

better still, into the cervical canal. This is a skilled job done by trained technicians generally using semen that has been stored in liquid nitrogen. In many countries there are licensed commercial and/or governmental agencies that undertake a travelling cattle AI service. Travelling AI services may be a significant factor in the introduction of disease (eg bovine viral diarrhoea, *Salmonella*, Johne's disease).

It is possible to synchronise the heat periods in a group of reproductively active cattle by means of prostaglandins (for details see Roche 1989). It is usual in these circumstances for two inseminations to be performed on each of the animals on two successive days. The advantage of this synchronisation technique is that a number of inseminations can be carried out at one time, and it also means that the synchronised group will usually all calve down at approximately the same time.

Determination of conception ('pregnancy diagnosis') can be carried out at:

- 21–26 days after insemination, by estimating the progesterone content of the cow/s milk (a cow-side test is available);
- 6–8 weeks after insemination by palpation per rectum of the reproductive tract, by a veterinary surgeon or specially trained technician.

As the pregnancy progresses there is an increase in the size of the abdomen and after about the 6th month an increase in the size of the mammary gland. These changes are more readily detected in heifers than in cows. The signs of imminent parturition are as follows:

1. behavioural changes such as restlessness, seeking solitary areas, vocalisation;

2. increasing distension of the udder and stiffening of the teats;
3. slackening of the pelvic ligaments each side of the tail, which may appear some 3–4 days before calving;
4. the vulva may become swollen;
5. drops of honey-coloured colostrum (first milk) may appear some 6–8h before the birth;
6. abdominal discomfort with possible straining

Most cows and heifers deliver their offspring without any real difficulty and should, wherever possible, be allowed to calve without human interference.

Parturition can be induced in cattle, in the last 2–3 weeks of their pregnancies, by the injection of short acting corticosteroids and/or prostaglandin  $F_{2\alpha}$ . The drug or drug combination used depends upon the nearness of the normal delivery date. If induction is required 2–3 weeks before the normal delivery date, long-acting corticosteroids can be used alone. Within a week of delivery, short-acting corticosteroids with prostaglandin  $F_{2\alpha}$  will be effective and, within 1–2 days of parturition, prostaglandin  $F_{2\alpha}$  alone will often be adequate.

The calves produced under these induction regimes may initially need greater care on the part of the animal attendant. The earlier the induction, the greater the need for such care. There is also a tendency for induced cows to retain their placentas (for details see Hartigan 1995).

Parturition should be allowed to take place either inside a clean draught-free loose box or, weather conditions permitting, outside in a field. The animal should not be tied by its neck and should have sufficient space to turn round easily, stand up and lie down at will. The loose box should have a well bedded non-slip floor; water should be provided and there should be a good source of artificial light. Once abdominal contractions (second-stage labour) have started the calf should be born in under 4h. Expulsion of the placenta (afterbirth) is usually completed within 30 minutes to 12h.

### The young

In beef suckler herds, the newborn calf is left with its dam until natural weaning occurs at 6–8 months of age. In dairy herds, calves are removed at birth or some 48h later and placed on milk replacer foods. Whichever system is adopted, it is essential that the calf takes in up to 4l of colostrum as soon as possible. The immunity of the newborn calf towards infectious diseases is largely dependent upon its absorbing, within the first 6h of birth, the antibodies contained in high concentrations in its dam's colostrum. The abdomen of the newborn calf can be palpated around 6h after birth to check if it has a full stomach. If it does not, colostrum should be milked from the dam and fed (stomach tubed) to the calf. Calves weaned at birth will need to have their dam's colostrum collected (hand milked) from the udder and fed to them using a teated bottle. The level of circulating antibodies in the calf's blood can be estimated by a number of simple tests (for example the zinc sulphate turbidity test for serum globulin) carried out on the calf's serum.

Calves which have been deliberately separated from their dams, or purchased at an early age, should be accommo-

dated in clean, dry draught-free straw-bedded pens. They should be kept in buildings with an air temperature of about 20°C and relative humidity not greater than 70%. Calves should have clean water and good quality hay available at all times. All calves should have frequent human contact during their first 6 months. This makes them easy to manage throughout their lives, reducing stress for both the animal and care staff (see section on handling and training).

Calves can be fed on liquid food (milk or milk replacers) two or three times a day or *ad libitum* for at least the first 3 weeks of life. Young calves start picking at hay in the first few days after birth; they start eating small quantities of palatable early-weaning mixtures from the first week onwards. They can show signs of rumination from 1–2 weeks of age, and can be weaned from liquid food when they are eating 1kg/day of a suitable concentrate ration. This may be as early as 3 weeks, but it is preferable to leave them on liquids for at least 3 weeks longer as there is usually a general setback to their health on weaning. Calves normally obtain their ruminal micro-organisms from being in close contact with their dams.

For further information on feeding, housing and health of calves see Roy (1990), Thickett *et al.* (2003) and Allen (2004).

### Breeding systems

Breeding stock must have the desired genetic and physical characteristics and should also, where possible, have a long history of freedom from disease and be docile in temperament.

### Feeding

#### Diets

Cattle are essentially grazing and browsing animals, and if allowed to roam freely will consume considerable quantities (up to 90kg in total) of forage material (grass, clover or browse) each day.

Cattle spend an average of 8 out of each 24h grazing (range 4–14h); usually in four to five bouts during the hours of daylight. During this time they may walk a distance of up to 2km. In very hot conditions, cattle will graze at night and lie and ruminate during the day. It is important from the point of view of environmental enrichment that, wherever possible, the diet offered to cattle should contain sufficient forage material to allow a normal duration of rumination. Total ruminating time is usually some three quarters of normal grazing time (ie, about 6h). If the herbage is succulent, ruminating time is reduced in relation to grazing; if it is coarse and fibrous the animals will ruminate for longer.

Because of their great economic importance, and because their growth and production are largely dependent upon how they are fed, a large body of theoretical knowledge and practical experience exists on cattle nutrition (see Agriculture and Food Research Council 1993; Owen 1995; Greenhalgh *et al.* 2002). Modern feeding systems for cattle are designed to first meet the nutritional needs of the cow's ruminal micro-organisms and then to supply the requirements of the

cow with metabolisable energy and metabolisable protein from the products of ruminal and post-ruminal digestion. Agriculturalists and nutritionists can give advice on the design of cattle feeding regimes based on the body size and physiological needs of the cow (eg, growth rate, stage of pregnancy or lactation), and veterinarians are used to dealing with the diseases associated with faulty feeding. There are many commercial firms that can provide an efficient advisory service and which can contract to supply correctly balanced cattle rations.

### Dietary requirements

The theoretical background to the nutrition of cattle has traditionally been approached by first finding their energy requirement, then their need for protein and finally by considering the intake of dry matter which they are capable of taking in (Table 33.4). These needs have then to be matched with the energy values and the protein and dry matter contents of the foods available (see Table 33.5 for examples). Finally, the ration has to be examined to see if it is likely to contain adequate amounts of essential vitamins and minerals.

This simple approach to calculating the dietary requirements of cattle is being replaced, in the UK, by more complex systems using concepts such as: is the diet likely to contain adequate amounts of the essential vitamins and minerals; and does it provide fermentable metabolisable energy (energy available for the ruminal micro-organisms) and effective ruminal degradable crude protein (the protein available for the ruminal micro-organisms). For details of systems that take into account these and other factors and for outline accounts of other systems used outside the UK, see Greenhalgh *et al.* (2002).

The main parts of the daily ration of a ruminant consist of:

1. bulk food – supplying energy, some protein and fibre;
2. concentrate food – supplying extra protein and/or energy, additional vitamins and minerals;
3. water.

Cattle out on good-quality grassland can sometimes take in all their daily needs by grazing up to 90 kg of grass per day.

**Table 33.4** Energy and protein requirements for maintenance\* and dry matter intake limits of cattle.

Body weight of animal (kg)	Metabolic energy (ME) (MJ/day)	Digestible crude protein (DCP) (g/day)	Limit of dry matter intake (kg/day)
200	27	150	5.0
300	36	200	7.5
400	45	250	10.0
500	54	300	12.5
600	63	350	15.0

\*For production each kilogram of live weight gain requires a further 34 MJ of ME and 320 g of DCP. The additional ME required by animals in lactation can be calculated from the formula  $1.694(0.0386 \text{ BF} + 0.0205 \text{ SNF} - 0.236)$ , where BF is butterfat and SNF is solids not fat (both in grams per kilogram of milk).

However, most modern high-yielding dairy cows, often require far higher levels of energy, protein and fibre than can be provided by grass alone – in itself a crop varying in analysis from region to region and season to season. Many cattle in modern intensive systems are fed a total mixed ration of grass by (grazing) or as grass silage/maize silage/straw (hay) plus some sort of concentrate – the whole being designed to fulfil the specific nutritional requirement of the particular production system.

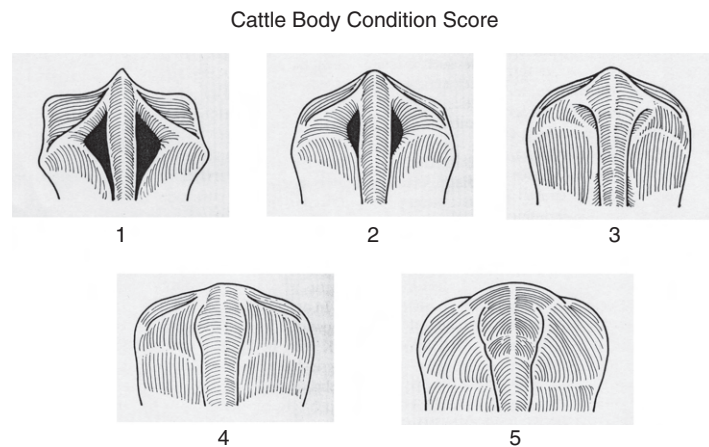

Cattle indoors may be given their bulk ration as silage (up to 70 kg a day) or hay (10–15 kg a day), and this is often supplemented with relatively small quantities of high-protein concentrate foods. Water must be supplied. Cattle need 40–50 l/day and, if they are lactating, they need additionally about five times the volume of milk produced. If they are being milked there will also be a requirement for additional water to keep clean the milking stall, to wash and sterilise the milking equipment and to cool the milk.

Whatever the system or means by which cattle are fed, the end results can be judged by the body condition, weight, health and production of the animals. These must be monitored at frequent and regular intervals and any loss of condition etc, must be assessed and, if necessary, action must be taken to overcome the cause. Sometimes all that is needed is a gradual increase in the quantity and/or quality of the food provided.

A body condition scoring scheme can be useful. In these, an assessment is made, on a scale of 1–5 (or 8), of the weight for age and the relative proportions of muscle to fat of cattle using a graded set of photographs or drawings (Figure 33.3) of scored animals; see Bazeley & Hayton (2007) for further details.

**Table 33.5** Typical metabolic energy (ME), digestible crude protein (DCP) and dry matter (DM) contents of some common foods.

Food	ME (MJ/kg DM)	DCP (g/kg DM)	DM (g/kg)
<b>Succulents and roughages</b>			
Swedes/turnips	12.8	91	120
Kale	11.0	110	140
Grazing (rotational)	12.1	225	200
Grazing (extensive)	10.0	170	200
Grass silage (good)	9.3	107	200
Maize silage	11.2	70	250
Meadow hay (good)	9.0	58	850
Dried grass	10.6	120	900
Barley straw	7.3	8	860
<b>Concentrate foods</b>			
Barley	13.7	84	860
Maize	14.2	70	860
Oats	11.5	77	860
Soyabean cake	12.3	405	900
Decorticated cottonseed cake	12.3	365	900
Decorticated groundnut cake	11.7	427	900
Linseed cake	13.4	300	900
Sugar beet pulp, dried	12.7	59	900

**Figure 33.3** Condition score of cows assessed for fat cover over tailhead and loin area. 5, grossly fat; 4, fat; 3, good, 2, moderate; 1, very poor. Drawing: J. Webster (from Webster 1993).

## Laboratory procedures

### Handling and training

Cattle reared from a young age with human contact are usually quiet and easy to manage. They respond well to a calm but firm approach. There are many advantages in having experimental subjects exposed to a minimum of non-experimental (and usually non-quantifiable) stressors. See Stookey & Watts (2007) for a general account of low-stress restraint and handling of cattle.

When handling cattle all staff should be aware of the risks. Mature bulls should never be handled by one person alone; they are often large, sometimes bad tempered, quick in action, and are not to be trusted. Accommodation for this type of animal should be designed with safe refuges for staff. Cows with young calves at foot can sometimes be very protective towards their young and must also be handled with care.

Most cattle can be trained to tolerate many minor routine experimental procedures, such as blood sampling, injections etc, with the minimum of physical restraint: see Dickfos (1991).

Depending upon their size and situation the subject animals are usually tied by the neck (chain or yoke; see Figure 33.1), tied and/or held by means of a leather head-collar (head stall) or rope halter or restrained in a cattle crush (squeeze). Under the direction of the unit veterinarian, sedative type drugs can be given (such as xylazine intramuscularly at 5–30 mg/100 kg body weight, chloral hydrate by mouth at 6–12 g/100 kg body weight to nervous animals or in anticipation of a potentially stressful procedure.

Within a research establishment, cattle can be moved in small groups by being quietly driven by one or two handlers. It must be made obvious to the animals which way they are expected to go by the correct deployment of handlers and barriers and by opening and closing gates in the correct sequence. It is not usual to employ cattle dogs to move experimental stock, but it may occasionally be necessary, for example, on extensive grazing trials. Where dogs are used they must be quiet and well under control.

In an emergency it may be necessary to restrain cattle by holding them with a finger and thumb in the nostril pressing on the nasal septum or by grasping them in the same place

using a metal pincer device ('bulldog'). A looped cotton rope tightened round the abdomen just in front of the udder generally prevents cattle kicking with the hindlegs, and thus can make it easier to examine and/or manipulate the hind end of the animal. It must be emphasised that it should not be necessary, except in an emergency, to use these physical means of restraint when carrying out routine procedures on trained cattle.

There are advantages to the safety of both handlers and other cattle with which naturally horned breeds may be in contact if they have had their horns removed. This can be done once they are adults, but it is better to remove the horn buds of 1–2-week-old calves by firstly anaesthetising the horn buds and then burning them out with a hot disbudding iron.

For further information on cattle handling see Holmes (1991); Fowler (1995); Albright & Fulwider (2007); Ewbank & Parker (2007); Grandin (2007a, 2007b); Humane Slaughter Association (2008).

### Physiological monitoring

The body temperature of cattle is readily taken by carefully inserting a lubricated blunt-ended clinical, or digital thermometer, into the rectum and holding it there for 1 minute while, at the same time, ensuring that the thermometer is touching the rectal wall.

Depending upon the nature of the scientific investigation other measurements that can be made include: weight and condition score for general health; respiration rate; the presence or absence of nasal discharge if respiratory disease is being studied; and rumination rate if digestive function is of concern.

### Collection of specimens

#### Blood

General advice on blood sampling techniques can be found in the report by the Joint Working Group on Refinement (JWGR, 1993). Blood can be readily obtained from the jugular or coccygeal veins of cattle. As long as the animals are used to being handled, a very sharp and appropriately sized bleeding needle is used and a precise technique

employed; very little restraint is usually required. The skin over the vein site should be clipped (if necessary) and then cleaned and, if thought necessary, disinfected.

- Jugular vein: this large, external vessel is a ready source of blood. The vein is raised either by the use of a neck rope or by digital pressure and a large cattle-bleeding needle (up to 1.5mm diameter × 20mm long) is then inserted with, usually, the point directed towards the head. A local analgesic can be injected by means of a fine needle into the skin over the jugular vein prior to the insertion of the large needle, but this is usually unnecessary.
- Coccygeal vein: blood can readily be taken from the coccygeal vein, which lies on the underside of the tail. There are advantages in using single-use disposable needles. Coccygeal vein blood sampling is a particularly convenient technique when the animal is restrained in a cattle crush, which has easy rear access.

#### Milk

Mixed samples from the udder can be obtained from the milking-machine bucket. An individual sample from a teat (quarter sample) can be collected by first cleaning and disinfecting the teat end and then squeezing out, by a stripping action of the first finger and thumb, the contents of the lumen of the teat into its own small collecting vial. To reduce contamination it is usual to discard the first five squirts and then collect the sample into the vial. The end of the teat should then be disinfected and the cow allowed (or persuaded) to stand for 30 minutes in order for the teat to reseal properly.

#### Faeces

These can be collected from the floor behind tied-up cattle or from a special bag fitting over the hindquarters, or removed manually from the rectum.

#### Ruminal contents

A rounded-end 'stomach' tube is passed via the mouth and oesophagus into the rumen, and the ruminal contents are then drawn out by a hand-operated pump, or large veterinary 'syringe' attached to the stomach tube.

For details of experimental techniques used with cattle see Grassland Research Institute (1961), Chapman (1969), Wood (1975) and Leaver (1982). Guidance as to the care, management and welfare of the cattle confined in metabolic cages can be found in Olfert *et al.* (1993), and Harrison (1995) provides a detailed account of surgical techniques used on experimental farm animals, including cattle.

### Administration of medicines and test substances

General advice on the administration of substances can be found in JWGR (2001).

#### Dosing and injection procedures

Non-bitter tasting, non-volatile medicines which are active in the alimentary tract or which are absorbed by the oral

route can, if suitably formulated, be given in the food – a good, if variable way of dosing a large group of animals. If accurate dosing is required then one of the following methods may have to be used:

- making the dose up as a drench (usually with water) and giving by means of a specially designed drenching 'gun' or, where very large volumes are required, by stomach tube;
- putting the substance into gelatine capsules and placing them far back in the mouth of the animal by means of a specially designed balling gun.

Many medicines are precisely and easily given by injection via the appropriate intravenous, intramuscular, subcutaneous, or intraperitoneal routes. For more details of the various techniques see McNitt (1983), Holmes (1991), Fowler (1995) and appropriate chapters in Battaglia (1998).

### Anaesthesia and analgesia

Cattle are very suitable subjects for regional analgesia, for example paravertebral blocks, caudal epidurals or perineural blocks. They can be given general anaesthetics but must first be starved of concentrate food overnight and forage should be removed a few hours prior to induction. They are then sedated with a drug such as xylazine (iv or im) and induced using a quick-acting intravenous anaesthetic agent. They should then have a cuffed tube placed in the trachea to allow the administration of gaseous anaesthetic and to stop inhalation of regurgitated rumen contents. They should also have their front end propped upright on their sternums so that dangerous levels of gas do not accumulate in the rumen interfering with venous return. Alternatively local analgesics can be injected at or close to the operation site. See Hall *et al.* (2001) for more detailed descriptions of these various techniques.

A recent and full account of the anaesthetic agents and methods which can be used on ruminants can be found in Riebold (2007).

### Euthanasia

The act of euthanasia is most easily and humanely carried out on quiet co-operating animals. It may be possible and indeed desirable to sedate 'non-co-operating' cattle, when the experimental protocol allows this, by the use of an injectable sedative.

The most humane and efficient way to kill cattle is to first render them unconscious by means of a captive-bolt stunner or a specially designed free-bullet humane killer, and then to cut their throats. In the case of the captive-bolt stunner, death occurs through blood loss, resulting from the throat cut; in the case of the free-bullet humane killer, from damage to the brain.

The muzzle of the captive-bolt stunner or the specially designed free-bullet humane killer should be placed in contact with, and at approximately right angles to, the forehead of the animal at the crossing over point of two imaginary lines joining the eyes of the animal with the base of the

ears on the opposite sides (Figure 33.4). The point of aim for calves should be slightly lower. In old heavy-headed animals the aiming point should be 1 cm to the right or left of the cross-over point. Once the animal has fallen to the ground it can be pithed (ie, a cane or piece of wire can be inserted into the hole in the skull and moved around to destroy the brain). Pithing is not allowed if the carcass is to enter the food chain. The animal usually kicks out when this is done. Once it is still its throat can be cut to sever the carotid arteries and jugular veins.

In an emergency, a standard shotgun, handgun or rifle may have to be used. The shotgun is the best for use under farm conditions. The muzzles of these standard weapons should not be placed in contact with the animal; they should be fired with the muzzle some 8–10 cm away from the point of aim. The animal's throat is then cut.

An overdose of an intravenous anaesthetic agent can be used to kill experimental stock. This technique preserves the brain for pathological examination, but it usually leaves drug residues in the tissues and renders the carcass unsuitable for some chemical analyses, or for human or animal consumption. For practical details of cattle slaughter see Sibley (1995) and Humane Slaughter Association (2005, 2006).

## Common welfare problems

### Prophylaxis and disease control

Cattle obtained from a known good source, which are in a stable social group, fed and housed correctly, and which are well looked after by their attendants, usually remain disease free. There may, however, be a need for the routine prophylactic use of vaccines, regular treatment for parasites and drying-off mastitis control. This should be part of the health plan agreed with the unit veterinarian.

In long-term cattle projects, attention should be paid to the feet and the diet. Commercial diets are usually designed

to feed growing beef cattle or productive dairy cows; long-term cattle which have reached maturity need a diet which maintains their weight and provides them with suitable amounts of vitamins and minerals. It is important to prevent the development of urolithiasis in entire and castrated males.

### Signs of health and disease

Healthy cattle usually graze for about 8 h a day and ruminate for a further 6–7 h. They should chew their cud without difficulty and have a normal rumen turnover rate of about three times in 2 minutes. They should have a rumen fill (concavity of left paralumbar fossa) and a body condition score appropriate to the nature of the experiment they are on. About half of every 24 h is spent lying down. Cattle stretch themselves when they get up. They usually have a moist cool muzzle and a sweet smelling breath, and generally have a shiny coat, which they lick. They should be free from lameness, excessive salivation and from nasal eye discharges; they should only cough occasionally. Cattle should urinate and defaecate without any signs of distress, and the consistency of their faeces should be appropriate to the nature of the bulky part of their daily ration. If, for example, they are eating grass their faeces should be fairly loose, whereas when fed on hay their faeces should be firm. Their respiration and pulse rate and their body temperature should be within the normal range (see Table 33.1).

The more obvious signs of ill health in cattle are the following:

- loss of appetite;
- separation from the group or herd;
- fall in milk yield;
- loss of body condition;
- cessation of rumination;
- rise in body temperature;
- lameness, salivation, excessive coughing;
- sudden change in consistency of faeces.

Many countries have statutory schemes as listed in the Office International des Epizooties's (2009) manual for the control of the important infectious diseases of cattle, such as anthrax, brucellosis, rabies, foot and mouth disease, blue-tongue, tuberculosis, rinderpest and BSE. There may be duty in law for the owners and/or keepers of cattle to know about the common symptoms of these diseases, and to report to the appropriate government authorities when they suspect that their animals may be suffering from them.

The control of infectious disease usually depends upon some or all of the following actions:

1. Early recognition of the disease.
2. Treatment (ideally to cure) or disposal of infected animals (and possibly in-contact stock).
3. Cleaning and appropriate disinfection of the premises in which they were kept.
4. Testing of the remaining animals for disease-carrier status, and the isolation and possible disposal of positive reactors.
5. Vaccination (when appropriate) of susceptible animals.

**Figure 33.4** Diagram of the head showing the point of aim when using a captive-bolt stunner or free-bullet humane killer.

6. Taking care not to re-introduce the disease, for example by setting up barrier fences, controlling pest rodents and birds and establishing quarantine facilities.

### Common diseases

Some diseases are of common occurrence and/or zoonotic. Keepers of experimental cattle should be acquainted with their characteristics.

#### **Bovine viral diarrhoea (BVD)**

A viral disease causing infertility, poor-doing calves and, in some cases, fatal diarrhoea. Carrier animals occur in some herds. Vaccines are available.

#### **Ectoparasites**

Lice can be a problem in housed cattle. They can be treated with an appropriate non-toxic injectable or pour-on insecticide. Ticks are important as transmitters of viral and rickettsial diseases. Cattle kept outside in some tick-infested areas may have to be regularly treated.

#### **Endoparasites**

Gastrointestinal parasites are a cause of diarrhoea, debility and loss in young cattle, but can be treated with anthelmintics. Many oral and pour-on preparations are available. There is an increasing problem with certain parasitic worm populations showing a resistance to many of the currently used drugs. Veterinary advice should always be sought when setting up a control and treatment programme.

Liver fluke causes a persistent wasting disease but can be treated. Control programmes are mainly based on eradicating the intermediate hosts (a snail) by draining the cattle-grazing areas and the by use of molluscicides. Lungworm causes coughing and debility in young animals. A vaccine is available and a control and treatment programme should be instigated based on regular dosing with suitable medications, pasture control of the parasite and, where appropriate, the use of a vaccine.

#### **Johne's disease**

This is a disease caused by *Mycoplasma avium paratuberculosis*. It commonly affects adult cattle and is characterised by chronic wasting and profuse diarrhoea. It is untreatable. Clinically affected animals should be disposed of and, under veterinary guidance, an effective preventative control scheme should be started.

#### **Lameness**

There are many causes of lameness in cattle, such as injury, overgrown feet and specific bacterial infections. Individual cases should be treated, and if the problem is common veterinary advice will be needed. Preventive measures (attention to floor surfaces, routine trimming of feet, the regular use of footbaths etc) should be undertaken.

#### **Leptospirosis**

Leptospirosis is an important and sometimes common cause of abortion. The disease is transmissible to humans. Carrier animals can be detected by blood test and should be eliminated. Vaccines are available.

#### **Mastitis**

This is caused by a variety of bacteria; but in many instances there may be predisposing building and environmental factors. Individual cases can be treated with antibiotics but preventive programmes should first be set up (attention to environments and buildings; hygiene at milking time; ensuring the milking machine is working correctly; post-milking teat dipping; the rational use of intra-mammary antibiotic treatments; the possible use of vaccines) after taking veterinary advice.

#### **Metabolic diseases**

These are caused by the breakdown of internal metabolic processes, and their development is influenced by environmental stress, the nutritional state of the animal and the production demands being made of it. A preventive programme can be set up, taking veterinary and nutritional advice.

#### **Pneumonia**

There are many causes of pneumonia in cattle, both bacterial and viral, and it is particularly prevalent and severe in young cattle when they are mixed from various sources. There can be a wide range of bacteria and viruses involved and vaccines are available, although to be effective, they need to be combined with suitable management and husbandry practices (eg vaccination prior to mixing; logical antibiotic treatment of individual clinical cases; buildings designed to allow suitable ventilation).

#### **Ringworm**

This specific fungal infection is indicated by round, raised whitish lesions on the skin of young cattle. Vaccines and treatment regimes are available, but even untreated animals usually recover. The disease is transmissible to humans.

#### **Salmonellosis**

This is a bacterial infection mainly affecting calves and young cattle, which causes diarrhoea and dysentery. A vaccine is available. The condition is usually responsive to antibiotic treatment, although multidrug resistance is an increasing problem. Some strains of *Salmonella* can be transmitted to humans.

#### **Scours (diarrhoea)**

Many diseases may produce scour in calves and adult cattle. Most of these may be related to the animals' environment. Sufficient good quality colostrum given soon after birth will often considerably reduce the problem in calves.

Common causes may include rotavirus, coliform bacteria, coccidiosis, *Cryptosporidium*, endoparasites, BVD and Johne's disease.

### Tuberculosis

This is a notifiable, infectious bacterial disease and a zoonosis. Cattle should be tested for tuberculosis regularly (dependent on country disease status) and removed if they are infected. Only animals shown to be free from the disease should be kept.

### Currently uncommon but still important diseases

#### Anthrax

This is an acute infectious bacterial disease causing sudden death in cattle; it is a zoonosis and is notifiable in many countries. All cases of sudden death should be investigated by a veterinary surgeon. Prophylactic vaccines are available for use, under licence, in anthrax areas.

#### Bluetongue

Bluetongue is a notifiable disease and on the increase in Europe. It is vector-borne (by a *Culicoides* midge) viral infection. Prevention may involve substantial biosecurity measures to protect cattle against midge bites as well as routine annual vaccination.

#### Brucellosis

Brucellosis is an infectious bacterial disease causing abortion and infertility; it is a zoonosis and is notifiable in many countries. All cases of abortion should be investigated by a veterinarian. Cattle should only be used if a blood test has shown them to be free from the disease.

Standard texts, for example Blowey (1999), Andrews *et al.* (2004) and Divers & Peek (2007) should be consulted for details of these and other cattle diseases.

### Abnormal behaviour

Cattle kept outdoors on pasture or fed large quantities of silage, hay or other bulky fodders do not usually show abnormal behaviours. This is thought to be a result of them spending some 8h out of the 24 consuming grass, or somewhat less time eating hay, and a further 6–7h ruminating – so that they are 'gainfully occupied' during most of the day. As herd animals, an important component of providing an appropriately enriched environment is the presence of other cattle.

However, cattle kept tied up for long periods of time, or confined within metabolism crates, sometimes show oral stereotypies such as compulsive licking, tongue sucking, tongue rolling and horizontal bar grasping. Once established these behavioural abnormalities are very difficult to eliminate, but they largely disappear once the animal is turned out to graze.

### Reproductive problems

Infertility is an important source of economic loss in cattle and has many causes. The causes of infertility can be usually identified by an experienced veterinarian and a control programme instigated.

#### Dystocia

If a cow's normal calving behaviour ceases and, on physical examination there is no sign that the calving is progressing normally, then it should be considered as a dystocia. There are many potential causes and veterinary advice should be taken.

#### Metritis

This is characterised by infection of the uterus and is usually seen in the post-parturient period. A foul-smelling discharge from the vulva is observed. It may be predisposed to when foetal membranes are retained and metritis has occurred previously in the cow. Treatment should be undertaken by a veterinary surgeon.

For details of the prevention, control and treatment of reproductive problems see the appropriate chapters of Meredith (1995), Noakes *et al.* (2001) and Ball & Peters (2004).

Cattle are delightful creatures to work with. They respond well to gentle treatment; they can be readily trained to cooperate in many scientific procedures but they are big, sometimes a little clumsy and obstinate and, of course, they are expensive to keep. The latter fact has probably been instrumental in the decline in their use as an experimental animal.

The validity and usefulness of the results obtained from animal experimentation depends upon many factors, not least of which is the quality of life being experienced by the subject animals. Animals which are healthy, thriving and contented and which are kindly handled are most likely to yield sound data. Cattle are no exception to this – they give the best experimental results when they are humanely housed and treated with care and consideration.

### Further reading

The literature relating to the care and management of cattle is immense. One of the best general introductions is Webster (1993) *Understanding the Dairy Cow*. There is much relevant material in the husbandry section of Andrews *et al.* (2004) *Bovine Medicine: Diseases and Husbandry of Cattle*. There are useful chapters on dairy cattle (Leaver 1999) and on beef cattle and veal calves (Webster 1999) in Ewbank *et al.* (1999) *Management and Welfare of Farm Animals*. Blowey (1999) *A Veterinary Book for Dairy Farmers* provides an excellent general introduction to cattle disease, welfare and the health aspects of husbandry. A recent book (Bazeley & Hayton 2007) deals in detail with many practical aspects of cattle care and management. The UK Department for Environment, Food and Rural Affairs issues in 2003 the most recent version of its useful *Codes of Recommendations for the Welfare of*

*Livestock – Cattle*. Similar codes of practice have been produced by the Ministry of Agriculture and Fisheries of New Zealand (1992) and for Australia by Primary Industries Standing Committee (2004). There has recently been published a substantial and most useful book entitled *The Welfare of Cattle* (Rushen *et al.* 2008) and the US Federation of Animal Science Societies has issued the 2009 edition of its *Guide for the Care and Use of Agricultural Animals in Research and Teaching*.

# 34 Sheep and goats

Colin L. Gilbert and Keith M. Kendrick

## Biological overview

### Introduction

Sheep and goats have been domesticated by man and used for meat, milk and wool for several thousand years. It may therefore seem somewhat surprising that behavioural traits such as flocking for protection and running from humans remain so well defined. The likely reason for this is that these instincts have been exploited rather than repressed through the ages to facilitate animal management and handling in groups. The same instincts can and should be used in the laboratory environment when working with groups of animals, but it may also be necessary to work with separated individuals. It is always important to remember that sheep and goats are gregarious by nature, and isolation will result in stress (Parrott 1988). However, sheep and particularly goats, respond very well to gentle handling over a period of time, and in most cases will eventually lose their flight instinct even when penned singly. This accommodation to environment should be the first objective of all laboratory users of small ruminants for medium- to long-term experiments. Benefits will accrue to animal handlers, the quality of data, and most importantly to the animals themselves.

### Perceptual and cognitive abilities of sheep and goats – social organisation

It is entirely wrong to equate the strong retention of flight instincts in these animals with a lack of intelligence. Indeed, behavioural and neurobiological studies of the perceptual and cognitive abilities of sheep and goats have revealed that they make sophisticated use of both visual and olfactory cues from their environment to enable them to rapidly learn to recognise individual offspring, flock members and humans as well as palatable and unpalatable foods. Their ability to do this almost rivals that seen in higher primates including man; and one obvious conclusion that must be drawn from such studies is that, if they need to be able to recognise a number of specific individuals and objects and, if their brains are specialised for carrying out this process, then their social requirements and interactions must be far more complex than a cursory view of their behaviour within a flock might suggest. Research has also shown that sheep have individual personality traits. Therefore, as an intelli-

gent species with a degree of sentience, the use of sheep in experimental procedures should be undertaken thoughtfully and only when specific need arises.

There has been a tendency to overlook the possibility that sheep and goats, or for that matter other domestic ungulates, use vision to learn about and interact with their environment. While they lack an accommodation reflex, their visual acuity in the frontal eye field is very good and probably lies somewhere between that of a cat and a monkey (Piggins 1992). They are capable of recognising individuals from visual cues from the face region and are able to visually discriminate between different types of grass, clover and concentrates (Kendrick 1992; Kendrick *et al.* 2001; Tate *et al.* 2006). Indeed, sheep can identify and remember at least 50 different sheep and 10 different human faces and even after long periods of absence (Kendrick *et al.* 2001; Peirce *et al.* 2000). For this reason, it is important to take care that fleece or horn growth does not significantly interfere with an animal's line of sight. Both sheep and goats can be trained to perform operant tasks (eg, choices indicated by pressing panels with their nose); to discriminate between different faces or other visual stimuli (Baldwin 1979, 1981; Tate *et al.* 2006); or to choose between faces or geometrical stimuli in a Y-maze (Kendrick *et al.* 1995, 1996; Tate *et al.* 2006). Animals can be easily trained to use this apparatus either for food or social rewards.

Faces clearly have an important emotional significance for sheep. Studies have shown that when they are exposed to social isolation stress, the sight of pictures of familiar sheep can alleviate behavioural, autonomic and endocrine indices of stress and reduce activation of brain centres controlling stress and fear responses (Da Costa *et al.* 2004). Showing animals video sequences depicting other sheep can also evoke profound interest and relieve stress (Elliker 2006). Recent work has also shown that sheep can detect and respond to human face expressions (smiling and angry) and emotion cues in sheep faces (fearful vs calm) (Kendrick 2004; Elliker 2006; Tate *et al.* 2006) and that they may be able to form and use mental images of faces (Tate *et al.* 2006).

Both sheep and goats also have a remarkably acute sense of smell and can discriminate between a large number of biological and chemical odours in operant experiments (Baldwin & Meese 1977). However, in spite of possessing a highly developed sense of smell they do not appear to need it for food recognition or even individual recognition in most cases, although it is entirely possible that olfactory cues might complement visual ones to speed up recognition or improve

its accuracy. The main exception to the predominance of vision over olfaction is the selective olfactory recognition of offspring which develops in both species very quickly after they have given birth and which seems to be essential since accurate visual and vocal discrimination of offspring develops much more slowly (Kendrick *et al.* 1996). Another context in which olfactory cues are important appears to be synchronisation of oestrus which occurs in response to odours from the fleece of a male – the so-called ‘ram effect’.

The hearing sensitivities of sheep and goats are broadly similar to those of humans with the exception that they can hear frequencies above the human upper limit of hearing (ultrasonics). However, their ability to localise sounds is relatively poor compared to that of some other mammals (Heffner & Heffner 1992) and may reflect their greater reliance on vision. Sheep also only have a limited vocal repertoire which essentially falls into three different types. These include a high-pitched or protest bleat which can be used to signify anything from slight agitation or mild impatience to extreme fear; a low-pitched more rumbling bleat used specifically by maternal ewes to call their lambs; and a similar type of low-pitched vocalisation sometimes used by rams engaged in courtship with ewes. While there is evidence that maternal ewes can learn to recognise their lambs’ voices, and vice versa (Shillito & Alexander 1975), the ability of sheep to recognise individual members of the flock from their high-pitched bleats has yet to be demonstrated convincingly (Kendrick *et al.* 1995; Elliker 2006), although sound spectrograms show clear individual differences in sheep voices. It seems fair to conclude at this stage that the main function of the high-pitched bleats is for an individual to express some degree of concern or impatience and, in certain circumstances, to warn other flock members of some impending danger.

The cognitive abilities of sheep and goats enable them to cope successfully with changing environments. Abilities to follow rules and abstract ideas are more limited although they do show some capacity to form concepts. For example, sheep are capable of discerning that there is a physical barrier between them and a human no matter what form that barrier may take (wire fence, chain fence, gate etc). Even with a single-stranded electric fence a sheep appears to know that what keeps it in will also keep humans out. Thus a sheep will often tolerate the presence of humans at much smaller distances to themselves when there is an intervening fence and will often not show an alerting response when a human approaches the fence. However, in other respects their conceptualisation does show clear limitations. For example, whereas sheep will normally run away from a human walking towards them when the human is 10m or more away from them, they will often let a human crawl in amongst them providing that he or she keeps their eyes averted downwards. Thus their concept of a human shape appears rather limited.

Learning skills of sheep are also dependent, to some extent, on the type of objects that they are being trained to visually discriminate. Thus when they are trained to discriminate between totally unfamiliar geometrical symbols (triangles, squares, circles, lines etc) they are relatively slow at learning (Baldwin 1981; Kendrick *et al.* 1996). However, if they are required to discriminate between familiar types of

real object, such as faces, they can learn very rapidly (Kendrick *et al.* 1996; Peirce *et al.* 2000), and have been shown to recognise and remember at least 50 different sheep and 10 different human faces for up to 2 years. Thus an important consideration with these species is to use familiar types of objects as discriminanda or reinforcement signals if speed of learning is an important issue. They also clearly have a long-term memory for both other sheep and humans who interact with them.

One other important aspect of behaviour in sheep and goats that should not be overlooked is developmental influences on learning and preferences. While such influences are still poorly understood, certain principles have nevertheless emerged which have direct bearing upon how experimental animals should be reared. In both sheep and goats, where a selective and initially exclusive bond exists between mother and offspring, the mother is an enormously influential role model. There is evidence, for example, that dietary preferences learned from the mother can be retained for periods in excess of 3 years. Moreover, work on the effects of cross-fostering between sheep and goats has shown that the mother rather than the genetic species dictates social and sexual preferences in adulthood and that her influence appears to be practically irreversible in this respect (Kendrick *et al.* 1998). Therefore, it is clearly preferable to rear infant kids and lambs with a mother since this close emotional mother–infant relationship is of great importance to their normal social and emotional development. In addition, it is important to recognise that trying to make an animal do something which goes against what it has learned from its mother is always going to be difficult or even impossible. This might simply involve the effects of changing diets but can also extend to attitudes towards humans. Lambs will learn to avoid humans from the actions of their mothers within a few days of birth and this attitude can be extremely difficult to overcome, even with the best possible interactions between them and humans. Conversely, adult sheep that were reared by hand as orphan lambs tend to be less fearful of humans. For experimental purposes that require close interactions between sheep and humans, it is preferable to ensure that a positive initial attitude to humans is passed on from mother to offspring by attempting to create a positive attitude in the mother first. With goats this is not so much of a problem since most breeds are tolerant of, and even interact with, humans. Nonetheless, even with this species positive human interactions with the mothers may result in easier interactions with their young.

### Standard biological data

Standard biological data for sheep and goats are shown in Table 34.1 and comprehensive haematological and biochemical data for these species may be found in Wolfensohn and Lloyd (2003) and Aitken (2007).

### Choice of breed

This is to some extent dictated by climatic conditions and availability. Theoretically almost any breed of sheep should

**Table 34.1** Some standard biological data for sheep and goats.

Parameters	Sheep	Goats
Normal temperature (°C)	38.5–39.5	38.5–39.5
Chromosome number	54	60
Lifespan (years)	10–15	10–15
Heart rate (beats/minute)	65–110	70–120
Resting respiratory rate (breaths/minute)	15–20	15–25
Dental formula	$I^0_3 C^0_1 P^3_3 M^3_3$	$I^0_3 C^0_1 P^3_3 M^3_3$

readily adapt to most experimental conditions provided that they are treated correctly, although an exception to this would be feral breeds. However, a number of criteria should be assessed when deciding which breed is suitable for a particular research project. There are over 200 breeds of sheep worldwide, many of which are localised to specific countries or conditions and are rare elsewhere. The most numerous breed internationally is the Merino, which is kept for wool production and is found predominantly in Australia and South Island, New Zealand. New Zealand also has a number of meat-producing or dual-purpose breeds, such as the Romney, the Perendale and the Drysdale. In the UK, lowland sheep breeds such as Dorset, Suffolk and Friesland, together with most breeds of goat tend to settle more quickly to individual penning and handling than do upland or hill breeds, such as the Scottish Blackface, Cheviot and Welsh Mountain, although these breeds may also adapt eventually. However, lowland breeds may become very large and heavy (80 kg or more) when compared to hill breeds (35–50 kg), or indeed the Soay (15–20 kg); so whilst lowland breeds may be easier to catch they often prove to be more difficult to move or carry and may become overweight when penned indoors for extended periods. Saanen and Anglo-Nubian goats are usually considerably larger than British Alpine or Bagot. Larger animals require more floor space and food.

Reproductive characteristics such as strong seasonality driven by day length (most breeds), a longer breeding season (Dorset) or large litter sizes (Finn or Boroolla Merino) may be important. Most breeds of goat and milking breeds of sheep such as Friesland lend themselves to lactation studies. Other special considerations might include growth rate, carcase quality, wool or coat colour. Using a purebred has advantages over using a crossbred ewe since buying in breeding stock can be minimised.

Some researchers find horns useful for attaching equipment although the horns should never be used as a sole means of restraint. The presence of horns can be a potential hazard to both handlers and other animals, and this should be part of the decision-making process on whether they should be removed. Horn buds may be removed safely between 3 and 7 days of age. Adequate anaesthesia and analgesia are essential during removal and providing the right balance of drugs for different circumstances requires experience. Sensory innervation to the horns varies between species. The removal of horn buds, particularly in kid goats, requires both skill and experience. The use of a hot disbud-

ding iron in goats can easily result in brain damage as the thin cranial vault offers little thermal protection to neural tissues. In the UK disbudding goat kids may only be performed by a veterinary surgeon. The UK goat veterinary society<sup>1</sup> has produced a DVD on the subject, for distribution to veterinary surgeons. The method of Boyd (1988), using general anaesthesia, is also reliable.

### Source of animals

Ideally an on-site breeding flock/herd should be maintained. This allows for continuity of supply, standardisation of genetic background and maintenance of a health barrier (see below). If maintaining flocks on-site is impractical then animals may be bought in, bearing in mind that known single sources of supply are generally better and more accountable than open markets, and that availability of animals is likely to be seasonal.

### Uses in the laboratory

Current areas of research that routinely use sheep and goats as experimental animals include studies into the seasonal control of reproductive activity, parturition, neonatal care and reproduction in general, lactation, growth, ruminant metabolism and physiology, and behavioural and neurobiological studies of cognitive and motivational processes. They have also been used as large-scale producers of antibodies in blood and trialled for synthesising bioactive compounds in milk through transgenic manipulation. Other studies include those related directly to disease conditions which cause harm to sheep (such as foot and mouth disease and bluetongue). A particular recent interest has been the transmissible spongiform encephalopathies (TSEs). Models of human disease include bone metabolism studies and polycystic ovarian disease.

### Management and breeding

#### General husbandry

#### Housing

Generally speaking, well fleeced sheep are very tolerant of low temperatures providing that the fleece is dry. Hill breeds of sheep are more tolerant of poor weather than lowland breeds, but even the hardiest animals require some protection from wind and rain. Goats are also fairly tolerant to cold weather providing they are dry, but prefer warmer climates and should have access to shelter at all times. Shelters can take the form of small huts in pastures during the summer time (with the entrance way sheltered from prevailing winds), but these can be inadequate in the winter. Both sheep and goats benefit from access to shade during the summer to prevent heat stress. Goats have a tendency to eat their shade, which may constitute an enrichment in

<sup>1</sup><http://www.goatvetsoc.co.uk>

the short term but can then contribute to both overheating and poisoning, so should be monitored carefully. A key enrichment is the presence of other animals with which to form stable social groups. A dry lying area should always be made available. Animals at pasture need to be protected from predators and harassment by dogs.

#### Group housing

Where possible, sheep and goats should be kept in groups of two or more animals (species and sexes are normally kept separate). An open-plan floor area which can be partitioned off with hurdles under a high roof provides a versatile solution to varying group sizes (Figure 34.1). The use of straw bales can complement the hurdles. In this system, a floor of rammed chalk or similar is ideal to provide natural drainage on top of which a deep-litter bed of straw can be laid. Impervious floors such as concrete are an alternative and can be more easily decontaminated between groups, but must be sloped to prevent pooling of liquids. The system depends absolutely on sufficient straw laid often enough to provide a dry layer on top in which animals can make themselves comfortable. Inadequate drainage leads to waterlogged pens, damp fleeces and skins, a humid atmosphere, condensation, chilling of animals and compromised well-being. An increase in respiratory disease may also result.

Animals may also be group-housed on wooden slats, through which urine and faeces fall to a collecting pit below. This system has the advantage that animals are always dry, and need less labour in the winter. However the slats are less comfortable than a straw bed, are expensive to maintain and, if allowed to deteriorate, can result in severe leg injuries to sheep (especially fine-boned breeds) treading on broken slats or into gaps. The belly draughts which rise through the slats make these systems unsuitable for goats and for parturient animals. Recent guidance within the Council of Europe ETS 123 revised appendix A for sheep and goats (Council of Europe 2006), and which has been adopted by the European Commission (2007) that the entire enclosure should have a 'solid floor with appropriate bedding provided' indicates that

slatted floors systems may be superseded by more modern alternatives.

Good ventilation is the key to successful housing of sheep and goats. Inadequate air movement produces similar problems to those encountered by poor drainage. In high-ceilinged barns the walls need not be solid and may consist of hit and miss boarding or heavy duty netting in temperate climates to reduce the effect of prevailing winds. Netting is very versatile if kept on a roller blind apparatus, so that it can be easily lifted clear during fine weather. In buildings with low ceilings or solid sides, adequate ventilation will require the provision of ceiling-mounted extractor fans (with a reliable power supply) and wall air inlets above animal height. High-roofed buildings should have a gap running along the roof apex to allow warm humid air to escape. This is helped by providing insulation on the underside of a sloping roof, particularly if the roof is metal, preventing the warm air from cooling and falling back, forming condensation and a stagnant atmosphere.

Group housing of laboratory sheep and goats depends absolutely on a reliable method of identification (see later in this chapter). Adequate trough space must be supplied to allow all animals to feed together when concentrates are offered (Table 34.2). Less space may be needed when food is offered *ad libitum*, but close observation is required to ensure that no bullying occurs at the food rack, especially if a fine mesh is used for the rack (see section on feeding for more details), or if some of the animals have horns.

#### Individual penning

Experimental demands may require sheep or goats to be housed individually. Researchers must always critically review the need for single housing before imposing it. Animals with long-term surgical preparations may need to be singly housed to prevent damage to implants from curious pen-mates. Sexually active males may require single penning to avoid fighting. Singly penned sheep and goats should always be able to see and hear companions. Prior to any experimental procedure animals require a period of acclimatisation to a new environment, routines and staff.

**Figure 34.1** An open-plan barn accommodating sheep during the winter. Notice: (1) a layer of straw thick enough to present a dry top layer to the animals; (2) front gates large enough for tractor access; (3) strip lighting to allow thorough inspection of animals whenever needed; (4) netting at the rear of the barn cuts the force of prevailing wind and rain without reducing ventilation; (5) hay racks (on wheels) of sufficient length to allow all animals simultaneous access, fitted with lids to prevent soiling of the feed.

**Table 34.2** Recommended minimum pen dimensions for sheep and goats being used for scientific procedures. From Appendix A of the European Convention for the protection of vertebrate animals used for experimental and other scientific purposes (ETS 123) (Council of Europe 2006).

Animal weight (kg)	Minimum individual enclosure size (m <sup>2</sup> )	Minimum floor area/animal (m <sup>2</sup> )	Minimum partition height (m)*	Minimum length of ad libitum feeding space (m/animal)	Minimum length of restricted feeding space (m/animal)
<20	1.0	0.7	1.0	0.1	0.25
20–34	1.5	1.0	1.2	0.1	0.3
35–59	2.0	1.5	1.2	0.12	0.4
>60	3.0	1.8	1.5	0.12	0.5

\*May need to be higher for goats

Goats tend to adapt more rapidly to penning than do sheep and generally show fewer escape behaviours when being caught and handled.

Table 34.2 shows minimum space allowances under European Union recommendations for laboratory sheep and goats. Floors for permanent indoor single housing of sheep and goats should normally be of an impervious material such as concrete or tiles, with at least a 1 in 15 slope to provide drainage. Floor texture needs to achieve a compromise between minimal abrasion to exposed skin and good grip to hooves. Warmth from radiant heat or underfloor heating may be of value for young, sick or infirm animals, or in a surgical recovery area especially for goats or shorn sheep. Gentle underfloor heating can also help to maintain a dry floor and reduce humidity in buildings of low volume, but is costly both to install and maintain. Straw bedding or wood shavings may be provided, although shavings achieve little more than to absorb urine and do not otherwise add to comfort. Bedding in individual pens needs to be changed very regularly, preferably daily.

Pen walls can be solid and impervious to fluids to animal head height, above which a barred arrangement may continue, or barred to floor level to keep animals in but allowing easy observation by staff and between animals. Horizontal bars near floor level are dangerous as limbs may poke underneath when animals lie down and then break when they attempt to rise. All pens must be free from projections such as bolts or sharp metal edges. Concentrate food may be provided in free-standing plastic bins or troughs. Built in metal troughs tend to be cumbersome, are difficult to clean *in situ*, hard to replace when they rust or rot and can cause pain when kicked by either sheep or handler. Removable hayracks can be hung from partitions. Water may be provided in automatic drinkers or in bowls that hang from the gate, filled by hoses. The latter are preferable in being easy to remove when necessary for cleaning, or to deprive animals of water prior to surgery; and when in use give the animal technician an immediate indication of individual water intake. Individual drinkers of whatever type should be cleaned and checked daily and under normal circumstances should never be allowed to become empty. In exposed locations, the pipes may need frost protection. A typical individual sheep or goat pen is shown in Figure 34.2.

Occasionally it is necessary to hold sheep in metabolism cages or slings. The former are used when collection of urine and faeces is required and the latter for behavioural testing, visual discrimination experiments or similar. Due to their

**Figure 34.2** A pen suitable for individual housing of sheep or goats in a research environment. Notice: (1) a water bowl, mineral lick and hay rack are all provided but easily removable, the free-standing plastic food trough has been removed; (2) the floor consists of a textured tile which is non-abrasive but gives good grip even when wet, a covering of sawdust helps to maintain dryness; (3) the floor slopes gently to a drain in front of the gate; (4) the bars in the gate allow singly penned animals to see adjacent companions; (5) a convenient electricity supply is provided.

restrictive nature both of these holding methods should only be used when a clear scientific need arises for which normal penning would be inadequate. When using metabolism crates a minimum of a week of acclimatisation is recommended prior to experimentation and in slings the same period is necessary with animals only spending 6–8 h per day in slings, under constant supervision. Both systems should use animals already familiarised to human contact and a laboratory environment.

In order to induce out-of-season breeding or to study other light-related phenomena, controlled lighting rooms may be required, but a light-tight space must not be achieved at the expense of compromised ventilation. When lights are turned off the light level must be less than 3 lux to be considered as 'dark' by the day length detection systems used by sheep.

In a large laboratory it may be useful to set aside a separate area or building for special care and quarantine of sick, injured or convalescent animals.

## Identification

A reliable and easily read method of identification is vital for animals kept in groups. Ear-tagging is popular and generally effective, but two tags should be used to mitigate against the likelihood of one being lost. Poorly designed tags with sharp edges or protruding surfaces can catch in fencing and tear out of the ear, causing pain and potential infection. A non-toxic spray applied to the flanks allows animals to be identified over a considerable distance but must be regularly renewed and is lost at shearing. Electronic identification devices (EIDs) in rumenal bullets or subcutaneous implants are becoming more popular, especially for valuable individuals. An ear tattoo can be useful for animals with white ears, although these tend to fade and become difficult to decipher with time.

## Maintenance of health

Keeping stock healthy is more difficult to achieve in open flocks than closed (those with a non buying-in policy). Veterinary advice should be sought in advance of acquiring new animals. Any bought-in stock must be quarantined for at least 4 weeks on a pasture or in a building well away (more than 100m) from other stock. Bought-in animals should come with a comprehensive clinical history of the flock from which they originate. On arrival, the animals should be carefully and individually examined for signs of ill-health (see later) by a veterinary surgeon and animals suspected of having particular problems rejected. Further investigation may include serological testing for diseases such as border disease, chlamydia or toxoplasmosis using blood samples taken after 2 weeks of quarantine to allow for seroconversion to diseases experienced immediately prior to purchase. During quarantine, routine measures such as vaccinations, treatment against parasitic worms and immersion dipping (or the use of suitable pour-on agents) to control ectoparasites, should be undertaken as necessary to correct for any imbalance between the health status of incoming animals and that of the parent stock. Despite these precautions it is still possible to import disease with new animals. A closed flock is therefore highly desirable.

Sheep intended for research are no less susceptible to disease than stock in commercial flocks. Maintenance of a high health status amongst research animals is an important ethical responsibility for research groups and will also improve data quality through minimising intercurrent, and possibly subclinical disease, during procedures and reducing between-animal variation. Strategies to exclude disease include: membership of national disease eradication or notification schemes; local barriers such as quarantining and well maintained fencing; and use of disease prevention measures such as vaccinations and strict worming policies. Veterinary advice should be taken on these matters, bearing in mind the geographical location and standard practice routines built into the annual cycles of flock management. It is also important to maintain disease prevention routines when an animal leaves the stock pool and enters a laboratory.

## Transport

Never begin to move animals from place to place until adequately staffed and fully prepared. The vast majority of sheep will try to run from humans, and animals which are surprised and excited by an impatient handler will run sooner and more quickly. 'Stampedes' of animals may result in self-inflicted injury to animals or handlers and must be avoided. Animals move more easily from place to place in groups. All routes except the desired route should be closed, and then the animals should be allowed to go at a steady walk with gentle encouragement from behind. Single animals are very difficult to move by this method and should be loaded into some form of crate or transporter (Figure 34.3). A very confined transporter is best for this purpose as it prevents a frightened animal from accelerating into an obstruction. For moving flocks over longer distances, specialised animal wagons are required and national regulations regarding animal transport apply. Loading ramps must have barriered sides and ridged walkways. All transporters and transport procedures should comply with current animal transport legislation requirements.

## Breeding

Sheep and goats are both seasonally polyoestrous, with shortening day length inducing oestrous cyclical activity in females. Ewe lambs and kids may be large enough to be mated in the autumn of their first year if born early in the season with no subsequent growth check (75% or more of final adult weight). It is preferable not to breed from the smaller ewe lambs or from goats until the following season when they will be at least 1 year old. The rearing conditions used for prospective working rams are also important since there is evidence that rearing rams together from weaning in single sex groups with no access to females can lead to a

**Figure 34.3** A home-made crate suitable for transporting one or two sheep or goats. Notice the couplings to allow carriage by tractor, plus the wheels and handle for manual pulling. Both ends can be lowered to form a stepped ramp, and the top can be lifted to access the animal.

high incidence of homosexual rather than heterosexual preferences. It is, therefore, better to let the ram lambs run with the ewes for as long as possible whilst the ewes and any ewe lambs remain in anoestrus. A good introduction to reproduction in the sheep and goat is provided by *Salamon's Artificial Insemination of Sheep and Goats* (Evans and Maxwell 1988).

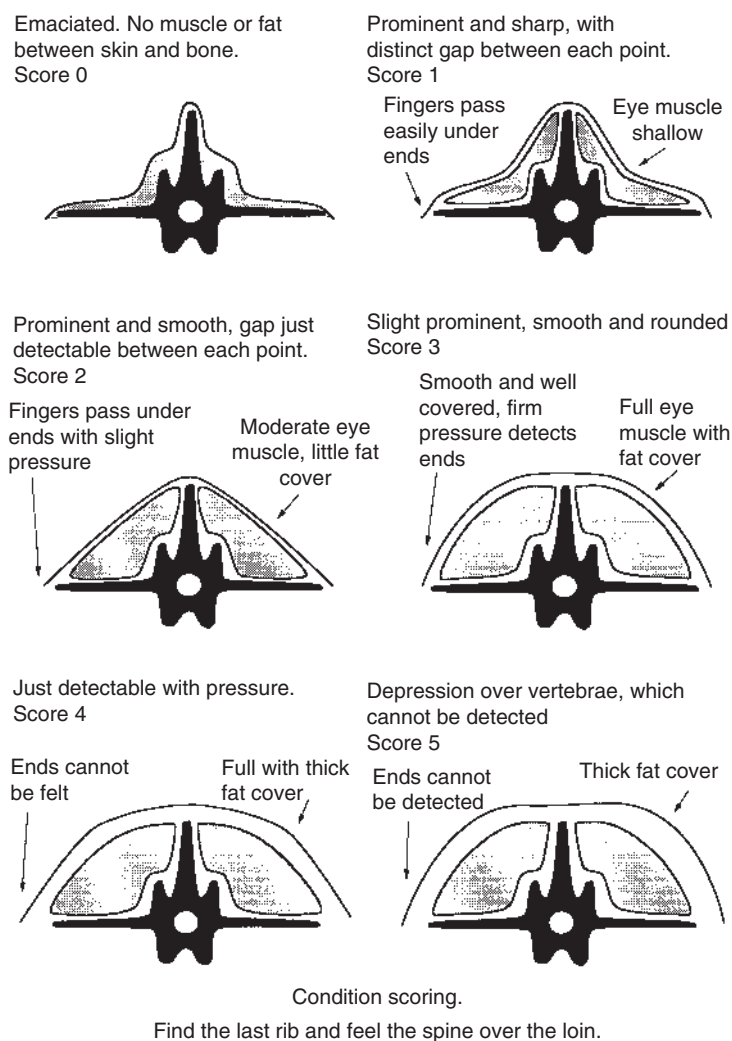

Behavioural changes in oestrous ewes are difficult to detect under farm conditions, so rams or teasers (vasectomised males) usually wear coloured crayons on their brisket which leave a mark on a ewe's rump following service. Some goats show inappetence, a drop in milk yield, restlessness and increased vocalisation during oestrus but these signs are not reliable, and willingness to accept the billy is the only sure indicator. Under laboratory or controlled field conditions it is possible to show that female sheep and goats can display a number of proceptive (invitational) and receptive behaviours which can be quantified for experimental purposes to produce an overall receptivity index (Fabre-Nys and Venier 1987).

Although the normal reproductive pattern of sheep and goats leads to the production of one set of offspring in the spring of each year, some breeds, such as the Dorset or the

Finnish Landrace, are capable of producing offspring more frequently than this. However, this requires early weaning of the lambs and places pressure on husbandry systems and maternal physiology. A realistic target for more frequent breeding is for the ewe to produce three sets of offspring over 2 years, or five over 3 years. Exceeding this rate is not recommended and such systems are rarely required in a research environment.

At different periods of the reproductive cycle, nutritional requirements are higher. Ewes from mid-pregnancy (especially late gestation) and during lactation need a higher energy intake, and diets may need to be adjusted to give more energy per unit of bulk to supply sufficient nutrition at the limit of appetite. Both rams and ewes may require supplementary feeds in the pre-mating period, to help the rams through to the end of mating and to improve ovulation rate in females (a practice known as 'flushing'). A body condition score of 3 (Figure 34.4) is ideal for a ewe at mating, on a rising plane of nutrition.

Melatonin implants may be used to advance the onset of the breeding season. Strategies for encouraging oestrus early in the breeding season include the use of teaser (vasectomised) rams, intra-vaginal progesterone sponges and

**Figure 34.4** Drawings of transverse sections through the lumbar spine of sheep with different body scores. Reproduced with permission from Hindson, J. (1989) *In Practice*, **11**, 152.

injections of gonadotropin-releasing hormone (GnRH) analogues or pregnant mare serum gonadotrophin, although none of these are wholly reliable.

The inter-oestrous period is 16.5 days in the sheep and 21 days in the goat. A number of management strategies exist to synchronise oestrous activity in females in order to produce tight lambing/kidding patterns, including the use of intra-vaginal progesterone sponges or by giving intramuscular injections of prostaglandin  $F_{2\alpha}$  or an analogue. A disadvantage of synchronising oestrus is that more rams are needed per ewe. A good-quality fertile ram may be able to serve up to 50 unsynchronised ewes, but only 10–12 ewes in a synchronised flock.

Pregnancy is indicated by non-return to oestrus, and may be confirmed using blood or milk progesterone assays in goats, or through the use of ultrasound scanning, which carries the additional advantage of determining the number of offspring. A skilled interpreter of ultrasound images can identify a pregnancy at 30 days but more usually ewes are scanned at 50–90 days post mating. Other methods, now mostly superseded, include vaginal biopsy, X-rays and abdominal ballotment.

The gestation period is normally 145 days in the sheep and 150 days in the goat with 5 days variation in either direction being normal. Signs of imminent parturition include: seeking isolation from the main group, restlessness including circling and pawing the ground, mammary development, the ability of handlers to express milk from the teats, lifting of the head with licking of the lips and, finally, powerful abdominal contractions. If some control over lambing is required for experimental reasons then an intravenous injection of dexamethasone (0.25 mg/kg) can be given between days 140 and 142 of gestation and ewes will give birth around 48 h later (usually between 40 and 54 h). Intramuscular administration of dexamethasone is not nearly as reliable in this respect. Earlier induction of parturition is not recommended as lambs will be progressively weaker with more respiratory problems.

Clear and simple guides to obstetrics in sheep are provided by Eales and Small (2004) and Winter and Hill (2003). Knowing when to intervene in lambing or kidding requires considerable experience, and the novice should never be put in a position of supervising lambings without skilled back-up. As a general rule of thumb, ewes or nannies which do not produce young within 1 hour after the appearance of fluid-filled membranes or a rush of fluid from the vagina may need assistance. Earlier intervention may be required if the animals become weak or unwell. Ewes or nannies which show just a head or one limb protruding from the vagina need assistance immediately. A number of diseases causing abortion are zoonotic, and human contact with parturient ewes should be strictly controlled.

Normally, ewes and nannies will stand following birth, consume the foetal membranes as they are expelled, and bond with their offspring. Following birth the ewe's udder should be checked to ensure that milk is normal and abundant. The majority of lambs and kids are able to stand and feed soon after birth. Weak newborn animals need special attention, particularly warmth, dryness and food. Initial feeds must be given as colostrum (or a colostrum replacer) at 50 ml/kg within 6 h of birth, repeated at 6–8-hourly inter-

vals for the first day if artificial rearing is needed. Colostrum from donor ewes can be frozen and stored for up to 12 months. Stomach tubing may be necessary for neonates that will not suck but should be performed only by a competent person. In severe, hypothermic cases an intraperitoneal injection of a calculated dose of warm sterile isotonic fluid containing glucose may be life saving. Dams and offspring should only be separated if this is essential for their well-being as hand rearing is time consuming and affects behaviour when lambs reach adulthood.

### Maternal behaviour and selective bonding

Sheep and goats do not normally show maternal behaviour towards lambs and kids respectively until they give birth, although some stealing of young can occur in experienced mothers towards the end of their pregnancies. When they give birth, maternal behaviour and selective bonding are triggered by feedback to the brain from receptors in the vagina and cervix activated during labour contractions and the expulsion of the foetus. Thus lambs delivered from pregnant ewes by caesarean section or following an epidural anaesthetic block are often not mothered. Birth also triggers selective bonding behaviour with offspring in both sheep and goats, whereby the mother rapidly learns to recognise the odour signatures of its individual lambs or kids and will subsequently refuse suckling attempts from offspring other than its own. In sheep, this process of selective bonding generally occurs within 1 hour post-partum, although with Saanen goats as little as 15 minutes may be sufficient in some cases. Primiparous ewes and nannies take longer to bond with their offspring, often 4 h or more (Kendrick 1994), since maternal experience is required to alter the brain to respond to the feedback from the vagina and cervix during birth. This then promotes changes in olfactory processing structures that underlie the bonding process. Thus, bonding between first-time mothers and their young relies almost exclusively on physical interactions between mother and offspring and removal of the offspring for even short lengths of time or contaminating them with strange odours (including human ones) may result in the mother rejecting her own young.

While selective bonding may ensure the offspring an exclusive milk supply and, for that matter, an individual role model, this has caused farmers problems for hundreds of years when they want to foster orphan or triplet/quadruplet lambs. Where large numbers of animals are giving birth in the same period then 'wet' fostering becomes possible since both maternal ewes and nannies will accept other young prior to forming a selective bond with their own. Once the bond has formed however, the authors have found that its selectivity can be overcome by manually stimulating the vagina and cervix of a post-partum mother for 2 minutes even up to 3 days after she has given birth. To do this the ewe's or nanny's own offspring are temporarily removed from her to a warm place and out of earshot. The stock person then dons lubricated sterile elbow gloves (to prevent transmission of potential zoonotic pathogens eg, *Chlamydophila*, orf etc), and using light restraint, a gloved hand is inserted into the vagina and rhythmically pushed up to the neck of the cervix and withdrawn over a period of

2 minutes. The animal will usually push backwards onto the hand to help the procedure and will normally lie down and exhibit behavioural signs of being in labour. If a strange lamb or kid is then introduced the ewe or nanny will, in around 80% of cases, accept it and their own offspring can be re-introduced to them within 15–30 minutes. This process works since it merely mimics nature in convincing the mother that she has given birth again and has been successfully used by farmers in the UK and other European countries during the last few years. It is also possible to treat multiparous non-pregnant ewes and nannies with vaginal sponges containing oestradiol and progesterone to induce lactation (including colostrum formation) and they can be induced to mother orphan or triplet lambs or kids by the same process of stimulation of the vagina and cervix (Kendrick *et al.* 1992). It is not recommended to use this latter procedure in nulliparous ewes or nannies.

While there are other methods used to promote fostering in maternal animals after they have bonded these are either not very effective (using added artificial odours, for example) or represent poor welfare (physically restraining/yoking the mother so she cannot reject the offspring, which may be needed for up to a week or more to be successful).

### Weaning and rearing

Once lambs and kids have received colostrum, it is possible to rear them artificially 'on the bottle' using milk replacer powders, introducing solids from 7 days of age. Such lambs should be abruptly weaned no later than 6 weeks old to avoid problems of abomasal bloat, from too rapid ingestion of milk substitute.

Lambs and kids reared naturally normally start the process of weaning themselves at 3 weeks of age and can be offered specialised creep feed from 2 weeks old, in addition to the milk from their mothers. This creep feed should be given in a feeder which restricts access to the lambs or kids and does not allow the mothers to eat it. While it is possible to leave offspring with their mothers indefinitely, it is usual to wean lambs and kids completely onto solid food at around 16 weeks of age. This allows the mother to recover fully prior to the next breeding season. If a schedule of enforced weaning is not used, especially with prolific breeds, the condition of the mothers can deteriorate markedly as a result of persistent suckling by the offspring. In frequent-breeding systems, where an earlier than usual return to sexual receptivity and pregnancy is required, early weaning at 6–8 weeks is necessary as lactating ewes rarely undergo oestrous cycles.

Acute weaning is best carried out by separating a group of lambs/kids from their mothers at the same time. It is best to relocate the ewes/nannies rather than take the offspring to new accommodation, because the young then remain familiar with their surroundings and can easily find water and feed hoppers. The ewes/nannies should be removed to a location out of earshot and regular checks should be made to ensure that none of them develop mastitis. The lambs/kids can be fed on creep feed and hay or grass during this time and if necessary can be re-introduced to the flock after 3–4 weeks, at which time their mothers will not accept any suckling attempts.

### Feeding

The feeding of sheep and goats for maximum productivity and health is a large and complex field beyond the scope of this article. Bretzlaff *et al.* (1991) and Calhoun (1991) provide reviews on this topic for goats and sheep respectively and numerous publications are available from agricultural advisory services and colleges. Sheep and goats are ruminant animals which possess a digestive system and physiology that is highly specialised and adapted to the extraction and metabolism of usable nutrients from plants, and in particular the cellulose in plant cell walls. The rumen is little more than a fermentation vat where a delicate mix of micro-organisms is provided with the right conditions and substrates from which to produce short chain fatty acids from cellulose; the adapted biochemical systems of the adult ruminant are able to use these as an energy source or as a substrate from which to manufacture glucose. Rapid changes to diet, particularly a sudden excess of nutrient-rich food, are likely to upset the fermentation process with disastrous and potentially fatal consequences. It therefore follows that dietary stability should be a prime feature of any feeding regime, and any changes in either quality or quantity must be introduced gradually.

In the wild, the natural food of the sheep is grass, whereas goats tend to browse on the leaves of bushes and trees. The inquisitive feeding habit of goats is well known and care must be taken to keep poisonous plants, for example, yew trees, and dangerous objects, such as electric cables, out of reach of a goat even at full stretch. Presentation of strictly limited quantities of safe hedge trimmings or freshly fallen branches with leaves can be a treat for goats.

Sheep and goats kept indoors can be fed fresh cut grass (but not lawn mowings), but more usually are given hay, which is readily but slowly broken down in the rumen and helps to maintain rumenal stability. Mouldy or rotten hay will be rejected. Goats tend to be more selective than sheep with hay, and will eat the leafy parts and seed heads at the expense of the stalks. Silage is an acceptable alternative to hay for sheep and goats, but is less palatable for some animals and all stock adapt to it with some hesitation. Silage is heavy and more difficult to manhandle in a laboratory environment. Poor-quality silage will be rejected.

The design of fodder racks is an important consideration, particularly with goats. Goats are agile climbers and will readily stand on their hindlegs to pull down fodder. They will also climb onto racks if allowed to, and subsequent contamination of feed with urine and faeces will cause much wastage. Feed racks should therefore be designed with a cover.

A fine mesh (1.5cm square) for hay racks is preferable since it increases feeding time and slows intake to more closely match time spent grazing. This increase in time spent acquiring food may also be considered as a welfare refinement, especially for singly housed animals. It also reduces waste. Sufficient rack space is essential to avoid bullying.

Other bulk foods used for sheep include good-quality barley straw, chopped maize and roots such as mangolds. These foods are only generally suitable as part of a balanced diet that also includes forage and concentrates. Bulky foods are useful to control obesity when animals have limited

opportunities for exercise. Sugar beets may be used as a treat for penned animals. Roots may be inedible to animals with poor front teeth and may accelerate tooth wear if fed for long periods.

Concentrate foods are widely available as proprietary products with 'guaranteed' nutritional content shown on the food bag label. The actual constituents of these diets may vary seasonally. Vitamins may 'go off' in the bag so freshness and a dry cool food storage area are important: always observe any 'use by' dates. Animals kept indoors for prolonged periods should be supplied with mineral licks to provide supplementary metal ions and minerals. Particular attention should be paid to copper, selenium and cobalt levels, and to vitamin D in animals with no access to natural daylight. Copper and selenium, in excessive quantities, are toxic to sheep and goats. Licks and concentrate feeds should always be specific for the species concerned as some foods for eg, cattle and pigs may contain inappropriate amounts of copper.

As both pasture-grass and hay have variable nutritional values, animals should be regularly assessed for body condition score, and the quantity of supplementary feeds such as proprietary concentrates adjusted accordingly. A body condition score scale of 1–5 is universally employed in sheep, with the muscle and fat coverage of transverse processes of the cranial lumbar vertebrae used as the criteria for determining the score (see Figure 34.4). Sheep with a thick fleece are impossible to condition score properly without being caught and palpated. It is normal for healthy goats to carry relatively less external body fat than sheep.

The diets for lambs and kids need special attention, particularly when they are newly weaned. A careful balance needs to be drawn between providing sufficient nutrient-rich food for rapid growth and avoiding over-feeding which can lead to diarrhoea and acidosis.

Given the variables outlined above it will be clear that there are no universally reliable rules by which to calculate how much food to offer any one animal. A starting point might be that individually housed ewes at maintenance only will receive 1.5–2.5 kg of fresh good-quality hay and 0–150 g of 16% protein concentrate food daily, depending on condition score. All animals should have constant access to clean fresh water.

## Laboratory procedures

### Handling and training

The key to catching and handling sheep and goats in a confined space is to move calmly and confidently. Once acclimatised to humans, the animals should be handled with the minimum frequency that is compatible with experimental success. The increasing use of telemetry for physiological monitoring and even blood sampling which requires minimal restraint and creates animals who are their own 'mobile labs' is to be greatly encouraged, although the cost of such systems is high.

Nervous animals may need two catchers in a large pen. Guide the animal into a high-walled corner with no protrusions. Reduce freedom of movement gradually until the animal can be grasped firmly with one hand under the chin

and the other used to draw the body against the handler's legs. Resist the temptation to make a wild lunge if an animal tries to escape, but rather let it go and begin again. Do not grab or hold animals by the fleece, ears or tail, as they will struggle and injure themselves. Goats are so inquisitive that they often approach handlers (especially those with a food bucket) and can be caught easily. Once the head is held, the body of a sheep or goat can be pressed gently against a wall with one knee against the lumbar vertebrae in front of the hip and the animal thus restrained by one person.

Some procedures may require an animal to be cast (tipped over onto its rump). To cast a sheep or goat first turn the head round horizontally using mild to moderate force until the neck is bent and the head faces towards the tail. Then apply moderate downward pressure on the rump, back and turn the animal away from the head around a bent knee, and the animal should fall to the ground. The head and shoulders may then be lifted and held between the handler's knees with the animal on its back (Figure 34.5).

Beware rams and billy goats! These animals are larger than ewes and nannies and may elect to charge rather than run, especially when sexually active. Horned males are potentially dangerous.

Sheep and goats which have been treated gently by diligent staff using positive reinforcement techniques respond well to regular handling and this facilitates efficient and stress-free completion of tasks. Nervous or newly acquired animals require particular patience which will eventually benefit all. Comprehensive guides to shepherding sheep and handling goats are provided by Holmes (1991) and Mews and Mowlem (1991).

### Recording body temperatures

Measurement of an animal's temperature is usually done using a lubricated clinical thermometer inserted into the rectum.

### Administration of medicines

#### Oral

Liquids can be given to sheep and goats using a strong smooth-sided bottle or dosing gun introduced gently into the diastema (the gap rostral to the premolars). A calibrated dosing gun may also be used. Plastic syringes are easily chewed and destroyed. The head should be held steadily and tilted slightly upward. Liquids should be dribbled in slowly and animals allowed to swallow. The process must be stopped at the first sign of choking. This method always results in some spillage. Stomach tubing requires a mouth gag and is a skilled procedure. Some substances may be delivered in accurate dosages using rumenal boluses.

#### Injections

Subcutaneous injections should be given under the loose skin above or behind the scapulae. Short needles (less than 25 mm with a diameter 0.4–1.2 mm, 23–18 G (for oily liquids)) are suitable. Intramuscular injections may be given into the

(a)

(b)

(c)

(d)

(e)

**Figure 34.5** Restraining and casting sheep. (a) Restraint. The animal's head is held by the lower jaw, with the thumb passing through the diastema (a natural gap in the dental arcades behind the incisors and before the premolars). The body is restrained between the handler's knee and firm pressure from the hand in opposing sublumber fossae (the depressions in the flanks behind the ribcage and in front of the hip bones). For additional control the animal may be backed into a corner or gently pressed against a wall with a knee in one sublumber fossa. (b) Casting. The animal's head is turned away from the handler in a horizontal plane so that it points towards the tail, using moderate force. The hindquarters are kept under control using the knees and the spare hand without pulling on the wool. (c) The animal is pushed backwards using the hand controlling the head, and rotating the body in a horizontal plane around the knee in the sublumber fossa, using downwards pressure with the hand placed on the animal's flanks. The sheep will collapse to the ground. It is important that this stage is performed quickly to prevent the animal from adjusting the position of its feet, which will enable it to remain standing. Practice is required. (d) The grip is transferred to the forelegs (moving the hand that was on the flanks first) and lifting the ewe's forequarters. The animal is lifted using the knees and not the back. (e) The animal is held resting on its tail with the shoulders gripped between the handler's knees. Inspections of the animal's feet and undersurface are now possible.

gluteal muscles caudal to the tuber coxae, the quadriceps muscle groups in front of the femur or the muscle bellies dorsal to the neck vertebrae in the midpoint of the neck; 25 mm needles of 0.8–1.2 mm diameter (21–18 G) are suitable. Injections into the muscle behind the femur should be avoided as there is a risk of damaging the sciatic nerve. Intravenous injections may be given and intermittent blood samples withdrawn using a 0.8 mm, 21 G (small volume) to 1.6 mm 16 G (large volume) needle inserted into the jugular vein. Vacutainer systems can be a convenient alternative for taking blood samples, and also allow immediate mixing with anti-coagulants if required.

If repeated access to the blood stream is required an indwelling catheter should be placed in the jugular vein using a sterile technique under local anaesthesia. By far the best method is that described by Seldinger (1953) and Harrison (1995), which involves passing a wire through a needle and into the vein, which, after withdrawal of the needle, acts as a guide over which a nylon, vinyl or silastic catheter may be passed and sutured in place. See Joint Working Group on Refinement (JWGR) (1993) for guidance on limits to blood volume that can be acceptably withdrawn.

### Anaesthesia and surgery

Anaesthesia of sheep and goats, including premedication and post-operative analgesia has been described by Flecknell (2009). Due to the large capacity of the gastrointestinal tract, it may be necessary to deprive animals of food for 24–48 h and water for 12–24 h prior to surgery. This reduces gas formation in the rumen and passive regurgitation of fluids when the animals are lying prone. Hungry animals may eat their straw bedding during the pre-surgical phase, so this should be removed.

A cuffed endotracheal tube must always be used when sheep or goats are kept under general anaesthesia, to prevent rumenal fluids or saliva (which is copiously secreted) from entering the trachea. A laryngoscope is necessary to visualise the larynx over the large dorsum of the tongue. After intubation a slight incline to the surgical table allows the head to be lower than the body and will help secretions to drain from the mouth.

Pressure on the diaphragm and the great veins due to the weight of the rumen contents or from the accumulation of rumenal gas (bloat) is a hazard of all ruminant anaesthesia. It may be helpful to pass a stomach tube into the rumen to reduce this risk during long operations. Surgical preparations commonly used in research are described by Harrison (1995). Techniques for placement of probes or cannulae into specific areas of the central nervous system and making electrophysiological recordings or measuring *in vivo* transmitter release have been described in detail elsewhere (Fabre-Nys *et al.* 1991; Kendrick 1991; Kendrick & Baldwin 1991).

### Euthanasia

Sheep and goats may be humanely killed using an intravenous injection of pentobarbital (150 mg or more/kg body

weight). If suitable equipment and expertise is available then shooting a captive bolt directly into the brain is an acceptable alternative, bearing in mind that the approach must be from directly above or behind the skull, not between the eyes (Humane Slaughter Association, 2006). Once unconscious, great vessels should be severed. The booklet *The Casualty Sheep* (Sheep Veterinary Society 1994) provides further details of all methods of euthanasia, and see also Chapter 17.

### Common welfare problems

Assessing the health and welfare of any stock must be based upon a sound knowledge and experience of what is normal. Signs of ill-health might include an elevated temperature (over 40°C is a cause for concern), reduction in appetite, changes in behaviour, colour change of the mucous membranes (pale pink is normal), a cessation of rumination or abnormal discharges from mouth, nose, eyes, ears, anus or genitalia. Sheep and goats lagging behind the flock when driven should be caught and examined. Animals in pain or distress may be reluctant to rise, display an abnormal posture and often grind their teeth noisily. Although harsh and laboured breathing is an indication of respiratory disease, moderate hyperventilation can be deceiving in the sheep as healthy animals tend to breathe more rapidly than other species, especially when being handled. Likewise, the heart rate may be considerably elevated in a normal but nervous animal.

### Common diseases

Sheep and goats are susceptible to a wide variety of diseases. Many of the more common diseases are preventable using vaccination (for example clostridiosis, pasteurellosis, contagious pustular dermatitis (orf), and infectious abortion caused by *Chlamydophila* and *Toxoplasma*) or prophylaxis (for parasitic infestations including coccidiosis). Wherever a particular disease is known to occur, preventative steps should be taken in preference to treatment after the disease appears. Contagious pustular dermatitis and chlamydia abortus are amongst the more worrying zoonoses transmissible to humans. Other potential zoonoses include toxoplasmosis, louping ill, listeriosis, campylobacteriosis, leptospirosis, Q fever and salmonellosis.

The following brief outline of the more common clinical signs and diseases of sheep and goats is intended only to introduce the reader to the complexity of the subject. For a general introduction to sheep management and disease, *The Veterinary Book for Sheep Farmers* (Henderson 1990) is useful, whilst *Diseases of Sheep* (Aitken 2007) is the standard reference work in the UK. Amateur diagnosis and treatments should never be attempted: a veterinary surgeon should be consulted.

### Weight loss

Weight loss in a group of animals is usually due to poor diet, poor teeth or parasitism by intestinal nematodes or liver

flukes. Nutritional deficiencies may occur as a result of diets with insufficient carbohydrates, proteins, minerals such as cobalt, or vitamins, or a combination of these. Weight loss may, of course, also occur if the diet has an adequate composition but is fed in inadequate amounts. The dietary requirements of growth and pregnancy must be considered. Weight loss in individuals may be the result of any chronic condition; for example, lameness, abscessation, maedi-visna, Johne's disease, caseous lymphadenitis, ovine pulmonary adenomatosis or rarely a tumour.

### Diarrhoea

Diarrhoea is usually a consequence of over-feeding, intestinal parasitism or coccidiosis. Diarrhoea in lambs is frequently associated with bacterial infections and can result in a rapid deterioration in condition due primarily to dehydration. Bacterial infections are less commonly a primary cause in adult sheep. It is important to encourage fluid intake whilst awaiting a diagnosis.

### Nervous signs

Nervous signs and ataxia owing to disease processes are relatively common in sheep and goats of any age. A wide variety of causes exist, such as thiamine deficiency, copper deficiency, scrapie, listeriosis, plant or chemical poisoning, brain space-occupying lesions due to tapeworm cysts, abscesses or tumours, louping ill, metabolic disorders, etc. Some conditions may progress to convulsions or coma (see later). Accurate and early diagnosis is essential.

### Intestinal worms and liver flukes

Most adult sheep and goats carry a limited burden of these parasites, which with proper treatment and management are not clinically significant. Clinical disease is more often seen in young stock. In all cases, to minimise the impact of worms on animal health it is necessary to pay careful attention to pasture maintenance. Significant numbers of infective nematode larvae can develop, even on fields used only for occasional grazing, if the adult stock are inadequately wormed, pasture access is not properly rotated or stocking density is too high when animals are allowed access. This can make small paddocks adjacent to research facilities which are used for animal exercise potentially dangerous locations for unprotected grazing animals. Nematode resistance to wormers (anthelmintics) is an increasing problem worldwide, and appears to be particularly prevalent in goats. A strategic control programme should be developed. Boggy areas of pasture should be drained to discourage the snails that act as intermediate hosts for liver flukes.

### Foot care

Animals housed indoors for prolonged periods tend to develop overgrown hooves. Overgrown hooves lead to lameness, bad posture, cracking of the hoof wall and infection running into damaged white line areas. Animals at pasture are susceptible to damaged feet produced by poached soils, sharp stones and the like. Such damage pre-

disposes to interdigital dermatitis (scald) and to footrot, caused by *Dichelobacter nodosus*, which is a common and debilitating problem worldwide. All sheep and goats should therefore be turned regularly (see the section on handling for techniques) the feet cleaned and hoof walls pared as necessary by a skilled person. Beware over-paring and causing damage to the sensitive structures of the hoof, as this can lead to permanent lameness. Standing sheep and goats with clean feet three to four times a year in shallow non-irritant footbaths containing 10% zinc sulphate solution (followed by a period on concrete to allow the chemicals to dry) helps to maintain strong disease-free hooves. The likelihood of wet and damaged pastures precipitating foot problems is particularly high in areas of high rainfall, and strong consideration should be given to housing animals indoors over winter in such locations.

If access to the outside is intended to be for exercise only on a daily basis, and space is limited, a concrete floored yard may be better than a pasture. These are washable, will help to stop hooves becoming overgrown and will not retain a significant worm burden. Pasture is of course preferable but needs more work and a bigger area to keep a given number of animals healthy and contented. Further information on the important topic of foot care in sheep can be found in *Lameness in Sheep* (Winter 2004).

### Shearing and fleece care

Sheep are normally shorn annually in the late spring. It is advisable for animals with surgical preparations, such as rumen fistulae, cranial implants or blood vessel loops, to be shorn separately from the main flock and with great care. Policies of regular control measures should be put in place to control or prevent skin parasites, especially sheep scab (caused by a *Psoroptes* mange mite), and blowfly larvae (maggots) which are prevalent during the summer. As with worming and foot care, animals under experiment or permanently housed indoors should not be excluded from routine skincare treatments. Housed sheep and goats are particularly susceptible to infestations by lice.

### Special health problems

Occasionally sheep and goats will present with veterinary problems with a rapid onset that are immediately life-threatening or very serious.

1. Rumenal bloat. A grossly dilated abdomen is seen, accompanied by rapid shallow breathing and eventual collapse.
2. Urolithiasis. This is particularly common in young male kids and rams. A rigid stance and inability to urinate freely are characteristic. Sometimes urine can escape in small quantities which stains the coat around the penile sheath. Excessive straining may cause a rectal prolapse and if this is seen in a male animal urolithiasis should always be suspected.
3. Poisoning or metabolic disorders caused by ion imbalance. These diseases may be difficult to distinguish. Signs including hyperexcitability or deep depression, tremors and convulsions may all be seen in one or more individuals.

4. Diseases caused by clostridial organisms. Very high rectal temperatures (42°C or more) and rapid deterioration in condition are seen, leading to recumbency and death.
5. Obstetrical problems.
6. Acute mastitis. Signs are a discoloured udder, thin, blood-coloured milk, high temperature and a very sick animal.
7. Acute pneumonia. Often occurs following stress, with *Mannheimia* (formerly *Pasteurella*) species predominating. Animals have a high temperature and severe respiratory distress. This can be confused with heat stress following transport in a poorly ventilated vehicle.

Extreme clinical signs of these types should be recognisable to technicians and help sought immediately.

## Acknowledgement

The authors would like to thank Chris Trower, secretary of the Laboratory Animals Veterinary Association and past President of the Sheep Veterinary Society (both organisations affiliated to the British Veterinary Association) for his helpful comments and amendments to the text.

## The horse

Fernando Montesso

### Biological overview

#### Introduction

The horse was domesticated around 2500 BC. Its relatively compliant behaviour, together with its speed, agility and strength, gave it a unique role amongst domesticated animals. Because it could be trained to harness or the saddle, the horse provided humans with a means of transport and traction for work, war or recreation.

With the increasing use of the internal combustion engine in the early part of the twentieth century, the number of horses declined and, with it, equine research. However, over the past 50 years, horse numbers have steadily increased because of the renewed interest in using horses for recreational purposes. This has led to greater equine research into diverse areas such as nutrition, reproduction, sports injuries, infectious diseases and welfare. Although the ultimate beneficiary of this research is the horse, horses are also used for the production of hyperimmune antiserum for humans and animals and also for production of conjugated oestrogens for use in human medicine.

#### Social organisation

Horses are herd animals and, in the feral state, live in small family groups with a clearly defined hierarchy. Social facilitation (same, or similar, behaviour initiated as a response to the occurrence of a behaviour by another animal within the social group) is common both within and between groups, and the pattern of behaviour involved includes resting, grazing, walking, rolling, eliminative behaviour (defecation and urination) and sucking. Mutual grooming, although usually a response to the irritation caused by ectoparasites or coat shedding, is also an important form of social contact (Tyler 1972; Crowell-Davis 1986).

The individually stabled horse is denied these social interactions, and this may contribute to the development of abnormal behaviour such as box walking and weaving. However, the attention given to stabled horses, for example daily grooming by knowledgeable and sympathetic stable attendants, may provide some compensation to horses for the reduced social interaction with their own species, but are not complete substitutes.

When kept at pasture or housed in groups, the group size is often larger than in a typical horse herd, and is not a

family group, but consists of horses introduced as adults. This results in social reorganisation, and on occasion, to fighting when the groups are first formed or when they are crowded together. Injuries are likely if there is no room to escape, and at feeding times subordinate horses may be denied access to food (Haupt 1991).

#### Biological data

Normal biological values are summarised in Table 35.1. The first, second and third permanent incisors erupt at 2.5 years, 3.5 years and 4.5 years, respectively. All permanent teeth (incisors, premolar and molars) are present by 4.5 years. A horse's height is traditionally measured in hands, one hand being equal to 4 inches (1 inch = 2.54 cm). The measurement is taken from the ground level to the highest point on the horse's withers. Horses range in height from about 60 cm (6 hands) to more than 173 cm (>17 hands). They frequently remain fit and active into their twenties and some will live in excess of 30 years.

Because of the stay apparatus of the hindlimbs, adult horses can rest and sleep while standing, but rapid eye movement sleep can only occur when the horse is in sternal or lateral recumbency. They enjoy rolling, especially in mud and dust, and stabled horses will frequently roll in their beds if still warm and sweaty from exercise.

They change their coat twice yearly in the spring and autumn. The winter coat usually provides sufficient protection from inclement weather for most native breed horses not in work in northern temperate areas, though field shelters or wind breaks should be available. If living out, the winter coat should not be groomed as this would remove secretions which assist in keeping the animal warm and dry. In more extreme climates, horses are usually housed during the winter months. A full winter coat would result in excessive sweating during ridden work, and so it is customary to clip the winter coat off and rug the horse. Clipped horses should also be housed, though they can be turned out, suitably rugged, into paddocks for a short period every day during the winter months.

#### Reproduction

Mares first show signs of oestrus at puberty (about 18–24 months of age) and continue to cycle until 20–30 years old.

**Table 35.1** Normal biological values for horses.

Parameter	Value
Rectal temperature (°C)	38 ± 0.5
Resting pulse (beats/minute)	25–45
Respiratory rate (breaths/minute)	8–12
Permanent teeth	$I^3_3 C^{*1}_1 P^{3or4}_3$ $M^3_3$
Deciduous teeth	$I^3_3 C^0_0 P^3_3 M^0_0$

\*Rare or rudimentary in mares.

†First premolar (wolf tooth) is vestige and remnant of a tooth well developed in ancestors of the horse. Often shed, but if retained and thought to be associated with biting problems, it is usually removed by a veterinarian.

The majority (80%) of mares are seasonally polyoestrous with regular cycles during the breeding season (spring–summer) and a period of sexual quiescence in the winter months. Daylight length (photoperiod) is the most important regulating factor, increasing daylight length in the spring in temperate regions being the main stimulus for the initiation of ovarian activity. However, even at the equator, where day length is approximately 12h throughout the year, mares show a definite seasonal pattern to oestrus. Good nutrition and housing to protect mares from harsh weather conditions will increase the likelihood that they cycle and ovulate normally at the beginning of the breeding season (van Niekerk 1992). The breeding season, under natural conditions, for example in pony herds, is usually later than that artificially imposed on Thoroughbreds where the idea of producing foals as near as possible to January 1<sup>st</sup>, the official birthday of all Thoroughbred racehorses, is aimed for at stud farms.

Spermatogenesis starts during the second year of life in colts receiving adequate nutrition, and the testes are usually functional by 2 years of age. Colts of less than 2 years of age have lower sperm production rates than older stallions, and rates in the non-breeding season are about 75% of that in the breeding season (Thompson 1992).

## Normal behaviour

Healthy equids are active and alert. When stabled they frequently nicker or whinny to their attendant, particularly at feeding time. They are usually keen to eat, and some will paw or kick at the stable door whilst waiting to be fed. Some horses will also weave (see Abnormal behaviour) whilst waiting for feed. Some horses, especially entire males, will lay their ears back and swish their tails as the attendant enters the box with feed. This aggression may be feigned or real: if the latter, care must be taken when feeding the horse if injury to the attendant is to be avoided, and the reasons why this behaviour is being displayed should be investigated. Horses urinate about six times daily and defecate approximately every 2h. Attendants should check faecal consistency and quantity automatically as they clean the stable, as any changes from the normal pattern could be indicative of illness. They should also note the state of the

bedding: evidence of excess activity could indicate distress, for example due to colic. Alternatively, the bed may be relatively undisturbed, indicating that the horse had not lain down in sternal or lateral recumbency to rest.

When at pasture, horses usually graze as a group and an animal separated from the group may be unwell. When resting, at least one number of the group often remains standing whilst the remainder rest in sternal or, if warm and sunny, in lateral recumbency. Before getting up, horses frequently roll. Once up, they will often stretch and shake themselves before moving off to start grazing. Whilst in groups at pasture, the affiliations between pairs of horses will become obvious, as they usually graze together and mutually groom. Attendants should be aware of these relationships so that they are allowed to continue during the winter housing period: accidental splitting up of these affiliations can be stressful and so should be avoided.

## Uses of horses in research

The majority of equids used in research are bought in from outside sources. However, there is occasionally a need to breed them within an institute, for example, when helminth-free foals and weanlings or horses with a specific blood type are required. Sound, ex-racehorses are a good source of animals for use in exercise physiology research, as they are adjusted to stable routines and training procedures. Having been handled frequently since the early stages of life, they are usually amenable to most minimally invasive procedures such as the collection of blood samples.

Ponies are frequently used in behavioural studies, in reproductive physiology, pharmaceutical, infectious diseases and nutritional research. The Welsh Mountain pony is a well established breed used in research. These ponies are small, hardy and overall have a very good and easy temperament, adapting quickly to new routines and procedures. As they are usually obtained directly from breeders or dealers, they may have had minimal exposure to humans and will need regular handling and training to ensure they accept being restrained during common procedures, including routine husbandry measures such as farriery.

Blood and serum production horses are usually former recreational horses, which may not be able to work at the level expected of them because of an irreversible injury such as a tendon strain or joint damage. They should, however, be healthy and capable of light exercise without discomfort.

## General husbandry

### Housing

Traditionally the horse has been housed individually in loose boxes or communally. A modern variation on the individual loose box is the American barn style of housing (Figure 35.1), which comprises rows of individual loose boxes under a single roof. Unlike the traditional loose box where the partitions between the boxes are usually solid from floor to ceiling, the upper half of the boxes in the

**Figure 35.1** American barn.

**Table 35.2** Types of housing suitable for horses and their advantages and disadvantages.

Type of housing	Advantages	Disadvantages
Loose box	Freedom of movement Individual air space Visual contact if top half door open Can provide thermal comfort and good ventilation	Solitary confinement Reduced visual contact Labour intensive Extensive use of bedding material
American style barns	Freedom of movement Easier working conditions for staff Visual and some social contact (through bars)	Shared air space Ventilation often inadequate
Loose yarding	Freedom of movement Full socialisation possible Less labour intensive	Shared air space Aggression especially at feeding may lead to injuries. Timid horses may be denied food

American barns are not usually solid and comprise vertical bars or metal mesh. Horses can also be kept loose in groups, in barns similar to those used for cattle. The advantages and disadvantages of the various types of housing are summarised in Table 35.2.

Statutory recommended minimum floor areas for individually housed horses are illustrated in Table 35.3. These are minimum permitted dimensions in the UK listed by the Home Office (1989). For the revised guidelines for accommodation and care of animals used for experimental and other scientific purposes from the European Commission (2007) please refer to Annex II of European Council Directive 86/609 (see 2007/526/EC) (European Commission 2007, also Council of Europe 2006).

**Table 35.3** Dimensions recommended for housing horses in loose boxes (Home Office, 1989). Note that housing may be subject to statutory requirements in some countries.

Height of horse at withers	Minimum floor area when housed individually
Up to 147 cm	12 m <sup>2</sup>
148–160 cm	17 m <sup>2</sup>
>160 cm	20 m <sup>2</sup>

Three-sided field shelters should be provided for horses and ponies at pasture and 1.6–2.5 m<sup>2</sup> of space should be allowed in these per 100 kg liveweight. The shelter should face the sun and be bedded in cold regions, and should face away from the sun in hot regions. Feeding racks should be situated outside the shelters in a protected position. Four-sided windbreaks (Figure 35.2) or natural hedging sufficient to supply shelter from driving weather and the prevailing wind can be used for native ponies kept outside.

### Housing and respiratory disease

A major drawback of all housing for horses is the potential for respiratory disease. The stabled horse is exposed to a variety of airborne contaminants (viruses, bacteria, fungal and actinomycete spores, dust mites, noxious gases such as ammonia, and plant material). Infectious causes of respiratory disease can spread rapidly through a population of housed horses, particularly when they share air space, and although vaccines are available, they are limited in their spectrum and duration of effect. Lower airway inflammation can affect young and old animals. Recurrent airway obstruction (RAO) – referred in the past as chronic obstructive pulmonary disease (COPD) – usually affects middle-aged animals (7 years old or more). Inflammatory airway disease (IAD) affects horses of any age. In young horses it is usually associated with bacterial infection, however, non-infectious IAD can occur in horses of all ages and ways of life (Allen & Franklin 2007). RAO is a pulmonary hypersen-

**Figure 35.2** Four-sided windbreak to shelter animals kept outside.

sitivity to inhaled allergens present in hay and straw. The allergens are the spores of fungi and actinomycetes, and these are the major constituents of respirable dust in stables. They are usually less than  $5\mu\text{m}$  in diameter, and remain antigenic after death. Concentrations of airborne pollutants can be reduced by increasing clearance rates (mainly by ventilation) and by reducing release rates, by modifying the source materials, namely hay and straw. Ideally both approaches should be used. The specific cause of IAD is still unclear and it is likely that several factors are involved.

#### Optimising air quality in stables

When bedding management is good, a minimum of four air changes per hour, under still air conditions, is required to ensure optimal ventilation (Webster *et al.* 1987). Well designed loose boxes, with the top half of the stable door open, provide this. In very cold weather, it is better to provide the horse with extra rugs and to resist the temptation to shut the top door, as the number of air changes per hour will drop to dangerously low levels. Ventilation rates in barns are usually poorer, but can be improved by either providing draught-free inlets (at least  $0.3\text{m}^2$ ) on the outside wall of each box, or by using spaced vertical boarding (Yorkshire boarding) along the walls starting 2m above the ground.

Modifying source materials, such as hay and bedding, is the second important means of optimising air quality. Some degree of fungal contamination is present in all hays. Lucerne and clover hays, despite the high price they command, can be heavily contaminated. Totally immersing the hay, contained either in a haynet or other suitable receptacle, in water for 12h will minimise the respirable challenge, though any spores present will still be ingested. Cleaner alternatives to hay are haylage and silage, both of which must be packed airtight at harvesting, and used within a few days of opening. These alternatives are to be recommended if hay quality is suspect, and for routine use in animals with respiratory disease. Feeding hay from floor level is the most natural way for the horse to eat, encourag-

ing good natural posture. The other major source of fungal spores is bedding. Straw baled when damp is as dangerous as heated hay. Horses prefer straw bedding and it may act as a stimulant for investigatory behaviour. Alternatives to straw, such as wood shavings, peat moss and shredded paper, may be poorer in terms of enrichment. Whilst these are practically free of fungi when fresh, they too can become heavily contaminated in poorly ventilated stables and in deep litter systems. Commercially available non-biological bedding material such as rubber matting is clean, thermally efficient and does not provide a medium for fungi, but is even more barren behaviourally. The risk of stabled horses developing allergic respiratory disease and the recovery time from infectious causes of respiratory diseases can be reduced by ensuring ventilation is optimal, by feeding good-quality dust-free hay, silage or haylage, by managing bedding well (daily removal of dropped hay, faeces and urine-soiled straw) and by avoiding 'dust raising' procedures, for example shaking out fresh straw bedding while the horse is in the stable.

#### Exercise

Horses and ponies not in work, but kept at pasture or loose yarded when housed, will usually get sufficient exercise for their needs. The individually stabled horse in work will benefit from being kept loose in a paddock or arena for as much time as practicable. However, there are situations where specific provision must be made for some form of daily exercise: for example for horses used for serum and/or blood production and which are individually housed during the winter months, and horses or ponies being raised helminth-free and thus denied access to pasture. For these animals it is just as important that exercise and social interaction are part of the daily routine, and they can be turned out in small groups into winter grass paddocks, sand or peat arenas for at least 1h daily. This will allow them to have complete freedom of movement and to interact socially with each other, although care must be taken to ensure compat-

ible grouping if injuries are to be avoided. Other forms of non-ridden exercise are lungeing, where the horse is exercised on grass or other suitable surface on a circle at the end of a long lead, or the use of horsewalker machines. Lungeing is labour intensive, whereas horse walkers allow several horses to be exercised at once. Both, however, are poor substitutes for the freedom provided when the horse is turned out loose.

### Hoof care

The growth rate of horses' hooves depends on age, season and nutritional status, and is normally faster in young horses and in the spring. The average rate of growth is about 10mm/month (Butler 1992). The feet should be inspected daily and trimming should be done as regularly and as often as is necessary. Although a 6-week interval is the average for many horses, it can vary from 2 weeks to 2 months. Horses in work require shoeing, as they invariably have to exercise on hard surfaces. However, serum-producing horses and ponies rarely require shoeing and, if being kept in groups, should never have hind shoes on because of the risk of causing serious injury from kicks. Foals should start to have their feet trimmed when about 1 month old, or earlier if they have limb deformities, many of which can be corrected by foot trimming and exercise alone. During dry weather, horses at pasture may develop vertical cracks in the feet and require regular foot rasping or even the application of a light shoe to limit damage. Stabled horses should have their feet cleaned and examined at least once daily.

Puncture wounds of the foot with the subsequent development of a subsolar abscess are a common cause of acute lameness, and require immediate treatment by a farrier or a veterinarian.

### Identification

Horses usually differ sufficiently in their colour, markings and conformation for individuals to be recognised, even within a breed. Under current European Union legislation, all horses, ponies and donkeys must have a horse passport which is a permanent record of colour distribution, together with the position of whorls (areas where the hairs are radially arranged). Other permanent methods of identification, which can act as a deterrent to thieves, are freeze branding and microchips.

### Management of newcomers

All newcomers should be isolated from the resident horse population for a minimum quarantine period of 3–4 weeks before they join the resident population. A full clinical examination, including a routine blood examination, should be conducted as soon as possible after arrival. The collection of nasopharyngeal swabs once a week for three consecutive weeks for *Streptococcus equi* profile is recommended as 'strangles' is common in animals being sourced from dealers. Teeth should be checked and rasped if necessary. Hooves

should be checked and the hind shoes removed if the horse is to be group housed or at pasture with others. Vaccination against tetanus is essential. The administration of other vaccines will depend on the research programme the horse is entering; for example it would be contraindicated in vaccine research. Unless there is specific reason for not doing so, incoming animals should be treated for endo- and ectoparasite infections. Colts may need to be castrated if they are to be group managed.

### Transportation

Horses and ponies are usually transported in purpose-built motorised horse boxes or trailers, though they may also be transported in modified cattle lorries. Broken, adult horses should be fitted with a strong, properly fitting headcollar (halter) and are usually loosely tethered. If shod, their lower limbs should be protected from tread injuries by the application of either woollen bandages (stable bandages) on top of cotton wool or a similar material or purpose-made padded leggings, from below the knee or hock to the coronet. Kneecaps will protect them from injury should they stumble and fall during loading and unloading, and poll guards, hock guards and tail guards are other protective items of clothing that may be used. When transporting mares and foals, each mare and foal usually occupy the area needed for two adult horses. The mare is usually loosely tethered, the foal not. Foals adapt remarkably well to being transported so long as they are in close proximity to their dam and they frequently suck during travel. Short rest periods (10 minutes for every hour of the journey) should be provided during longer journeys. Unbroken ponies are best transported loose in small groups.

Patience and care are needed when loading and unloading both experienced travellers and unbroken animals if injuries are to be avoided. The ramps of the vehicles should have a non-slip surface and sidewings to ensure that the horse walks down the middle of the ramp: as horses have an aversion to stepping on such surfaces, the floor of the box should be covered with straw or other suitable material. Studies have been undertaken to try to clarify the effects of forward and rear-facing travel. Works from Clark *et al.* (1993), Smith *et al.* (1994) and Waran *et al.* (1996) found that there was some benefit from rear-facing travel for some horses. Later studies by Collins *et al.* (2000) and Toscano and Friend (2001) found that neither orientation when travelling had a clear overall effect. The individual preference to which direction to face when being transported seems to play a part but the reasons for their choices are not clear.

### Breeding

General reproductive features of the mare (average values) are summarised in Table 35.4.

Stallions are used to detect oestrus in mares, though some mares will indicate receptivity to geldings grazing with them. Teasing can either be done on an individual or group basis. With the former, the mare is separated from the stallion by a padded, solid barrier. The barrier should be about

**Table 35.4** Reproductive features of the mare.

Parameter	Normal value
Onset of puberty (months)	18–24
Oestrus cycle (days)	
In spring	25 (range 9–50)
In late spring/summer	20.9
Duration of oestrus (days)	5–7
Duration of dioestrus (days)	14–16
Ovulation (days before end of oestrus)	1–2
Foal heat (first oestrus post-partum) (days)	9 (range 5–18)

the same height as the withers, so that limited physical contact is possible. With the latter, the stallion can be led past the paddocks where the mares are grazing. Alternatively the stallion can be placed in a small pen near the paddock.

The mare in oestrus adopts an urination posture where the hindlegs are extended backward and the tail is raised. Small amounts of urine are expelled and the clitoris is exposed in a rhythmic fashion ('winking'). The intensity of the signs of oestrus varies considerably between animals. They increase progressively during oestrus and are maximal as ovulation approaches; some mares are very reluctant to be separated from the stallion at this time. In contrast to this, the mare in dioestrus shows hostility to the stallion by biting, kicking and laying her ears back. Mares which are overly protective of their foals, even when in oestrus, will sometimes display hostility to the stallion, particularly if their foal is within earshot.

Mating ('covering') is usually carried out with the mare and stallion suitably restrained. Both should be bridled, and covering should be done in an enclosed area with a good surface so that neither the mare nor the stallion are likely to slip. Hind shoes should always be removed from the mare. When using valuable stallions, it is customary to fit felt boots to the hindfeet of the mare to prevent injury to the stallion. A nose twitch may be applied for additional restraint if necessary (Figure 35.3). If the mare has a foal at foot, it should be kept out of sight and earshot during mating, in a loose box with the top half of the door shut. As the results of teasing are not always conclusive, the optimum time for mating can be determined by veterinary examinations per rectum where the ovaries, uterus and cervix are palpated, and/or by scanning using ultrasonography, or by vaginal examination using a speculum where the colour and state of relaxation of the cervix are determined.

Pregnancy can be confirmed using several techniques. Ultrasound echography, using an ultrasound probe carried into the rectum and directed over the uterus, can be used to detect pregnancy as early as 14–16 days post-conception. Repeated scans are essential, as early pregnancy failures can occur. Scanning should be used in conjunction with the other methods of pregnancy diagnosis, for example manual palpation, per rectum, of the uterus. The changes experienced with manual palpation are described in a review by Sharp (1992). This examination should only be performed by trained personnel. Biochemical tests for pregnancy are available commercially if the technology and/or expertise

**Figure 35.3** Nose twitch for restraining. Other types of twitch with rope or chain loop can also be used.

for ultrasound and palpation techniques are not available. The most useful test is the measurement of equine chorionic gonadotrophin (eCG) in the plasma. This test can only be done after day 40 of pregnancy and is not effective after day 120. False positives can also occur. Although not as infallible as a pregnancy test, teasing of pregnant mares can be used.

#### Management of the in-foal mare

In-foal mares should lead as natural a life as possible. In temperate areas, they are usually at pasture by day and housed by night. In warmer climates, they can remain at pasture 24h per day. Shelter from sun and insects may be required. Their nutritional needs will increase as the pregnancy progresses, and increasing amounts of concentrates are usually fed to meet these, particularly in the latter third of pregnancy. However, they should not be allowed to become fat as over-fat pony mares, in particular, run the risk of developing hyperlipaemia in late pregnancy if their management is suddenly changed; for example, a sudden fall in energy intake. They should be up to date with their tetanus and influenza vaccinations. Mares should also be vaccinated against equine herpesvirus 1 and 4 according to the manufacturer's recommendation, to help reduce clinical signs of respiratory disease and abortion caused by this virus. Routine anthelmintic treatments should also be given (see later).

#### Preparation for foaling

In temperate climates, mares are normally foaled indoors where they can be observed frequently and easily, and given assistance if needed. Pony mares and mares in warmer climates are often left to foal outside. They should still be closely observed as parturition approaches, and lights can be used to provide some illumination of the foaling paddocks. Mares foaling inside should be provided with as large a loose box as possible (a minimum of 30 m<sup>2</sup>): it should have a deep, clean bed, and the bedding should be extended and banked up along each wall to provide further protec-

tion. Hay should be fed off the ground and mangers and water buckets are better at chest height. Small red light bulbs (10 Watts) will provide sufficient light for observation without disturbing the mare. Closed circuit television can be used to observe when the mare or mares are due to foal at the same time. Foaling alarms are available commercially and can work as an aid to alert the staff when birth is imminent.

### Parturition

Mares usually foal at night, and seem to be able to delay foaling until conditions are right for them, for example when the stable yard is quiet. They seem to prefer to foal unobserved: hence any lighting should be dim. Signs of impending parturition are not consistent and can only serve as a rough guide. Udder development starts 3–6 weeks pre-foaling, and distension of the udder with colostrum occurs in the last 2–3 days. When colostrum begins to ooze from the teats and forms honey-coloured wax-like beads at the teat orifice ('waxing'), foaling is imminent. Mares can deviate from the predicted foaling date by 1–2 weeks or more. This is quite normal and does not require veterinary intervention: each pregnancy is a unique combination of maternal and foetal traits, and will be terminated at the appropriate time (Sharp 1992). The various stages of parturition and their main presenting signs are given in Table 35.5.

Foaling is a normal physiological process, and attendants should be sufficiently acquainted with the normal pattern of foaling and resist the temptation to interfere unnecessarily. However, as parturition is very rapid in the mare compared with other domestic animals, experienced veterinary help should be readily available should it not proceed normally. Swift intervention is necessary if premature separation of the allantochorion is likely, as may occur if delivery is delayed. Any traction applied to the foal should coincide with the mare's own efforts at expulsion. The amniotic sac may be manually ruptured if it has failed to do so after the foal is delivered. The mare should be left undisturbed and

allowed to rest after foaling. The umbilical cord should be left to break naturally to allow passage of placental blood to the foal; this could take several minutes. Excessive human activity will stimulate the mare to rise too soon, and in nervous primiparous mares this could interfere with the normal bonding between the mare and her foal. The establishment of the bond between the mare and her foal is triggered by hormonal changes, which may be based on olfaction, as the mare licks the newborn for a few hours after parturition.

The normal healthy foal is in sternal recumbency within 1–2 minutes of delivery and a suck reflex is present within 2–20 minutes. On average, a healthy foal will take up to 1 h to stand and up to 2 h to suck. By 12 h of age it is able to walk, trot and gallop.

### Post-foaling activities

In the immediate postpartum period, the foal's navel should be dressed with 2% potassium iodide solution to reduce the chance of bacterial infection; this should continue twice daily until the navel is dry (about 48 h). It is important that the foal suckles as soon as possible (within 2 h) as absorption of protective immunoglobulins present in the colostrum is maximal at birth, marginal by 15 h and has ceased by 24 h post-partum.

Primiparous mares, in particular, may not accept their foals and may not allow them to suckle, either because of udder distension or possibly because of an association with pain at parturition. Occasionally these mares will attack their foals in addition to refusing to let them suckle. Assuming that no mastitis is present, they should be held by an attendant, with or without prior sedation, whilst another attendant helps the foal to suck.

The mare should be provided with a warm bran mash as laxative and her water buckets kept full. Tetanus antitoxin must be given to both mare and foal if the mare is unvaccinated. The mare should be checked for foaling injuries which should be stitched and repaired as necessary. The

**Table 35.5** Stages of parturition in the mare and their main presenting signs.

	Stage		
	1	2	3
	<i>Up to time of rupture of allantochorionic membranes</i>	<i>Delivery of foal</i>	<i>Expulsion of placenta</i>
Duration	Approx. 1 h	<30 min	Approx. 1 h
Activity	Uterine contractions begin; foal rotates head and forelimbs into dorsal position; allantochorion ruptures releasing fluid; amniotic membranes and forelimbs appear in birth canal	Foal completes its rotation, assumes diving position and passes through the birth canal	Continuing uterine contractions to expel the placenta
Behavioural signs	Mare increasingly restless; box walking; rolling/gazing at flanks; patchy sweating; often runs milk	Powerful abdominal contractions, usually when in lateral recumbency; may get up and down, adjusting position before the final push to give birth; profuse sweating	Mild colic signs and some straining; may move into sternal recumbency prior to expelling the placenta

foetal membranes should be examined to ensure they are complete and intact. If the foal is straining and having difficulty in passing meconium (the first faeces), proprietary enemas should be given *per rectum*. If in doubt about colostrum intake, the foal's blood IgG levels should be tested. If the weather is suitable, the foal should be haltered and led out to pasture with the mare: if not, the mare and foal should be turned into a covered arena for exercise.

If a mare dies at foaling, the foal should be given colostrum by stomach tube as soon as possible after birth. Most breeding studs keep deep-frozen supplies of mare colostrum for such emergencies. Rearing is best done using a foster mother, though foals can be reared artificially using commercially available mare milk replacers. Foals reared artificially may not grow as well as those raised by the mare, and so every effort should be made to find a foster mother. Mare's milk is lower in both protein and fat content than cow's milk, but higher in lactose. The milk replacer should be fed at a temperature of approximately 37.5°C. All utensils must be thoroughly washed and sterilised before and after use. The teat should be introduced carefully to the side of the foal's mouth and care must be taken to ensure that milk is not inhaled. The foal must therefore be given frequent opportunities to rest during feeding.

#### Post-parturient behaviour

For the first few days following parturition mares are extremely protective of their offspring. Stabled mares will rapidly circle their foals and even threaten their attendants. When outside, they will drive away other mares and foals, even if they have previously had an affiliative relationship with another mare. This protectiveness may be related to the fact that the young foal takes about a week to visually recognise its mother (Houpt 1992). A human-foal bond can be usefully established during the first few days of life, and is best done by an attendant with whom the mare is familiar and trusts.

#### Foal behaviour: early handling and training

Foals nurse about four times per hour in the first week of life: the duration of nursing increases as the foal becomes older, but the frequency of nursing decreases. If separated from their mother, even briefly, or if frightened, they will immediately nurse. Foals spend 70–80% of their time resting when very young. When they get up to nurse they generally stretch their limbs and arch their neck and back before going to the mare to feed. Since so much time is spent resting, usually lying down, it is important that young foals are not left outside in inclement weather, as they would then only rest standing. A healthy foal is normally very active, and within a few days of birth will be confidently galloping and bucking round its mother. As they get older they soon start to play with their mother and, if allowed to do so, play with other foals in the group.

Foals less than 4 weeks of age will often nibble at their mother's freshly passed faeces: this is normal behaviour thought to be important in the establishment of bowel flora and presents no hazard to the foal. The first faeces passed by foals, the meconium, are frequently difficult to pass.

However, once the foal has nursed, the laxative effect of the colostrum usually ensures no further problems. A transient diarrhoea often occurs on the foal at the time of the foal heat, the first oestrus after foaling; this usually resolves without treatment.

When first approached by humans, young foals will be nervous, try to evade being caught and may start snapping (also referred as 'champing' or mouthing). This is a submissive gesture and usually indicates fear: the foal's ears turn back slightly, the neck is stretched out, the corner of the mouth is drawn back and the jaws start to move vertically in a rhythmical fashion. This gesture is adopted by young animals when approaching older ones, including their mothers. A short time spent every day quietly talking to young foals and gently scratching their crest and along their spine will help them to relax and accept being handled. Their hooves should be picked up daily so that they habituate to the procedure. This will minimise problems with the farrier at a later stage. They should also accept being cleaned with a soft cloth all over their body in preparation for grooming when older. Handling the muzzle area and habituating the nose to a finger will help with tubing later in life. Special lightweight foal headcollars (foal slips) should be put on daily from birth onwards before the mare and foal go to pasture, and the foal taught to be led. A foal is usually led from its left side and close to its mother's left shoulder. A long piece of rope should be looped through the ring on the foal slip: if the foal should escape the handler, the rope will then pull free and not get entangled round the foal's legs.

Verbal commands should precede the physical commands so that, eventually, the voice alone is sufficient. Foals should be rewarded by scratching the withers rather than patting anywhere. If they misbehave and kick or try to kick, they should be discouraged immediately. In most cases this can be achieved by voice alone; alternatively use a slap across the pectorals accompanied by an appropriate verbal message. Other behaviour management techniques should be explored as an alternative to punishment. Colt foals, in particular, will strike out with the front feet, this should be discouraged promptly. It is better to spend time disciplining and teaching a foal 'manners' when it is small and manageable than to leave this initial training until it is 500 kg and unmanageable.

#### Weaning

As some mares will be in foal again within a few months of parturition, it is customary to wean the foals when they are about 4–5 months of age. By this age the foals are already physically fairly independent of their dams, will be grazing like adult horses, and have usually been introduced to concentrate feeding ahead of the anticipated weaning date. Thus, they have little, if any, setback. The time of weaning is a period of peak growth and a time when stereotypical behaviours can start. Post-weaning concentrates can be introduced 4–6 weeks prior to the foal being separated from its dam.

At weaning it is important that the mare is moved out of sight and earshot of the foal. The foal is usually kept in a loose box with the top door shut until it has settled down, which is usually within a few hours of separation. Being able

to see other foals will minimise stress at this time. Weanlings are usually turned out into a securely fenced paddock with the other weanlings within 24h of being separated from their mothers. If other foals are not available, quiet mares or geldings can serve as suitable companions. Alternatively, the mares may be moved from the paddocks one by one over a period of time leaving the foals with their usual companions. Gradual weaning is also an alternative method, where the time of separation is increased gradually over a period of days, either by placing the mare and foal in adjacent boxes, or adjacent small paddocks, allowing only visual contact. It is an area where more welfare research is needed.

Mares usually settle down quickly after the foals have been weaned. Their udders are usually distended for a few days but soon start to dry off. It is customary to cut back the amount of concentrate feed and ensure the mare can take exercise until the udder has 'dried off'. The milk should not be stripped off during this phase.

### Management of stallions

Stallions, like brood mares, should be allowed to lead as natural a life as possible. Pony stallions can be left to run out with their mares. However, because of the risk of injury and the greater value of the animal, non-pony stallions are individually stabled, and when turned out to graze, this is also on an individual basis. It is beneficial for them to see other horses, but they should not be able to make physical contact with them. The fencing surrounding stallion paddocks must be robust and sufficiently high to deter them from jumping out. They need to be fit for the breeding season if they have many mares to cover: regular exercise (ridden or in-hand) is required in the preceding months. They are less predictable than mares or geldings, and it is important for their optimum performance that they are not badly or roughly handled: hence the necessity for experienced handlers.

### Feeding management

#### The individually stabled horse

It has been shown that visual contact and the smell or noise of adjacent horses encourage horses to eat (Sweeting *et al.* 1985; Houpt 1991). The provision of a small window or grille in the partition between loose boxes and the repositioning of the manger may be sufficient to encourage shy feeders to eat. As a horse becomes fitter it may not finish its early morning feed, so the size of the individual concentrate meal should be adjusted down to what the horse is willing to consume at that meal; an extra feed can be included later in the day. Turning stabled horses in work out in a paddock or sand arena for a short period daily is invariably beneficial for the overall well-being of the horse, and is to be encouraged.

#### Groups of horses

The main problem of group feeding is ensuring that the more timid horses in the group get sufficient feed. If at

pasture, feed racks should be located in a sheltered position, not in a field shelter, on a well drained surface and in sufficient number to ensure that all horses get access without fighting. Group housing may aggravate the situation because of the greater restriction in space. Group-managed horses should be examined carefully daily, as long winter coats may mask thinness. Timid horses may need to be removed to a smaller group to ensure that they get sufficient feed.

### Feeding

The horse is a non-ruminant herbivore with significant microbial fermentation occurring in the caecum and colon. The stomach is only about 8% of the capacity of the total digestive tract, and is relatively small in relation to body size. In contrast, the hindgut comprises 62% of the capacity of the total digestive tract. The sacculations of the colon are thought likely to reduce the rate of passage of digesta, leading to enhanced microbial fermentation and digestion (Hintz & Cymbaluk 1994). As a herbivore, the horse is accustomed to continuous feeding, and in the feral state ponies spend most of their time grazing or browsing, particularly in the winter months when grazing is scarce and of poor nutritive value (Tyler 1972). By individually stabling horses, their movements are restricted and socialisation is reduced. Managing these horses, when they are in work and on a diet high in concentrates but low in roughage, is challenging. There is an increased possibility of both gastrointestinal (for example, colic) and behavioural problems arising from individual housing and intermittent feeding. Because of changing patterns in agriculture, the traditional horse feeds of hay and oats are not necessarily always readily available.

### Concentrates

Alternatives to oats are barley and maize, both of which have higher energy density than oats. In view of this, when they are substituted for oats, it should be on a basis of energy and not volume (see Table 35.6). Oats can be fed whole, crimped, rolled or ground. Maize can be fed whole, cracked, flaked or ground, but processing is probably only advantageous for very young animals, those with poor chewing habits or poor teeth. Barley should be processed (steam or dry rolled) in order to expose the barley kernel.

In addition to grains, there are now various proprietary horse feeds available in the form of pellets or as coarse mixtures. These are specially formulated to meet the needs of horses and ponies of different ages and at varying activity levels, and are very simple to use. It is always best to reduce

**Table 35.6** Oats and substitute grains suitable for feeding to horses, based on digestible energy values (after Cuddeford, 1986).

Feed	Replacement rate for 1 kg oats DM (kg)
Oats	1.000
Barley	0.930
Maize	0.869

the energy from carbohydrate and increase the amount from fats and oils.

Despite vitamin supplementation being heavily promoted commercially, it remains a controversial subject to how beneficial the effects of supplementation in exercising horses are. Salt (about 50g/day) is probably the cheapest and most useful supplement for all horses and is commercially available in the form of mineralised salt blocks. These provide salt and essential trace elements and should be provided all year round.

Dried sugarbeet pulp, as pellets or shredded, can be usefully added to the concentrate ration, but must be thoroughly soaked before use or else there is the risk of oesophageal obstruction (choke). Wheat bran and dried brewers grains can also be fed, but both have high phosphorus levels and should be used with discretion.

The concentrate ration is usually fed in mangers, which can be at chest height or on the ground. However, there is greater risk of fouling if mangers are at ground level. They should be kept clean, and rejected food should be removed before fresh feed is put in.

### Roughages

The hay requirements of horses range between 0.5 and 1.0 kg per 100 kg liveweight per day. Horses in intensive work that are fed large quantities of concentrate may only consume the lower amount of roughage. In this situation, the main function of the hay is mechanical to ensure normal gut function. Although it could be replaced by other sources of long fibre such as chaffed straw, hay occupies the horses' attention, which is an important consideration in avoiding behavioural problems in stabled horses. Where hay provides most of the dietary intake (for example, adult horses on maintenance rations and ponies during the winter months) any alternatives must provide both fibre and nutrients.

Silage, especially big bale silage, is now more readily available; if harvested at the correct stage of growth and stored properly, it should be superior to hay as it is not field cured for long periods. The risk of botulism can be minimised by ensuring that the bags are air-tight, that there is no smell of ammonia when they are opened, that the pH is less than 5, and there is no contamination with soil. It is also important that the dry matter content is not too low, to avoid horses in hard work having to consume inappropriately large quantities. Haylage, high dry matter silage, is another excellent (but expensive) product available for horses. Both silage and haylage are excellent alternatives to hay for horses with respiratory allergies.

In comparison with good or average hay, straws have low densities of energy, protein and minerals. Wheat and rye straw are not suitable for feeding to horses because of their high lignin content, which makes them indigestible, but spring sown oat or barley straw, which have been under sown with grass, are good feeding straws. However, they need to be supplemented with protein, energy and minerals. Treatment of the straw with ammonia improves energy values and significantly reduces fungal contamination. Ammonia-treated straw can be fed at up to 1.5 kg per 100 kg live weight, and used to replace hay on a kg/kg dry matter

basis, although it will still be necessary to provide a vitamin and mineral supplement (Cuddeford 1986).

Grass cubes, manufactured from chopped and not ground grass, and lucerne cubes usually provide sufficient protein and calcium, and could be fed exclusively to horses. However, these products and other 'complete cubed' diets have a major disadvantage in that they are usually consumed quickly and thus encourage the development of behavioural problems in stabled horses. Good-quality chaffed hay or straw with added molasses and minerals can be fed in place of hay on a weight for weight basis. They are frequently mixed with the grain ration to discourage too rapid consumption of the feed. Roughages can be fed off the floor, which is more wasteful but more natural. By lowering the head the tracheal mucociliary clearance is accelerated which contributes in avoiding lower respiratory tract disease (Raidal 1996). Alternatively hay can be fed in wall-mounted racks or in hay nets. Racks and hay nets should be at an appropriate height (head height) so that there is no risk of a hoof becoming entrapped. Hay nets should not be available for foals because of the risk of injury.

### Energy requirements

The energy requirements of horses vary according to size, activity level, ambient temperature and individual metabolic activity. The digestible energy (DE) requirements for the maintenance of horses weighing up to 600 kg liveweight can be calculated using the following formula (Hintz & Cymbaluk 1994):

$$\text{DE (MJ/day)} = 5.8 + (0.03 \times \text{LW})$$

where LW is the liveweight in kilograms.

DE requirements increase by 25–100% for mature horses in light to intensive work. These increases, including those required as a result of growth, pregnancy and lactation, are usually met by the introduction of concentrates (grain) into the diet. The energy requirements of the pregnant mare may increase to 110%, 113% and 120% of maintenance during the 9th, 10th and 11th months of pregnancy, respectively.

Requirements during lactation depend on milk yield, but can be double those required for maintenance. Horses in heavy training may require more energy than they can consume on a conventional diet. Increasing the energy density of the diet has been achieved by the addition of fat at levels of between 6 and 12% of the total diet. Supplementing protein as a means of increasing energy is not efficient, and there is no evidence of any benefits of vitamin supplementation above the required levels. For more detailed information on the nutritional needs of growing, breeding and exercising horses the reader is referred to an excellent review by Ott (1992).

Cold weather increases DE requirements. These requirements are best met by feeding good-quality hay (at least 50% of the ration), *ad libitum*. This encourages high voluntary intake of a feed with a good energy content and a high heat increment (HI). (HI is the heat of nutrition, metabolism, digestion and muscular activity involved during digestion.) In hot weather, the diet should not include excessive levels

of feeds with a high HI such as hay, as this would aggravate heat stress. The HI of grains or fat is lower than that of fibrous feeds.

### Water requirements

Whether stabled or at pasture, horses should have constant access to clean water. When housed in groups, the water supply should be sufficiently large to allow several horses to drink at one time. Cattle troughs are quite satisfactory for this purpose. Care should be taken to ensure that there are no sharp edges which could cause injury. When on a predominantly hay diet, stabled horses require 5l of water per 100kg liveweight per day; when on a hay and grain diet, 3l of water per 100kg liveweight per day should suffice (Cymbaluk & Chrislison 1990). Voluntary water intake is reduced in cold weather, so it is important that horses kept outside are provided with highly digestible feeds in order to minimise the risk of intestinal impaction. In cold weather water temperature should be 2–10°C in order to optimise intake (Cymhaluk & Christison 1990). Water can be supplied in plastic buckets or via automatic drinkers. The former, though more laborious, are to be preferred, as monitoring of water intake is possible. Water buckets should be scrubbed out daily.

## Laboratory procedures

### Restraint

Most horses and ponies will accept being restrained for various procedures if they have been well handled since birth. The voice should be used to calm them and they should be approached, in a firm and confident manner, from the shoulder area. A headcollar, with or without a bit attachment, should then be put on and a long lead, preferably with a quick release catch, attached to the centre back loop of the headcollar. Short-term, relatively painless procedures, such as the collection of venous blood samples, usually do not require additional control in a horse accustomed to the procedure. If more control is needed, then grasping a fold of skin in the neck with one or both hands and twisting it (neck twitch) is usually sufficient to keep the horse still until the sample is collected. Alternatively the lead rope can be wound round the front of the headcollar to provide more control. Grasping the ear is not to be recommended, as it could make the horse head shy. For more fractious animals, a twitch can be applied to the upper lip (Figure 35.3), although specific training should be considered as a long-term alternative. Twitches should only be applied by staff experienced in their use, and should only be used for a short period of time. Picking up and minimally supporting one front foot facilitates simple procedures at the hind end of the animal in many cases, for example, recording of rectal temperature and collection of fecal samples.

Young foals should be restrained by one arm around the front of the chest and the other around the back of the hindquarters, and held against a wall in the loose box: they should not be held round the chest/abdomen. If very unruly, they can be held round the front of the chest with

one arm whilst the tail is grasped firmly at the root with the free hand.

All the physical methods of restraint are suitable for short-term procedures in relatively amenable horses and ponies. The horse or pony should always be rewarded with a rub of the withers after all procedures and, on occasions, with a small handful of its favourite feed, particularly when it is being trained.

Special frames (stocks) designed to restrain horses for veterinary examinations are particularly useful during time-consuming procedures, for example, gynaecological examinations, biopsy collection and tracheal washes (Figure 35.4). They should have no sharp projections. The horizontal bars should be well rounded and the floor surface non-slip when wet or dry. Some means of quick side release should be available should a horse slip and go down. Chemical restraint is often advisable for longer term, more invasive procedures in both co-operative and uncooperative animals, for example, standing castration under local anaesthesia and stitching of wounds.

### Handling and training

The adult horse is potentially dangerous because of its size, strength and agility, together with its ability to bite and to kick with both front and hindlegs. Therefore, it is essential that it is handled and trained by experienced people. The very young foal should be introduced to normal stable procedures and trained to accept simple procedures by its handler as soon after birth as possible (see Foal behaviour). If more invasive procedures (for example, the collection of blood samples) are necessary, it is important that the foal is

**Figure 35.4** Rear view of type of stocks used for restraining horses for veterinary examinations and procedures. The boards on the sides can be removed if access is needed.

restrained by experienced, strong handlers, and that the person collecting the sample is adept at venepuncture. This will minimise stress, and with time and subsequent exposure to the procedure, the foal will usually accept it. Training a horse to be ridden does not normally begin until it is 3–4 years old, except in the case of the racing Thoroughbred. This is skilled work and should only be done by people with training and experience. If not required to be ridden, the basic training such as acceptance of normal husbandry procedures and being restrained in or out of stocks for different procedures should continue. Additionally, horses should be trained to accept the bit and should be taught to exercise on the lunge. The horse should always be rewarded when it has behaved well during procedures. Corrective action should be imposed at the time of the misdemeanour and not hours later. For safety reasons, during all the procedures described below, the horse should have an experienced handler present to restrain it if and when it is necessary. The person carrying out the procedures should have been correctly trained and be experienced in the techniques.

For large numbers of ponies a system of race and crush is advisable to use to facilitate the handling and the procedures (Figure 35.5). The ponies should be slowly introduced to this system from a young age. They are restrained in the crush and procedures like measuring body temperature, taking faeces samples and bleeding can be easily performed.

## Physiological monitoring

### Recording of body temperature

Temperatures are taken per rectum under suitable restraint. If necessary, the handler can hold up a front foot, thus making it difficult for the horse to use its hindfoot to kick the person recording the temperature.

## Collection of blood samples

These are usually collected from the jugular vein which is readily visible when the vein is raised by manual pressure in the jugular groove. Horses accustomed to the procedure require minimal restraint. Foals are more unruly, but experienced attendants can usually restrain them sufficiently for a sample to be collected. If large volumes of blood are to be collected, large-gauge needles (minimum 2mm) or sterile indwelling catheters are to be recommended. In this case the skin over the injection site is infiltrated with local anaesthetic first.

If frequent blood sampling is required, for example in a pharmacokinetic study, it may be better to insert an indwelling cannula under local anaesthesia, and suture it in place. The cannula is kept patent with sterile heparinised saline. With care, good technique and adequate supervision cannulae can be left *in situ* for several days. There is frequently a local reaction to their presence, but this subsides rapidly once they are removed. The decision to cannulate or not will depend on the number of samples, the temperament of the horse and how stoical it is to repeated injections (see also Joint Working Group on Refinement (JWGR) 1993).

## Virus isolation from the upper respiratory tract

A nasopharyngeal swab is inserted into the pharynx via the ventral meatus of the nares and rubbed carefully against the pharyngeal mucosa. Prior sedation is not usually needed, but the horse should be restrained in stocks and a nose twitch applied if necessary. If the twitch is necessary, and the process is to be repeated, consider whether there would be a welfare benefit in habituating the horse to the technique.

## Tracheal washes

This procedure may be carried out by percutaneous puncture or endoscopically. The latter is less invasive and is

**Figure 35.5** System of race and crush for handling large numbers of ponies.

preferable for multiple sampling. A catheter is directed down the biopsy channel of an endoscope which has been inserted via the external nares and pharynx. Sedation may be required. It is best if the horse is restrained in stocks.

#### Genital swabs/uterine biopsy

Swabs are routinely collected from breeding mares and stallions to check for the presence of infection, specifically venereal pathogens. Cervical and clitoral swabs can be taken with the aid of a speculum to dilate the vagina if necessary; the swab is passed into and through the cervix of the mare and rubbed against the mucosa of the uterus. Uterine biopsies are done to evaluate the histological structure of the uterus, particularly in relation to the mare's ability to successfully conceive and carry a foal to term. Mares should be restrained in stocks prior to carrying out these procedures. The sites for examination in the stallion are the urethral fossa, the sheath and the urethra.

#### Urine samples

Catheterisation of the bladder can be performed on mares; for male animals samples are collected at urination. Horse nappies may be an alternative collection technique.

#### Faecal samples

If collection from the floor will not suffice for the purpose required, faecal samples are best collected carefully per rectum: lubrication should be used, as horses have tight anal sphincters. Extra restraint may be necessary, such as picking up a front foot.

### Administration of medicines

#### Oral (pastes, suspension, granules, powders)

If they are palatable, administration of medicines in the feed is easy and involves no restraint of the horse. However, if large volumes of fluid have to be administered, this should be done, using a nasogastric tube, by operators correctly trained in the procedure, in order to avoid accidental introduction of fluid into the lungs. This procedure can be carried out in most horses without prior sedation. Paste formulations are usually administered directly into the oral cavity.

#### Parenteral

Many drugs are designed to be administered parenterally. The muscles of the neck, pectoral or gluteal muscles can be used for intramuscular injections. The risk of the operator being kicked is greater with the use of the gluteals. When several days' treatment are necessary the injection site should be varied. Occasionally horses will develop stiffness following intramuscular injection into the neck, despite it being correctly sited: care should be taken to ensure horses can reach their water buckets and feed mangers during this time. Injection into the pectorals may lead to dependent swellings, and occasionally the horse is stiff when asked to move forward. The gluteal area is well muscled, has a good

blood supply and is a good site for intramuscular injection despite the extra risk to the operator. Any complication here, such as abscess formation, would drain better than in the neck area.

#### Chemical restraint: sedation, analgesia and anaesthesia

General anaesthesia in the horse carries a slightly greater risk than for other domestic animals (Jones 2001), and should only be undertaken by a veterinarian assisted by trained staff. A major problem is the possibility of ischaemic muscle necrosis associated with the prolonged pressure of recumbency. However, the introduction of safer, effective and more reliable drugs allows many of the procedures which previously required general anaesthesia to be done in the standing horse using a combination of sedatives and analgesics together with local or regional anaesthesia. Before any central nervous depressant drug is administered, a full clinical examination should be carried out, in order to detect any pre-existing condition that may be exacerbated by the use of the drug or may potentiate the side effects of the drug. The patient should be kept in quiet surroundings before drug administration and while sedation is allowed to develop. Although some of the drugs may be given by the intramuscular route, the intravenous route is the most rapidly effective and reliable. The manufacturer's datashets should always be consulted beforehand, as there are important contraindications and possible side effects to be considered. The various drugs used for chemical restraint are well reviewed by Munro and Young (1991) and are summarised in Table 35.7. Although acepromazine may be used to sedate horses, they still respond to visual and aural stimuli and so arousal during sedation is possible. Other more serious side effects are priapism and paraphimosis.

#### Analgesics

Analgesics commonly used in horses are summarised in Table 35.8. Several are controlled drugs.

#### Anaesthesia

Xylazine, detomidine and romifidine can be used in combination with ketamine or sodium thiopental for short-term anaesthesia. The use of an intravenous cannula is essential in case of emergencies during anaesthesia, and to reduce the risk of accidental perivascular administration of sodium thiopental which would cause tissue damage and sloughing. Induction of anaesthesia is normally done in a padded induction and recovery room, the anaesthetised horse is then transported to an adjacent operating theatre where there is specialist equipment for the maintenance of long-term anaesthesia. However, short-term anaesthesia using intravenously administered drugs is possible under field conditions and is acceptable for minor surgical procedures, provided supplemental oxygen can be provided. A well-bedded cattle pen with straw bales lining the walls would be a suitable place to carry out the procedure.

**Table 35.7** Sedative properties.

Active ingredient	Dose <sup>†</sup> /route	Onset of peak sedation	Duration of useful sedation (dose dependent)
Xylazine*	0.6–1 mg/kg slow iv	Within 5 min	Approx. 20 min
Detomidine*	10–80 µg/kg slow iv	1–3 min	Approx. 30–60 min
Romifidine	40–120 µg/kg iv only	5 min	Approx. 30–180 min
Butorphanol in combination with detomidine or in combination with romifidine	20–25 µg/kg iv 12 µg/kg iv 40–120 µg/kg iv	5 min	Approx. 30–60 min

\*Xylazine and Detomidine may also be given im.

<sup>†</sup>Based on manufacturer's data sheet.

**Table 35.8** Analgesics suitable for use in horses.

Active ingredient	Route of administration	Use	
		Musculoskeletal pain	Visceral pain
Butorphanol*	iv	x	√
Flunixin	iv/oral (up to 5 days)	√	√
Detomidine	iv/im	x	√
Romifidine	iv only	x	√
Xylazine	iv/im	x	√
Phenylbutazone	iv/oral (long term)	√	√
Pethidine	im	x	√

\*Can be used in combination with xylazine and detomidine

## Euthanasia

A free-bullet humane killer or pistol of 0.32 calibre is the traditional way of euthanasing horses. In the hands of an experienced person it is fast and efficient, and disposal of the carcass is not complicated by the presence of chemical agents used for euthanasia. The weapon is aimed just above the point of intersection of lines joining the lateral canthus of the eye to the base of the opposite ear (the intersection is usually under the forelock at its base). There are chemical alternatives to shooting which may be more suitable under some circumstances. A new combination product containing quinalbarbitone and cinchocaine hydrochloride (Somulose, Arnolds Veterinary, UK) would appear to have considerable advantages over the use of anaesthetic overdoses. All chemical methods of euthanasia render the carcass unsuitable for pet food manufacture. For further reading on euthanasia of horses see Knottenbelt (1995).

## Common welfare problems

### Significant diseases

Some of the more common diseases relevant to horses entering or participating in research programmes are listed in the

following paragraphs. Some, for example colic, are often a consequence of poor management; others can be controlled by vaccination, for example tetanus and equine influenza, or, in the case of endoparasitism, by the use of an effective worm control programme. Others, such as amyloidosis, are generally specific to hyperimmune serum producing horses. It is important that stable staff are aware of the main clinical signs of the more common diseases so that veterinary advice is sought promptly, thus limiting the disease. The salient features of the diseases are briefly reviewed below. More information can be found in *The Equine Manual* (Higgins & Snyder 2006).

### Tetanus (lock jaw)

The causal agent is *Clostridium tetani*, a Gram-positive spore-forming bacillus present in soil and as a commensal in the gastrointestinal tract. The spores can survive for years in the environment. The disease is mainly seen following puncture wounds, as the anaerobic conditions in devitalised tissue provide the ideal environment for the spores to generate and release a neurotoxin. Treatment is often difficult and unsuccessful. It is imperative to vaccinate horses against the disease, and in countries where vaccination is common the disease is rare. It is essential that antitoxin is administered following injury if the horse's vaccination history is unknown. Mares are usually given a booster vaccination 1 month prior to the anticipated date of foaling: their foals are then passively protected from infection via antibodies in the colostrum for about 3 months, after which they can start their active immunisation programme. Foals born to unvaccinated mares should be given tetanus antitoxin at birth and 6 weeks later. The timing of the start of a foal's active immunisation programme will depend on the vaccine being used. The manufacturer's datasheet should be consulted for the optimum time to start. After the initial vaccine course, booster vaccinations are usually given every 2–3 years.

### Colic

Colic is the term used to describe pain arising from the gastrointestinal tract. All cases of colic should be regarded as potentially serious and, as 6–10% will require surgical intervention, it is essential that a diagnosis is made swiftly and the appropriate treatment initiated. Most cases of colic are related to the effects of intestinal parasites, or diet and

feeding practices. Signs will vary according to the type of colic, for example whether impactive or spasmodic, and will also vary in intensity. Signs include inappetence, scant faeces, restlessness, rolling, scraping the floor with a foreleg, gazing at the flanks, patchy sweating and kicking at the abdomen. Affected horses should be housed in a large loose box or cattle pen with a deep bed, the sides of which should be banked up along the walls. There should be no sharp projections. It is important to monitor frequently and record the vital signs (normal values in Table 35.1) so any deterioration can be detected in the early stages. Treatment consists of the control of pain with the use of non-steroidal anti-inflammatory drugs (NSAIDs) or using compounds such as xylazine alone or in combination with synthetic opioids such as butorphanol, together with any specific therapy indicated by the cause of the colic. Pethidine has excellent spasmolytic properties and is a cheaper alternative to synthetic opioids, but is a controlled drug in some countries. The underlying causes, for example endoparasitism or nutritional upset, should be rectified.

### Respiratory infections

Bacteria and viruses may cause upper and lower respiratory tract infections, the former playing a more predominant role now than was previously thought. Infection with equine influenza and equine herpesvirus (EHV) 1 and 4 are the more common causes of acute upper respiratory tract disease. Influenza occurs in susceptible horses of all ages, whereas herpesvirus infection is more common in young horses. Treatment includes rest, good nursing and antibiotics if bacterial infection, primary or secondary, is involved. Prevention of influenza and EHV is possible by vaccination, though EHV vaccines are not universally available.

### Strangles

This is a bacterial infection of the upper respiratory tract caused by *Streptococcus equi*. The infection is often introduced when young horses and ponies from varying sources are bought in. Recovered animals may remain carriers for long periods of time, and they are an important source of infection for in-contact animals. Hence the importance of isolation and a thorough clinical examination of all newcomers. The main clinical signs of infection are loss of appetite, pyrexia and depression, bilateral or serous purulent nasal discharge, and swelling and abscessation of the lymph nodes of the head and neck. Horses in contact with an affected horse and those in the very early stages of the disease (within 24h of onset of pyrexia) can be treated with benzyl penicillin in large doses to prevent progression of the disease; otherwise it is generally better to allow the infection to run its course. Good nursing is essential, and lancing and draining lymph node abscesses should be done as necessary. Following a disease outbreak, because the organism is able to survive for weeks in pus, disinfection of stabling, feeding and watering equipment, and tack and grooming equipment is essential. Vaccines are available in some countries but they have been of poor efficacy.

### Allergic respiratory disease

This is an important and frequent cause of disease, particularly in stabled horses. See Housing and respiratory disease section for details on prevention and management.

### Internal parasites

All grazing horses are infected with internal parasites. These include roundworms, tapeworms and bots (larvae of the bot fly, *Gasterophilus* spp.). Some roundworms are specific to unweaned foals and yearlings, for example *Strongyloides westeri* (threadworm) and *Parascaris equorum* (the large roundworm). However, the large and small strongyles (redworm) are found in horses of all ages, and are potentially very pathogenic. Migrating larvae of the large redworm *Strongylus vulgaris* cause arteritis and thrombus formation, which can result in ischaemia and necrosis of part of the large intestine. However, with the introduction of broad-spectrum anthelmintics over the last three decades, the prevalence of *S. vulgaris* has declined dramatically, whilst that of the small strongyles (cyathostomes) has increased. Cyathostome larvae undergo a prolonged period of development in the large intestinal mucosa, and are increasingly being associated with several clinical syndromes such as diarrhoea and weight loss which have a seasonal pattern. Tapeworm infections are also common, and there is a tenuous association with infection and the incidence of ileocaecal colic.

Traditional control programmes based on treatments every 2 months are now insufficient, and an integrated approach to control is necessary. This encompasses the use of the appropriate wormer at the correct time of the year for the particular target parasite, together with good pasture management. None of the available equine anthelmintics is effective against the full spectrum of endoparasites infecting horses, but each class of anthelmintic has a specific unique indication (Table 35.9). The manufacturers' datasheets should be read carefully prior to selection of an anthelmintic.

Mares should be treated in the last month of pregnancy to limit contamination of the pastures used by them and their foals: all the modern broad spectrum wormers can be used during pregnancy. Foals should be introduced into the worm control programme when about 6 weeks of age, and both they and their dams should be treated regularly throughout the rearing period. All horses grazing the same pasture should be treated with the same anthelmintic at the same time. Specific treatments for bots, tapeworms, mucosal cyathostome larvae and migrating large redworm larvae should be given at the appropriate time of the year for the climatic region. In general terms, in northern temperate regions, treatment for mucosal cyathostome larvae, tissue stages of large strongyles and bots is given in the autumn and/or winter months. In the warmer southern regions, treatment for these parasites may extend into the late spring and may require to be done twice yearly. Tapeworm treatments should be given twice yearly, in the late summer and again 6 months later. All newcomers should be treated with a larvicidal dose of fenbendazole followed by a double dose of pyrantel and kept housed for 48h after last treatment,

**Table 35.9** Modern broad-spectrum anthelmintics commonly used in the horse and efficacy spectrum.

<sup>c</sup>Larvicidal dose rate.

<sup>d</sup>Double routine dose rate.

before turning them out to graze with the resident population. Anthelmintics used routinely during the grazing season should be rotated on an annual basis to reduce the likelihood of the development of resistant strains of parasites.

Large paddocks should be subdivided so that they can be more easily managed: special electric fencing material is available for doing this cost effectively. Broad electric tape, easily visible, should be used when first introducing the horses to this area. Faeces should be removed twice weekly, particularly in warm moist periods when conditions are optimal for larval development on pasture. Machines are available which will both collect faeces and debris and harrow the pasture. Mixed grazing with cattle (or sheep) will reduce pasture infectivity, as the main parasites are host specific.

Pasture quality and palatability are also improved by mixed grazing, as ruminants will graze areas rejected by horses. Pasture should not be overstocked, and attempts should be made to ensure that young horses get the cleanest and best pasture. It is recommended to have 1 acre of grazing per horse and 0.5 acre per pony (1 UK acre = 4047 m<sup>2</sup>). This can be affected by a number of factors such as: length of time spent stabled, time of year, pasture quality and number of animals on the pasture.

#### Laminitis ('founder')

Laminitis is a common cause of lameness and disability in horses and ponies. It can affect both forefeet, both hindfeet, all of the feet or just one foot. The disease is metabolic in origin and is associated with overfeeding of grain and concentrates to stabled horses, and with over-fat, under-exercised ponies grazing lush pasture. It can also be a consequence of corticosteroid therapy and a sequel to systemic infections such as endometritis and enteritis. The extreme pain seen in the acute stage of the disease is caused by ischaemia of digital dermal tissue (Eustace 1990). Affected animals throw their weight back on their heels and are very reluctant to move. If permanent damage is to be avoided, veterinary assistance should be sought as soon as the lameness is

noticed. If a systemic illness such as endometritis is involved, then this must be treated. Additionally, drugs to reduce hypertension and anxiety, such as acepromazine, are given together with analgesics such as phenylbutazone. Good nursing and the provision of quality roughages together with supplemental methionine and biotin are essential (Eustace 1990). Affected animals must be confined in a well bedded loose box and provided with frog support. Prevention is by sensible feeding and grazing management. Further information can be found in Eustace (1992).

#### Hyperlipaemia

This is a disorder of lipid metabolism particularly common in pony breeds, especially Shetland ponies. It is characterised by gross lipaemia, elevated plasma triglyceride concentrations and fatty infiltration of body tissues leading to organ failure, especially of the liver and kidneys. The most common clinical signs are anorexia and lethargy, and the mortality rate is high, commonly 60–85%. Stress and obesity are important risk factors. Stressors include transportation, inclement weather and changes in management. The majority of affected ponies are in good or fat condition, and pregnant mares seem to be particularly susceptible. Diagnosis can be confirmed by measuring plasma triglyceride concentrations. Values in excess of 5 mmol/l indicate disease. Treatment involves identifying and treating any underlying disease. High-energy diets should be fed, as the animals are in negative energy balance. Intravenous fluids should be given to maintain circulatory volume and to correct electrolyte and acid–base balance. Intramuscular insulin, in conjunction with oral or intravenous glucose or galactose, may reduce mobilisation of free fatty acids from adipose tissue and intravenous heparin may increase the activity of enzymes responsible for the clearance of lipoproteins from circulation.

#### Skin infections

The more common skin infections are summarised in Table 35.10.

**Table 35.10** Common skin infections of horses.

Common name/incidence	Cause	Lesions/signs	Treatment and control
Ringworm; mainly stabled horses	<i>Trichophyton</i> and <i>Microsporum</i> species of fungi	Small tufts of hair agglutinated with serum especially in harness-abraded areas	Topical or systemic treatments available. Disinfection of buildings, trailers, tack, clothing and grooming equipment used by infected horses
Rain scald (body) and mud fever (legs); pastured ponies and horses in the winter months	<i>Dermatophilus congolensis</i>	Tufts of hair over crusts of exudate; pus underneath. Usually bilateral and symmetrical on back	House affected animals or provide with waterproof rugs if to remain at pasture
Sweet itch/summer itch; mainly ponies, sporadic cases in summer	Hypersensitivity to midge bites	Lesions at base of mane and tail head. Intense rubbing of affected areas	Topical insect repellents. House at dusk when midges are out; run a fan in the stable
Pediculosis; all horses and ponies susceptible mainly in winter/late spring	Sucking and biting lice	Intense rubbing of infected areas (chest/hindlegs/neck)	Control with pour-on synthetic pyrethroid; repeat every 14 days until cured. BHC powder, if available

### Amyloidosis

Although a rare clinical entity in the general horse population, amyloidosis is a frequent *post-mortem* finding in horses used for hyperimmune serum production, the liver and the spleen being the more commonly affected organs. Since liver rupture is a common cause of death in such horses, on welfare and economic grounds, regular monitoring of gamma glutamyl transferase (GGT) activity in serum would seem to be advisable. Studies in hyperimmune serum producing horses over a 5-year period have shown that GGT levels increase within 6–7 years of first starting the immunisation procedure, and that constantly high values seemed to correlate with advanced liver amyloidosis (Abdelkader *et al.* 1991).

### Abnormal behaviour

Ideally, management systems for equines should accommodate their natural behaviour, in particular the need to graze, exercise and socialise. They are flight animals and hence easily startled and this should also be taken into account (European Commission 2007). One of the most effective management strategies for reducing abnormal behaviour is to increase turnout time. Equines should be kept at pasture or have access to pasture for at least 6h a day. This encourages social contact, and also increases the amounts of time spent eating.

#### Weaving/box (stall) walking

Weaving, where the horse sways from side to side on its forelimbs, and box or stall walking where it endlessly walks round its box, are typical examples of behavioural stereotypes. They are usually the consequence of the stress, or thwarted motivation for locomotory behaviour, experienced by an open-country animal being kept isolated in a restricted area such as a stall or loose box (Haupt 1992). Endorphins are released from the central nervous system during stereotypic behaviour, possibly encouraging the horse to persist

in the behaviour. Amelioration can be achieved by providing the horse with sufficient windows or openings to enable it to see its companions and its immediate environment at all times. Placing mirrors in the stables of weavers significantly reduces this abnormal behaviour. The mirror is believed to mimic visual contact providing environmental distraction (McAfee *et al.* 2002).

#### Biting and kicking

Biting and kicking, or threatening to do so, are the horse's main ways of showing aggression. Normally this is reserved for other horses, especially at feeding time or to newcomers to a group. However, horses which have been maltreated will also threaten their attendants. With time, patience, experienced handling and expert advice, most of these horses can be retrained to trust their handlers.

#### Wood chewing

As mentioned earlier (see Roughages), low-roughage diets in stabled horses can encourage wood chewing; this can be rectified by providing more hay in the diet but it may also be necessary to apply creosote to chewed areas to discourage further wood chewing in the short term.

#### Crib-biting/wind-sucking

Crib-biting and wind-sucking are common oral stereotypes and both are perceived as detrimental to the horses' health.

Crib-biting is an oral stereotype where a fixed object is grasped with the incisors, the lower neck muscles contract to retract the larynx caudally; air is drawn into the cranial oesophagus, which produces the characteristic grunt (Nicol *et al.* 2002). No air is swallowed (McGreevy *et al.* 1995) but there is a view that this type of behaviour could be harmful. In wind-sucking the same posture and grunt are adopted but without grasping a fixed object.

The exact causes behind these two stereotypes remain unclear. Heritability, management, feeding practices, social

contact, crowding and many more have all been suggested as being responsible for their development or have been shown to increase the risk of them happening. A permanent cure is yet to be found and attempts to prevent it occurring have included surgery, acupuncture, environmental enrichment and others (McGreevy & Nicol 1998).

## Acknowledgement

This chapter is updated, but based considerably on the chapter previously written by Elizabeth Abbott published in the 7th edition of the handbook. Her substantial contribution is gratefully acknowledged.

## Further reading

Useful sources of general information on equine behaviour, care and breeding can be found in Houpt and Wolski (1982); Warren Evans (1992) Mills and Nankervis (1999) and Higgins and Snyder (2006).

## 36 Marmosets and tamarins

Hannah M. Buchanan-Smith

### Biological overview

#### General biology

The New World monkeys, of the family Callitrichidae, subfamily Callitrichinae, have seven distinct genera, and include the marmosets and tamarins. These species show a range of interesting pelage forms and colorations; some have ear tufts, others white crests on their heads or a large moustache, and some sport a golden fringe about the face. Why many of these small primates, which are vulnerable to predation by birds, snakes and mammals, are brightly coloured rather than cryptic, is poorly understood. Their small size, combined with their breeding success when housed in an appropriate environment, and easy handling make them a comparatively inexpensive primate to maintain in laboratories. Understanding the natural history and basic adaptations of any species is critical for providing appropriate captive environments, and Rylands (1993) provides excellent reviews of callitrichine ecology, mating systems and behaviour.

#### Marmoset species

There are 22 species of marmosets in four genera; six species from the Atlantic forest (*Callithrix*), 14 from the Amazonian forest (*Mico*), one species of pygmy marmoset (*Cebuella pygmaea*) and one species of dwarf marmoset (*Callibella humilis*), also from Amazonia (Rylands *et al.* 2000) (Table 36.1). The common marmoset, *Callithrix jacchus*, is the most extensively used callitrichine monkey in laboratory research (eg, Abbott *et al.* 2003; Mansfield 2003), and is therefore discussed in more detail. A full behavioural ethogram has been compiled for this species (Stevenson & Poole 1976; Stevenson & Rylands 1988) and should be consulted.

*C. jacchus* have large white ear tufts, a brindled black, brown and dark yellow pelage on their back and alternating wide dark and narrow pale bands on the tail. Young animals lack the adult body markings. This arboreal (tree-dwelling) species lives in north-eastern Brazil, occupying a wide variety of habitats such as the lower strata of gallery forests, secondary forests, scrubs, swamps and tree plantations (Hershkowitz 1977; Stevenson & Rylands 1988). Wild marmoset groups occupy a home range of 0.5–6.5 ha, which overlaps with neighbouring groups (Hubrecht 1985; Stevenson & Rylands 1988; Alonso & Langguth 1989; Scanlon *et al.* 1989; Ferrari & Digby 1996). They are classified

as Least Concern by the International Union for the Conservation of Nature and Natural Resources (IUCN 2009). Habitat destruction has reduced their original distribution and their numbers have declined (Mittermeier *et al.* 1981, cited in Rylands 1993). However, as they are adaptable, introduced populations are establishing themselves in areas outwith their original range (Rylands 1993).

All marmosets have specialised teeth for gouging trees, by using the lower teeth as a cutting-scoop (Coimbra-Filho & Mittermeier 1976). This enables them to consume the exudates from trees. Tree exudates are a major part of their diet and they have a specialised digestive system adapted for absorbing gum (Power 1996). *C. jacchus* spend up to 15–29% of their daily activity feeding on tree exudate (Maier *et al.* 1982; Alonso & Langguth 1989). In addition, marmosets eat fruits, flowers, insects and other small animals such as spiders, lizards, frogs and snails (Stevenson 1978; Stevenson & Rylands 1988; Rylands & de Faria 1993; Ferrari & Digby 1996). When foraging for insects, marmosets use a stealthy stalk and pounce technique. This foraging style allows them to glean foliage for insects (Rylands & de Faria 1993). Although primarily arboreal, *C. jacchus* will descend to the ground to cross forest clearings and pick up fallen fruits (Stevenson & Rylands 1988).

#### Tamarin species

Tamarins are distributed throughout the Atlantic and Amazonian rainforest and in the forests of northern South America and southern Middle America. There are four species of lion tamarins (*Leontopithecus*) living in the Atlantic forests and 15 species of tamarins (*Saguinus*) (Rylands *et al.* 2000) (Table 36.1) of which the saddle back tamarins (*S. fuscicollis*), the red bellied tamarin (*S. labiatus*), the moustached tamarin (*S. mystax*) and the cotton top tamarin (*S. oedipus*) are the most frequently used in laboratory experimentation (Rensing & Oerke 2005). These tamarin species are therefore the focus of this chapter. *Saguinus* can be divided into the Amazonian species, and those found in Panama and Colombia. They inhabit primarily tropical lowland humid forests, although some extend into highland forests, and most species adapt well to secondary forests (Snowdon & Soini 1988).

Tamarins are insectivore–frugivores and as such their dentition is not adapted for gnawing like the marmosets, and although they may consume tree exudates they lack the

<sup>2</sup>Rylands (2007).

<sup>3</sup>First described as a member of the genus *Callithrix* by van Roosmalen *et al.* (1998) but subsequently placed in its own genus *Callibella* (van Roosmalen & van Roosmalen 2003).

<sup>4</sup>de Vivo (1985, 1991) considered this marmoset from the state of Rondônia to be *Callithrix emiliae* (Thomas 1904). It is in fact distinct and geographically separated (Ferrari *et al.* 1999). It is being re-described with a new name (S.F. Ferrari, personal communication).

necessary digestive system adaptations to exploit its nutritional value fully. There are differences in foraging strategies amongst *Saguinus*. Three distinct insect foraging patterns have been described (Garber 1993). The first pattern is shown by *S. oedipus* and *S. geoffroyi* who hunt for insects on thin flexible branches in the low shrub layer of the forest understorey. The second is shown by *S. labiatus*, *S. mystax*, *S. imperator* and possibly *S. midas* who have a similar insect foraging style to the marmosets, exploiting insects on leaves and branches in the lower and middle levels of the forest. Visual scanning plays an important role in the detection of

their prey. The third pattern is shown by *S. fuscicollis* and possibly *S. nigricollis* and *S. bicolor*. These species are predominantly manipulative, specific site foragers, concentrating their feeding efforts on relatively large cryptic prey (Garber 1993). For example, orthopteran insects, have been found to make up to 61–67% of the volume of the stomach ingesta in *S. fuscicollis* (Garber 1993). In addition, ripe fruits have been found to account for 20–65% of total feeding time in those species of tamarin studied in the wild (Garber 1993). Plant exudates and nectar are also consumed, the latter principally in the dry season (Garber 1993).

Tamarins, like marmosets, are arboreal, but they are more reluctant to go to the ground. The home ranges vary from 8–120 ha (*S. fuscicollis* – 16–120 ha, *S. mystax* – 30–40 ha, *S. labiatus* – 23–41 ha, *S. oedipus* – 8–10 ha). Their home ranges overlap with neighbouring groups from 13–83% (reviewed in Garber 1993). Classification by the IUCN is Least Concern for *S. fuscicollis*, *S. labiatus* and *S. mystax*, but *S. oedipus* is critically endangered (Table 36.1). Figure 36.1 illustrates *C. jacchus* and the *Saguinus* spp. that are most frequently held in captivity.

### Goeldi's monkey

The jet black Goeldi's monkey (*Callimico goeldi*) also belongs to the Callitrichinae, but they differ from marmosets and tamarins in several ways. For example, they have 36 teeth (marmosets and tamarins have 32), and like *Callibella* (van Roosmalen & van Roosmalen 2003) they give birth to just one infant, whilst the norm of other members of the family is twins. As they are not considered to be true marmosets or tamarins they are not discussed further.

### Size range and lifespan

The Amazonian pygmy marmoset (*Cebuella*) is the smallest higher primate with both males and females weighing around 128 g (Ford 1994), *Callibella* weighs 150–185 g (van Roosmalen & van Roosmalen 2003), whilst wild-caught *Mico* and *Callithrix* are heavier, weighing 182–357 g (Ford 1994). In the wild, male and female *C. jacchus* weigh approximately 317 g and 322 g respectively (Araújo *et al.* 2000), but captive individuals have weighed as much as 600 g (Poole *et al.* 1999 and see Prescott & Buchanan-Smith 2004). *C. jacchus* reach puberty before 1 year of age and are skeletally and sexually mature by 2 years (Tardif *et al.* 2006). *Saguinus* are slightly heavier; the average adult body weight for both males and females is 387–560 g (Ford 1994) and can be up to 700 g for captive-bred *S. oedipus* (Savage *et al.* 1993). *Leontopithecus rosalia* weigh from 361–794 g (Ford & Davis 1992). It is not known how long callitrichines live in the wild, but in captivity they have lived to 18 years (Poole *et al.* 1999). However, the average lifespan of *C. jacchus* and *C. kuhli* that lived to weaning in the laboratory is only around 5.7–7.5 years (Tardif *et al.* 2003; Smucny *et al.* 2004; Ross *et al.* 2007a). The age of sexual maturity depends upon sex and species, but is usually 12–24 months (Yamamoto 1993).

### Social organisation and reproduction

In the wild, groups of *C. jacchus* usually contain between 3 and 15 individuals (Hubrecht 1984; Scanlon *et al.* 1989; Digby & Barreto 1993; Pontes & Da Cruz 1995). Groups are relatively stable (Ferrari & Lopes Ferrari 1989), although there are immigrations, emigrations, births and disappearances (Arruda *et al.* 2005). Females cycle throughout the year and males copulate with females, even during pregnancy. They ovulate soon after parturition, and can conceive again shortly after birth, when they are still lactating.

In captivity, *C. jacchus* groups are most stable when they consist of a monogamously breeding pair (eg, Gerber *et al.*

2002a, 2002b), and sexual behaviour is inhibited in subordinate females by pheromones, visual stimuli and aggression from the breeding female (eg, Saltzman *et al.* 1997). Occasionally, polygynous mating has been observed in captivity but the groups are less stable than those that consist of monogamous pairs (Rothe & Koenig 1991). In wild populations, monogamous groups have been documented (Albuquerque *et al.* 2001). There have also been numerous cases of two reproductive females in one group (Digby & Ferrari 1994; Digby 1995; Ferrari & Digby 1996; Roda & Mendes Pontes 1998; Arruda *et al.* 2005; de Sousa *et al.* 2005), although breeding is often alternated or one set of offspring does not survive, sometimes due to infanticide by the other breeding female (Digby 1995; Roda & Mendes Pontes 1998). Comparative data on key reproductive parameters for *C. jacchus*, *S. fuscicollis* and *S. oedipus* are shown in Table 36.2. Although some species breed seasonally in the wild (eg, *S. oedipus*) (Neyman 1977), they breed all year round in captivity. There appears to be no menopause, and females will continue to breed throughout their lives. *C. jacchus* that first breed at a later age (>4 years) have better survivorship than those first reproducing when younger (<2.5 years) (Jaquish *et al.* 1991; Smucny *et al.* 2004).

Twin offspring are the norm in the wild, and in addition to the mother, the father and other group members help rear the young by carrying, except for *Callibella* (van Roosmalen & van Roosmalen 2003). They may also provision the young with solid food, a behaviour that may be passive (all species studied) or active as recorded in *S. oedipus*, *Cebuella pygmaea*, *C. flaviceps*, *L. rosalia* and *L. chrysomelas* (see Feistner & Price 1991).

A fascinating twist that may underpin the evolution of co-operative rearing has recently been discovered (Ross *et al.* 2007b) and awaits confirmation. Due to genetic chimerism (when an animal has genetically distinct cells that come from different zygotes and are created by fertilised eggs or embryos fusing together) the patterns of relatedness between twins, and between other family members change. This chimerism applies to marmosets and tamarins with multiple births because in the womb, placentas grow quickly and fuse, creating a network of blood vessels through which cells can travel from one twin to the other. Chimeras may exist in almost any part of the body – blood, hair, liver, and even in sperm and eggs. Therefore, one brother may contribute the genetic makeup of his twin brother's offspring, effectively fathering nephews or nieces! The full implications of this phenomenon have yet to be explored, but in addition to the scientific interest in its role in the evolution of the co-operative rearing system, it may have implications for managing studbooks for optimal outbreeding, and in the selection of individuals for experimental protocols.

### Biological data

Rensing and Oerke (2005) provide a thorough overview of basic biological data (including reproductive, physiological, normative haematological and blood chemistry values) in a range of callitrichines. Table 36.3 provides a summary of key data for *C. jacchus*. Infant weights vary depending upon litter size, with mean values of 34.7 g  $\pm$  3.81 (n = 5),

30.24 +/- 3.33 (n = 59) and 27.73 +/- 2.03 (n = 30) for singletons, twins and triplets respectively (Tardif & Bales 2004). Growth rates of infants can be divided into an early stage of rapid growth, with a weight gain of around 1.15 g/day for all infants regardless of litter size, followed by a slower, later growth rate which is more variable but averages at 0.81 g/day (Tardif & Bales 2004). Factors affecting growth rates of infants and their adult weight are numerous and inter-related. They include maternal age and weight, and also litter size (Tardif & Bales 2004). Large litters result in high mortality; a meta-analysis of data from five colonies in the Americas (n = 625 dams) reported a mean of 50% loss between number of infants produced, and weaned at 3 months (Smucny *et al.* 2004). A very robust finding is that that triplets and quadruplets, especially if very small (<20 g) have significantly lower survival compared to twins and very large (>35 g) infants which are often singletons (Jaquish *et al.* 1991, 1997). Infant weight has also been shown to be related to abuse (defined as physical injury by other members of the group); abused infants have lower birth weights than non-abused infants (Tardif *et al.* 1998).

### Normal behaviour (wild and captive)

All animals should be allowed to express their natural patterns of behaviour in the captive environment. For callitrichines, this includes a range of locomotor and positional behaviours in relation to foraging strategies (eg, gnawing for tree exudate, food capture and processing), social activities (eg, resting, grooming, playing), the opportunity to explore novelty (either new environments, or objects) and having safe and comfortable places to sleep. The type of cage (construction materials and dimensions) and furnishings (substrate types, orientation and its placement) should be designed to allow and encourage specific-specific postures, behaviours and space-use preferences (Buchanan-Smith 2001).

Detailed descriptions of the development of young callitrichines have been described for *C. jacchus* (Stevenson 1976) and *S. oedipus* (Cleveland & Snowdon 1984). Yamamoto (1993) compares behavioural ontogeny across genera. Until infants are 3 weeks old, they are carried all of the time, usually by all group members, but often exclusively by the mother in *Leontopithecus*. By week 4 the infants are showing interest in their environments and beginning to explore, to touch, lick and smell objects, and they leave the carriers' backs for increasing periods of time. If startled, young will try to climb back onto carriers for protection. The first social interactions occur whilst the infants are still on their carrier's backs but after week 8 (week 12 in *Leontopithecus*) they are only carried occasionally. Weaning from lactation occurs from weeks 8–15, although infants taste solid food earlier. Infant development is affected by enrichment (an artificial gum tree, additional shelves, a hanging cloth and a variety of manipulable objects on rotation), with the appearance of certain behaviours (chewing wood, begging towards animal care staff, solitary play, exploration and scent marking) occurring earlier in enriched environments (Ventura & Buchanan-Smith 2003; see also Chapter 10).

## Senses and communication

Like other simians, vision is the dominant sensory modality of callitrichines. As both predators and prey, they use sight to detect prey items and potential threats. Their vigilance in captivity likely reflects that care staff may be seen as threats, and alertness has been found to increase after stressful events (Bassett *et al.* 2003). Callitrichines have binocular vision, with overlapping visual fields, and good visual acuity allowing them to manoeuvre themselves safely through complex three-dimensional worlds, judging depth and distance, and to respond to visual stimuli, be they potential threats, conspecifics, or prey items, such as insects. Marmosets perform headcocking where they move their heads in the lateral direction. Young *C. jacchus* headcock more than older marmosets, and often this is in the context of novelty (Stevenson & Rylands 1988). *Saguinus* perform a behaviour termed head flicking by Snowdon and Soini (1988) but it should not be confused with headcocking – head flicking is directed towards conspecifics as a hostile display. *Leontopithecus* will sometimes bob and up and down when staring threateningly (Kleiman *et al.* 1988).

Whilst the Old World monkeys and apes have colour vision that is similar to our own (trichromacy, based on three classes of cone receptors) (Jacobs 1996), callitrichines are polymorphic and show a wide variety of colour vision phenotypes. Females have either trichromatic or dichromatic vision (based on two classes of cone receptors, like humans with red-green 'colour blindness') (Jacobs *et al.* 1993). However, all males are dichromatic. Trichromatic colour vision has been shown to be useful for selecting ripe fruits from unripe and semi-ripe ones, and may also be advantageous for the detection of insect prey and predators (Regan *et al.* 2001; Smith *et al.* 2003; Buchanan-Smith 2005; Jacobs 2007). Individuals with dichromatic vision may not be able to differentiate well between yellows, greens, browns and reds. This has implications for choice of colour stimuli in experiments (Waitt & Buchanan-Smith 2006) and for choosing target colours for positive reinforcement training (Buchanan-Smith 2005).

All callitrichines have a well developed sense of smell, possess specialised scent organs, and have a rich repertoire of chemosignalling behaviours (eg, Epple *et al.* 1993). The most conspicuous of these are scent marking patterns involving the circumgenital and subpubic glands. Scent marking itself and the chemical signals deposited are important in many areas of their behavioural biology. They contain information on individual identity, rank and reproductive status, and play a role in reproductive suppression of subordinate females. It may also aid territorial defence, intergroup spacing and provide cues as to mate quality (Epple *et al.* 1993). The rate of scent marking in wild *C. jacchus* ranges from 0.19–0.45 scent marks/hour (Lazaro-Perea *et al.* 1999), much lower than is seen in captive conditions, where it exceeds 40 scent marks/hour post-stressor (Bassett *et al.* 2003). Adults scent mark more frequently than young in captivity (de Sousa *et al.* 2006).

Their acute sense of smell, together with taste, assists in food identification and selection. Callitrichines have a very varied diet (eg, Smith *et al.* 2003 found that two mixed-species groups of *Saguinus* consumed fruits from 833 plants

from 167 species in 87 genera and 50 families during 164 days of observation!). Providing a variety of nutritional and appetising food is likely to be beneficial for their psychological well-being and is often used as enrichment, but may lead to nutrition-related illnesses in the long term (Plesker & Schuhmacher 2006) (see Feeding/watering).

Callitrichines have a range of high-pitched vocalisations. Several vocal ethograms have been published including that of *C. jacchus* (Stevenson & Rylands 1988); *S. oedipus* (Cleveland & Snowdon 1982); *Leontopithecus* (Kleiman *et al.* 1988); and *Cebuella* (Soini 1988). The long calls, which serve many possible functions, including group defence against intruders, maintenance of group cohesion (eg, reuniting separated group members), and mate attraction, have been studied extensively (Pook 1977; Cleveland & Snowdon 1982; Snowdon 1993). Vocalisations are also important indicators in welfare assessment (Jones 1997). Callitrichines can hear higher frequencies than humans (see Heffner 2004 for a review). Ultrasonic frequencies present in the captive environment, such as a dripping tap, trolley wheels or computer monitors may adversely affect welfare (Clough 1982).

The sensory receptors in the epithelial and connective tissues of callitrichines respond to changes in temperature, touch, pressure and pain. These sensations then guide them in their behaviour. For example, Rumble and colleagues (2005) found that *C. jacchus* choose warmer, 'softer' wooden and plastic nest boxes over metal nest boxes. Providing different textures appears to be very rewarding for them (eg, when given a fleece-like hammock, or a technician's lap (Figure 36.2), they will often roll around in it. Tactile contact, through huddling and grooming, develops and maintains affiliative bonds, and may help individuals to cope with stressors (Schaffner & Smith 2005). Grooming plays a role in keeping a healthy skin and coat. Tactile contact when young may be particularly critical and it is known that repeated early parental deprivation of infant *C. jacchus* can have long-term effects on their behaviour and physiology (Dettling *et al.* 2002a, 2002b).

**Figure 36.2** Encouraging positive interactions between the monkeys and technicians can be rewarding for both parties. Hands would normally be latex-gloved. (Photo: Hannah Buchanan-Smith.)

## Behavioural welfare indicators

Behaviour, postures and vocalisations are the most immediate way to determine good and poor welfare, and it is critical that staff are trained to accurately recognise and assess key indicators, not only to recognise pain and distress, but also to recognise happy healthy animals. It is important that staff are familiar with natural behaviour as a reference point. Significant increases or decreases in natural behaviour should be noted (ie, abnormally high or low) as should the performance of unnatural behaviours. Although there has been a focus on poor welfare indicators in the literature, a callitrichine monkey could be assessed as having good welfare if it appears relaxed (in his/her social group and in the presence of humans) and engages in calm allogrooming, play and exploration. He or she should interact with other group members affiliatively and in social support. A few non-injurious aggressive threats and physical contact may be expected from time to time.

In *C. jacchus*, increases in calm locomotion (relaxed gait) and exploration, and decreased scent marking, scratching, agitated locomotion (but not in play context – may be fast like Stevenson and Rylands' (1988) gallop, or slow, but with piloerection) and inactive inalert behaviour are seen when conditions are improved (eg, access from laboratory cages to outdoor runs) (Badihi 2006). Furthermore, scent marking, scratching, inactive alert (vigilance) and locomotion are known to increase following stressful events (Cilia & Piper 1997; Bassett *et al.* 2003) and these increases are key indicators of reduced welfare. Inappropriate social behaviour, such as excessive grooming, or infanticide, are causes for concern. Abnormal unnatural behaviours exhibited by callitrichines include locomotor stereotypies such as circling and weaving (Hubrecht 1995), head bobbing and self-injurious behaviour (Box & Rohrer 1993).

Tail raised-present is displayed in marmosets when threatened (Figure 36.3), and other postures and facial expressions (eg, movements of the ear-tufts and baring of the teeth in open-mouth displays) serve as communication and can be used to monitor welfare (Stevenson & Poole 1976; Stevenson & Rylands 1988). If these behaviours and vocalisations are directed towards care staff on a regular basis, the staff are probably being viewed as predators and efforts should be made to improve the human–monkey relationship as this is arguably one of the most critical factors influencing welfare (Rennie & Buchanan-Smith 2006a).

## Sources, supply and transport

There are breeding programmes set up for all callitrichines used commonly in biological and biomedical research. These breeding programmes are often in-house, obviating the need for potentially stressful transport, quarantine and adaptation to a new colony. Breeding in-house also allows socialisation and training specific to their intended future use to begin early. However, some facilities may be too small, or lack expertise required for breeding, and therefore the primates must be transported to them. In these cases, legislation following the international trade in and transport of primates should be followed. A number of publications

**Figure 36.3** A male common marmoset performing a tail-raised present as a threat. (Photo: Hannah Buchanan-Smith.)

provide useful information on transport and should be consulted (Wolfensohn & Honess 2005; Joint Working Group on Refinement (JWGR) 2009).

If transport between facilities is required, callitrichines should be placed in a ventilated wooden box (a softer quieter environment than metal) with some soft substrate (Poole *et al.* 1999). There should be moist food available (eg, fruit and vegetables) and a window to allow monitoring and to supplement food and water on longer journeys. Familiar conspecifics should be transported together. It poses a serious welfare risk to transport females in late pregnancy. Moreover, females with young infants may attack them, so transportation is not advised. In addition, the separation of offspring under 5 months from their parents is not acceptable during transport (Poole *et al.* 1999). For further information see Chapter 13.

## Use in research

Callitrichines are used in a wide range of studies, including: behavioural, reproductive physiology, neuroscience, obesity, ageing, infectious disease, drug development and safety assessment (Abbott *et al.* 2003; Mansfield 2003). *C. jacchus* are frequently used for research on Parkinson's disease (Eslamboli 2005), and *S. oedipus* is used to study colon adenocarcinoma as these animals spontaneously develop colitis and/or colon cancer (Saunders *et al.* 1999).

## Laboratory husbandry, management and breeding

### Enclosures

Callitrichines need sufficient space to exhibit species-typical locomotor patterns, and to use the vertical dimension, as in

the wild they are arboreal and rarely come to the ground. In two-tier cages, monkeys in lower tiers are, by design, denied the use of the vertical dimension. Although few differences have been found in the behaviour of *C. jacchus* housed in upper and lower tier cages measuring 55 cm wide  $\times$  95 cm high  $\times$  110 cm deep (Buchanan-Smith *et al.* 2002; Badihi 2006), others have reported some differences. Activity is higher in upper-tier *C. jacchus* (Scott 1991) and *S. oedipus* (Box & Rohrhuber 1993) than lower-tier, with the tamarins also exhibiting more close physical contact. Furthermore, the behaviour of *C. jacchus* pairs improves (increases in calm locomotion and inactive rest behaviours and lower levels of agitated locomotion, inactive alert behaviours and watch observer) when they have access to a double enclosure incorporating both upper and lower tiers (Badihi 2006). Numerous other researchers have found behaviour indicative of improved welfare (such as increased play and exploration, and decreased stress-related behaviours) to be present in larger cages (eg, *S. oedipus*, Box & Rohrhuber 1993; *C. jacchus*, Schoenfeld 1989; Kitchen & Martin 1996; Gaspari *et al.* 2000; Pines *et al.* 2002). Given these findings, callitrichines should not be housed in two-tier cages.

Furthermore, light intensity in the lower tiers is reduced in comparison to the upper tiers (Scott 1991; Schapiro *et al.* 2000). Light intensity is known to impact behaviour and to improve reproduction. For example, Hampton and colleagues (1966) found that *S. oedipus* had markedly reduced activity when the light was dimmed, and Badihi (2006) found improvements in the behaviour of *C. jacchus* (eg, increased levels of calm locomotion and social play in youngsters) at higher light intensities. There has also been one report that reproduction in *C. jacchus* decreases at the very low light intensity of 20 lux (Heger *et al.* 1986).

Cages in laboratories generally consist of mobile enclosures (cages mounted on wheels), that can be autoclaved (Figure 36.4). The cages are often made of stainless steel, yet wooden cages provide a quieter environment, and although the wood can be protected from gnawing by wire mesh, they will require more frequent replacement. Ensuring the space is fully utilisable is of critical importance, and thus providing mesh or some climbing structures on solid walls is important. This also applies to the ceiling material, so that the monkeys can hang down and play. A mesh ceiling also allows a greater variety of enrichment to be attached, for example using cable ties or karabiner-type clips. Enclosures that have slide dividers can be very useful as they allow animals to be temporarily separated (for example for veterinary treatment or experiments) whilst maintaining the familiarity within the cage and close contact with the group.

Solid cage floors with sawdust/wood shavings/wood chips are often recommended, as callitrichines will often drop food, but later forage through the substrate for it. Care must be taken to ensure these do not harbour pathogens that might be transmitted between cages. A biofloor, which consists of a 25 cm covering of woodchips over a filterpad, with a concrete floor and drain, functions as a biological system to prevent build-up of pathogens or parasite infestation (Carroll 2002). Faeces may need to be spot cleaned, but urine drains away. The biofloor requires total replacement every 3–4 years and provides excellent continuity of familiar

**Figure 36.4** Cages on wheels that can be autoclaved easily. Note the rubber matting shelves at the front of the cage, which provide marmosets with good grip and a comfortable place to sit. The nest box is mounted on runners and slides into the cage in the corner. Food dishes are placed on the shelf at the front. (Photo: Keith Morris.)

scents for the monkeys and minimises the disruption of regular cleaning.

Specifying cage sizes is highly controversial, given the financial implications. Marmosets and tamarins are generally treated the same, as cage size is usually based upon their body weight (<1 kg; Buchanan-Smith *et al.* 2004; Prescott & Buchanan-Smith 2004). Poole and co-authors (1994) specified a minimum of 1 m<sup>2</sup> floor area for two animals and 0.25 m<sup>2</sup> for each additional animal, excluding carried infants (ie, a floor area of 2 m<sup>2</sup> for a group of eight). The minimum cage height they specified was 1.5 m. However, marmosets and tamarins differ in some critical ways that impact on their welfare and captive conditions (Prescott & Buchanan-Smith 2004). Tamarins are slightly heavier, have larger home ranges (up to 50–100 ha), and longer daily path lengths related to a more frugivorous diet and less dependence on gum-feeding. *Saguinus* have an even greater tendency than marmosets to avoid the ground where they behave nervously. Furthermore, *Saguinus* seem to be more susceptible to developing locomotor stereotypies and to self-injure than marmosets (reviewed in Prescott & Buchanan-Smith 2004). Prescott and Buchanan-Smith (2004) have argued that based on this suite of characteristics, *Saguinus* species should have larger minimum cages sizes in the laboratory than *C. jacchus*. Council of Europe Convention ETS 123 (Appendix A 2006) and the European Commission (2007) have taken this into account specifying a floor area of 0.5 m<sup>2</sup> for *Callithrix* and 1.5 m<sup>2</sup> for *Saguinus* (for one to two animals over 5 months), with a minimum height of 1.5 m, and the top of the enclosure should be at least 1.8 m from the floor. Each additional monkey over 5 months requires an extra 0.2 m<sup>3</sup>.

Although prescribed minimum cage sizes are increasing, as noted above, those exceeding current minimum size have been found to improve welfare (eg, *S. oedipus*, Box & Rohrer 1993; *C. jacchus*, Schoenfeld 1989; Kitchen & Martin 1996; Gaspari *et al.* 2000; Pines *et al.* 2002). An example of a larger walk-in cage is shown in Figure 36.5. The opportunities to engage in locomotion are far greater and the monkeys are known to engage in more solitary play and exploration (Badihi *et al.* 2007). However, care should be taken to ensure continuity for animals who are given larger enclosures, as if animals have to be moved to smaller enclosures there are severe welfare consequences (Schoenfeld 1989; Badihi *et al.* 2007).

Callitrichines scent mark territories and are aggressive to neighbouring groups, so physical or close (<1m) visual contact between captive groups should be avoided. At the very least, the monkeys should be given choice to avoid visual contact with group mates and neighbouring groups should they wish to, and stability within a colony room should be maintained, so individuals may become familiar with each other. This can be done by providing visual barriers, such as hanging screens within the cage (McKenzie *et al.* 1986). An alternative is to allow monkeys an opportunity to peep through a small hole at a neighbouring group (Moore *et al.* 1991). As the neighbours do not know they are being watched it is unlikely to have any detrimental effects on them.

Turrets or verandas have been used in several colonies, with mixed success. These are mesh additions to the enclosures that permit the monkeys to extend their visual field. Initial use may cause disturbances as animals unfamiliar with each other are able to directly threaten each other visually and vocally. They should not be placed too close so monkeys can physically touch each other. They may have some benefits in increasing predictability of negative events (see Bassett & Buchanan-Smith 2007), as the marmosets will have a better view of what care staff are doing (in relation to cleaning, capture for procedures etc).

Empirical studies have shown that access to outdoor environments has a positive effect the welfare of primates in captivity (eg, Novak & Suomi 1988) and the International Primatological Society (IPS) guidelines (2007) recommend a combination of indoor and outdoor housing, including exercise areas, where possible. Seasonal fluctuations in light and climate may contribute positively to the animals' welfare and allow animals a choice to experience a wider range of sensory stimulation such as sunshine and greater opportunities for exploration and manipulation (eg, Novak & Suomi 1988; Pereira *et al.* 1989; Buchanan-Smith 1998; Pines *et al.* 2007). Free access to warm indoor or sheltered facilities is critical whenever outdoor enclosures are used. *C. jacchus* prefer to spend time outside than in a large indoor enriched enclosure when given access from their home cage (Pines *et al.* 2007) and they engage in more positive welfare behaviours outdoors (including increased play, allogrooming, exploration, rest relaxed and calm locomotion and decreased stress-related scratching and scent-marking) than when housed indoors (Badihi 2006). Care must be taken to minimise the risk of disease transmission from outside vectors.

### Environmental provisions

A number of key aspects of the environment promote good welfare. These include the ability to express natural behaviour, and unpredictable positive environmental changes which can elicit an adaptive response from the animal, the opportunities for animals to choose and to facilitate change in the environment, and the perception of control (Sambrook & Buchanan-Smith 1997; IPS 2007; JWGR 2009; and reviewed in Rennie & Buchanan-Smith 2006b).

All callitrichines have claw-like nails to facilitate grip and all cage furnishings should take grip into account (eg, rough surfaces). Locomotion is primarily quadrupedal, but vertical clinging and leaping is seen in several species. Positioning of vertical supports is particularly important for *S. fuscicollis*

**Figure 36.5** An example of a large walk-in enclosure for marmosets. (Photo: Keith Morris)

which locomote extensively by vertical clinging and leaping. To allow full resting, huddling and grooming postures, flat surfaces which several individuals may occupy simultaneously should be provided. These may contain holes, to provide extra grip, and to prevent any puddles of urine from forming.

In the wild, most callitrichines sleep huddled together in tree forks or in dense tangles of vines and leaves and a secure place for sleeping is important in captivity. *Leontopithecus* are unusual in that they primarily use holes in tree trunks and branches as sleeping sites; therefore providing nesting 'holes' in captivity is appropriate. Nest boxes should be provided as they provide comfort and security, as evidenced by reduced vigilance (*S. labiatus*) (Caine *et al.* 1992). Rumble and colleagues (2005) showed that *C. jacchus* prefer wooden and plastic nest boxes over metal ones which may be related to comfort and temperature. They should be placed high in the enclosure. Nest boxes should be well ventilated so that moisture from breathing does not condense and so there is no risk of suffocation.

### Feeding/watering

Nutritional status influences growth, reproduction and longevity, as well as resistance to disease and environmental stressors (Knapka *et al.* 1995). Callitrichines have a very varied natural diet, that they have to work hard to get; getting access to food (eg, gnawing at trees to get exudates in marmosets, or removing inedible outer skin of fruits) and using memory (spatial, temporal and seasonal) for returning to fruiting trees. In the wild, they rarely encounter food in great abundance, and often they must search for it, with foraging occupying up to 50–60% of waking time, throughout the day (Garber 1984; Yoneda 1984). Providing a varied, appetitive and nutritionally balanced diet, and ensuring that foraging takes up a significant proportion of the day as it does in the wild, is critical. Food should therefore be made more difficult to find and process, and be provided at several times over the course of the day, taking their natural activity patterns into account. It is especially important to feed in the early morning, and early afternoon as they would in the wild.

Cafeteria-style diets in which commercially available pellets containing the required nutritional constituents are augmented with a range of additional food items, such as fresh or dried fruit, vegetables, seeds, nuts and animal protein (eg, insects, mealworms, hard-boiled eggs and boiled chicken) are often considered to cater well for psychological well-being, being varied and palatable. However, such a diet may lead to nutritional imbalance as pellets are generally not appetitive and callitrichids often avoid them in preference to the other food being offered. One solution to maintain the variability, but reduce nutritional imbalance is to soak the pellets in milk or flavoured juice to soften them and make them more palatable. Another solution is to use agar-based purified diets which are more appetising to marmosets, and have been used successfully (Layne & Power 2003). The National Research Council (NRC) (2003) provides a thorough review of nutrient requirements for primates, and Rensing and Oerke (2005) summarise the key points for

callitrichine nutrition. Vitamin D3 is a critical supplement for callitrichines who cannot synthesise it without access to ultraviolet light. Feed supplements, such as yoghurt, are often provided to females in late pregnancy and who are lactating, but there is no evidence that this benefits their offspring. Infants from mothers fed a higher protein diet did not have higher survival, nor growth. Indeed, at 42 days the mean infant body weight of supplemented mothers was less than that of infants of non-supplemented mothers (Layne & Power 2003).

Care should be taken on placement of food dishes. In *S. oedipus*, group members carrying infants were reluctant to approach food dishes placed near floor level. This was remedied by placing food dishes at least 1 m from floor level, whereupon group members carrying infants readily approached food dishes and fed (Snowdon & Savage 1989). Furthermore, by providing a meal in two or more sets of dishes in larger groups, competition between group members may be reduced, and each individual is more likely to get a more varied diet and an equal share of the preferred food items (Price & McGrew 1990).

Food choice and presentation should take their natural feeding adaptations into account. For example *Leontopithecus* and some *Saguinus* species are described as being extractive foragers, and feeding devices fashioned to stimulate these particular foraging skills can be used (eg, hiding food in bromeliads such as pineapple tops). Insects should be included as part of the diet if possible. Given the dental and intestinal adaptation to gum feeding, it is recommended that marmosets are given gum in such a way to encourage gnawing. It is easy to buy commercial gum Arabic that can be syringed onto branches in the enclosure and requires little time to prepare or administer (Kelly 1993).

Fruit is often chopped to ensure an even distribution amongst group members, but leaving skin on bananas, oranges and other fruits increases animal processing time (although fruit should be washed prior to presentation to remove pesticides). Spearling whole fruits on bamboo encourages callitrichines to hang upside down and spend time picking off bits of apple or orange (personal observation) in a similar fashion to how they would forage naturally. A similar technique is to suspend plastic film cases filled with small food pieces on string from the top of the cage.

These foraging techniques are preferable to scattering food items in the wood shavings or other floor coverings, as callitrichines do not go to the ground regularly in the wild, or if they do they are especially cautious as they may be more vulnerable to predation. However, foraging boxes containing a mixture of sawdust with dried fruits, such as raisins, bananas, or mealworms, attached higher in the enclosure work well. Fresh water should be available *ad libitum*, preferably from an automated watering system, as normal laboratory water bottles are potentially a source of infections such as *Pseudomonas* spp. (Brok, personal communication).

### Social housing

Housing callitrichines in harmonious social groups is fundamental to their welfare as it allows them to carry out

species-specific behaviours and buffers the effects of stressful situations (Schaffner & Smith 2005). Callitrichines (with the exception of *Callibella*) have a co-operative rearing system where the mother generally gives birth to usually twin offspring, and the father and other group members care for the young by carrying, food sharing and perhaps by looking out for predators (Buchanan-Smith 1984; Cleveland & Snowdon 1984; Price 1992). There are many published reports that if offspring are removed from their group before they have had experience with rearing infants, they have a much lower likelihood of raising offspring themselves (*S. fuscicollis*, Epple 1978; *L. rosalia*, Hoage 1977; *S. oedipus*, Cleveland & Snowdon 1984; Snowdon *et al.* 1985; Tardif *et al.* 1984a; *C. jacchus* Tardif *et al.* 1984a). It is recommended that callitrichines should have experience with at least two sets of rearing episodes; otherwise they will not make good parents themselves (Snowdon & Savage 1989). This applies to sons as well as daughters, because fathers as well as mothers care for the young and may be even more important for tamarins than for marmosets (Tardif *et al.* 1984a).

Optimal housing in captivity is in large family groups (up to 8–10 individuals if space allows), giving the offspring the opportunity for good social development. Offspring should not be removed until they are sexually mature. Pairing unfamiliar male and female callitrichines is usually a smooth process, but certain guidelines should be followed carefully (see JWGR 2009). With particular reference to callitrichines, the newly formed pair should be some distance away from the family as reproductive suppression through olfactory cues may still occur. If individuals have to be housed in pairs for experimental reasons, housing familiar siblings or vasectomised male or contracepted female pairs increases the likelihood of compatibility. Unrelated same-sex pairs of *C. jacchus* are often difficult to pair, unless one individual is younger (Majolo *et al.* 2003), or if in same-sexed rooms (Brok personal communication). However, as often they do not affiliate, unrelated same-sex pairs are not recommended (Majolo *et al.* 2003). Disturbance within a colony room should be kept to a very minimum, as the presence of unfamiliar individuals may cause anxiety and even redirected aggression towards group mates. If a parent dies, it is possible to introduce a step-parent, but care should be taken, and the step-parent should be allowed to interact with his/her intended pair mate in the absence of other family members, who may mob the unfamiliar group member (Tardif *et al.* 2003).

Single housing of callitrichines is never recommended unless it is unavoidable for justifiable veterinary or human health reasons. It should be kept to a minimum time and the monkey should be able to see, hear and smell familiar group mates. Although weaning to large same-sex 'gang groups' is relatively common, primarily for ease of management (Buchanan-Smith 2006), this practice is not recommended as it is an unnatural social grouping, and can lead to serious fighting.

### Identification and sexing

International guidelines (IPS 2007) recommend that all primates have permanent identification to ensure accuracy as

staff change and to permit matching with medical and research records. The best method to permanently identify a primate is using a microchip (Rennie & Buchanan-Smith 2006c; JWGR 2009). The microchip is implanted subcutaneously and holds a unique code which must be read using a scanner. Monkeys previously required sedation before the microchip was inserted under the skin using a specially designed hypodermic needle, usually supplied ready loaded with a microchip. However, the chips are now so small that sedation is not required (Morris, personal communication). For callitrichines, the chip is placed under the interscapular skin. The scanner wand needs to be 5–10 cm away from the chip (Poole *et al.* 1999) for reading. Callitrichids can easily be trained to stay still whilst the microchip is scanned (Savastano *et al.* 2003). Microchips have been known to migrate under the skin leading to a potential reduction in efficiency of identification.

Although marmosets and tamarins may all look pretty identical to the untrained observer, careful observation soon allows individuals to be identified by facial characteristics, size differences and markings. However, in large groups, or in facilities where a large number of callitrichines are kept, and there are regular staff changes, an easy method of accurately identifying individuals is strongly recommended (Fortman *et al.* 2002; Rennie & Buchanan-Smith 2006c). In addition to the benefits of immediate identification to assist with behavioural welfare assessment, it encourages naming individuals which facilitates positive staff–animal relationships to develop (Rennie & Buchanan-Smith 2006a). There are many different methods of temporary identification, including hair dyes, fur clipping (often done on the tail), and high-quality stainless steel ball chain collars with identity tags (Rennie & Buchanan-Smith 2006c). Tags/discs can be coloured and numbered. Dyes must be chosen so as not to cause irritation, especially to youngsters, and care taken to avoid injury with clipping. These methods may last less than a month, but dye can be re-applied without the need for capture and handling (Halloren *et al.* 1989). Collars and tags cannot be used until the animal has stopped growing. Collars and tags must be kept clean, and callitrichines may be trained to accept collar and tag cleaning without restraint.

Sexing of adult callitrichines is easy as males have prominent scrotal sacks, although females also have a pale glandular area around the genitalia and this should not be confused. Sexing young infants is more difficult, but the key differences are illustrated in Figure 36.6.

### Record keeping

In order to provide the best care, each monkey should have an individual file or 'passport'. This should include details of their biography (date of birth, sire, dam etc) and their prior experiences (eg, transport history, social groups, training, husbandry system, type of environmental enrichment, research project history and medical history) (see JWGR 2009). This information will assist with analyses of primate care, use and breeding, and to review the adequacy of systems in order to develop good practice (JWGR 2009).

**Figure 36.6** The external genitalia of (a) female and (b) male infant common marmosets. (Photos: Hannah Buchanan-Smith.)

### Physical environment and hygiene

As callitrichines are tropical primates, they require an ambient temperature of around 23°C (range of 23–28°C) and humidity of 40–70% (Council of Europe 2006). However, they will choose to go outside, often in much cooler temperatures, especially if the sun is shining and they have shelter from the wind. Fluctuations in humidity are not well tolerated by marmosets and tamarins and humidity should be kept higher than 40% as respiratory disorders may result. Callitrichines respond adversely to noise (eg, construction noise). The level of background noise should be kept low and if it is absolutely necessary to exceed 65dBA, it should only be for short periods.

Callitrichines should be kept in hygienic conditions, with regular cleaning to remove stale food, and excreta. Scent marking leads to sticky substrates that can lead to oily coats. A complete cage clean, by autoclave, or by scrubbing using a hot water, domestic detergent and bleach, together with thorough rinsing, should only occur at 1–2-month intervals. Because of the role of scent marking in territorial behaviour, in modulating reproductive physiology and their importance in social interactions, familiar scents should not be totally removed from the captive environments during cleaning. Alternating cleaning and sanitation of enclosures and substrates and enrichment devices will have beneficial effects by maintaining familiarity and reducing over-stimulated scent marking (Prescott 2006).

### Health monitoring and quarantine and barrier systems

It is important that callitrichines are checked at least twice daily for changes in behaviour, inactivity, nasal discharge and signs of diarrhoea. Deviations from normality should be marked on a standardised scale to ensure records are

accurately kept; Wolfensohn and Honess (2005) provide scales that may be modified to suit callitrichines. Veterinary advice should be sought if non-normal patterns persist, or if the monkeys are listless, remain in their nest boxes, or do not eat. Infants who have fallen to the floor, and have not been picked up by group members, should be examined carefully for injury and disease, but the decision to hand rear should not be made lightly as there are potential problems associated with this (Kirkwood & Stathatos 1992), and hand-reared individuals are unlikely to be suitable breeders or good models for scientific research.

Although callitrichines are commonly bred in-house (Rennie & Buchanan-Smith 2005), occasionally relocation is required. The animal passport should be available to the new facility before the monkeys arrive and every effort should be made to achieve continuity (or in some cases improvement) of care and also help to ensure rapid acclimatisation to the new facility (JWGR 2009). Food should initially be identical or similar to that of the source colony, and changes introduced slowly (Tardif *et al.* 2003). Individuals newly acquired from elsewhere must be quarantined for at least 30 days. The transport to the facility will have caused stress, and extra care must be taken upon arrival to ensure the monkeys are not dehydrated. It is also important to ensure continuity of water supply as some animals may not learn a new method of acquiring water (Tardif *et al.* 2003). During quarantine they should receive a thorough health check, including haematology and radiography to check for skeletal problems and tuberculosis (TB) (Poole *et al.* 1999).

There are no national or international standards of personal protective equipment (PPE) for humans interacting with callitrichines, although facilities usually develop their own. The health status/infectious state of the callitrichine dictates the level of PPE, but there are also a number of other considerations, including level of physical contact, staff experience, etc. Staff should wear protective clothing, including face masks if they display any sign of a cough or

cold. Particular care should be made to prevent contact with any human with cold sores, due to the herpes virus that can prove fatal.

## Breeding

The method of pregnancy testing is generally by abdominal palpation, and pregnancy can be detected from 5 weeks post conception (Kirkwood & Stathatos 1992), although as this can be disruptive and is not recommended on a regular basis. Weight gain and abdominal distension are clear signs of pregnancy in later stages. Ultrasound and urinary hormone measurement may also be used; callitrichines can be trained to accept ultrasound (Savastano *et al.* 2003). Marmosets and tamarins usually give birth at night (between 20.00h and 07.00h); if the female shows signs of labour during the day, veterinary intervention may be required. During birth the group members gather around the mother and may share in eating the placenta (Stevenson 1976; Price 1990). Although twins are the norm, *C. jacchus* are increasingly producing triplets (or even quadruplets) in captivity, due to their rich diet. This creates some problems for rearing them (see Reproductive problems).

Reproductive success and infant mortality vary quite substantially between facilities, suggesting there are numerous factors associated with successful breeding, including genetic factors, early rearing history, temperament, housing, husbandry and diet. *C. jacchus* are now successfully bred in many facilities, with mortality rates of less than 20% (Prescott & Buchanan-Smith 2004) although a meta-analysis of data from five colonies in the Americas (n = 625 dams) reported a mean of 50% loss between number of infants produced, and weaned at 3 months (Smucny *et al.* 2004). *Saguinus* are more difficult to breed (Tardif *et al.* 1984b), but there is a strong link between quality of captive conditions and breeding success; when they are housed in large complex enclosures and with a group composition resembling those in the wild, they have greater success (reviewed in Prescott & Buchanan-Smith 2004).

## Laboratory procedures

### Handling

Marmosets and tamarins generally do not like being handled, although with extensive gentle handling and desensitising (with small pieces of treat foods such as gum arabic, grape, raisin or marshmallow) some will tolerate it and a latex-gloved hand can be used. However, to avoid handling they can be trained using positive reinforcement techniques (see Chapter 16) to co-operate with routine husbandry procedures such as capture, weighing, veterinary procedures, oral administration or palpation, or to provide samples for analysis (such as saliva or urine). If there is good reason why they need to be handled, a firm but gentle approach is critical. When possible, callitrichines should be trained, using positive reinforcement techniques, to enter a transport box or Perspex cylinder, and capture by gloved hand from the box will be substantially easier than capture from within the

home cage. A detailed illustrated account of how to train marmosets to enter a transport box is provided by Prescott *et al.* (2005). Chasing individuals into nest boxes for capture is not recommended as the nest box should be seen as a safe place to rest, and not associated with any potential stressor (Rennie & Buchanan-Smith 2006c). Removal of a callitrichine from the transport box is best done by opening the door slowly and grasping the monkey around the shoulders as he/she exits. If heavy, the weight of the body should be supported with the other hand and the monkey should remain in an upright position so it can look around, as he/she will likely feel less vulnerable than in a supine position. Movements should be slow, and voices muted. When catching by hand the weight of the glove used must be carefully gauged to ensure that excessive pressure is not applied to the animal and that the handler is sufficiently well protected (Sainsbury *et al.* 1989). Callitrichines may bite the glove, and this has been known to cause dental problems (eg, broken teeth). They should not be left in a transport box for any longer than is absolutely necessary. The monkeys should be returned to their home cage as soon as possible following handling.

If monkeys are being caught within the home cage, the handler should approach calmly and wait until they are stationary, and then grip the part of the tail nearest the body whilst the other hand is placed around the shoulders. This approach is not recommended unless monkeys have been very well habituated to it. If they are being removed from wire mesh great care must be taken to remove their tight grip from the mesh as injuries can occur to their claws. Capture by net is not recommended as it causes fear and distress, can result in injury when the animals are chased around and entanglement during removal from the net. Great care should be taken not to allow individuals to escape as this creates disruption as individuals in other cages in the colony room may attempt to bite them (and have been known to bite off digits). Swift return to the cage should be a priority; if animals are trained they can be enticed back into their home cages with food rewards. However, if they are not, a net may be required as a last resort.

### Training/habituation for procedures

Although all methods of restraint can be highly stressful, much of this stress can be eliminated if the method is used sensitively (Fortman *et al.* 2002), and if the callitrichines are desensitised to the procedure, by pairing it with food rewards, and by making the procedure predictable, so they are familiar with what is going to happen.

There is now very good evidence that callitrichines can be trained for a variety of tasks related to husbandry, veterinary treatment, scientific studies and tests of cognitive ability with no need for food or water management (eg, McKinley *et al.* 2003; Savastano *et al.* 2003; Scott *et al.* 2003; Smith *et al.* 2004 and see Prescott *et al.* 2005). Cognitive testing within the home cage is preferred, for welfare and scientific reasons (Scott *et al.* 2003). Temperature is an important indicator of health, and callitrichines can be trained to accept a tympanic thermometer without restraint (Savastano *et al.* 2003). Temperature can also be read remotely in tele-

metric microchips (reviewed in Rennie & Buchanan-Smith 2006c).

*C. jacchus* have been trained to stand on a balance for weighing in the home cage (McKinley *et al.* 2003). The initial time investment is not high for this training (between two and twelve, 10-minute training sessions per pair, with a mean of six sessions, see Figure 36.7). If the marmosets were already taking food from the trainer's hand, it took a mean of just two, 10-minute sessions per pair. A comparison with the standard weighing procedure showed that this initial time investment can be quickly recouped. One of the many advantages of training for in-home cage weighing is that it avoids the need for capture and restraint. Poole and colleagues (1999) have suggested that even the weights of carried young can be measured in this way, by weighing the carrier with and without a single youngster on his/her back. Schultz-Darken and co-workers (2004) have described habituation of *C. jacchus* to sling harness restraint for neuroendocrine experiments, and Ferris and colleagues (2001) described habituation for functional magnetic imaging experiments. Restraint devices for sample collection are described later in this chapter.

### Monitoring methods

Surgically implanted telemetric devices have been used successfully in non-human primates to collect cardiovascular, blood pressure, temperature, motor, vocalisation, locomotion and pH data, and to record electrocardiograms (ECG), electromyograms (EMG), electroencephalograms (EEG) and electrocorticograms (ECoG) (Kinter & Johnson 1999). There are advantages and disadvantages to the non-invasive externally worn telemetry devices, and partially and fully surgically implanted devices (reviewed in Rennie & Buchanan-Smith 2006c). Fully implanted devices allow multiple subjects to be housed in pairs or groups; working instrumentation has been successfully maintained in *C. jacchus* for up to 2 years (Crofts *et al.* 2001), and used to monitor responses to a range of environments and events (eg, Gerber *et al.* 2002a).

Urine samples allow analyses of accumulation of metabolites, are easy to collect and provide sufficient volume. Marmosets can be trained, in a short period of time, to urinate into a collection vial on request (McKinley *et al.* 2003), or using a similar technique to provide a sample scent mark for analysis (Schultz-Darken 2003). Other methods of urine collection that do not necessitate social isolation have also been documented (Anzenberger & Gossweiler 1993; Smith *et al.* 2004). Steroid and protein metabolites can also be measured in faeces, but lag times must be well understood. Saliva has also been validated for cortisol in *C. jacchus* (Cross *et al.* 2004). The ease with which it is collected from known individuals, and the fact that it allows measurement of currently circulating cortisol, and may be collected at very regular intervals may make it the preferred method of cortisol analysis.

Training callitrichines to accept venepuncture has not been achieved, partially because their small size makes it difficult to access blood vessels, and because of the precision required. However, with training and desensitisation, the stress of capture and restraint can be minimised and thus the overall stress of routine procedures can also be reduced (Greig *et al.* 2006). Restraint devices offer some benefits over conventional handling techniques. First, they allow the procedure to be carried out by just a single person whereas sometimes two or three technicians are involved in manual restraint, one to restrain and the other(s) to carry out the procedure (eg, Hearn 1977; Buchanan-Smith, personal observation). Second, with the restraint device, the animal's movement is quite restricted, for a short period, and the chance of a haematoma and bruising is decreased. There is good back support, and the marmoset is held in an upright position allowing him/her to look around. Third, most marmosets habituate to the device; they appear comfortable and without obvious signs of stress. They accept a food reward following the procedure (Greig *et al.* 2006), and indeed food rewards should be offered following all procedures to desensitise them. Figure 36.8 shows *C. jacchus* in a restraint device.

Blood sampling requires a short, 0.4–0.5 mm diameter (25–27 g) needle, with a small 1–2.5 ml syringe (Poole *et al.* 1999). Single blood samples of up to 0.5 ml/100 g body

**Figure 36.7** A marmoset holding a target (plastic spoon), whilst sitting on scales for in-home cage weighing. (Photo: Jean McKinley.)

weight can be taken safely (Poole *et al.* 1999). If repeated sampling is required, no more than 15% of total blood volume should be taken per month (Diehl *et al.* 2001), approximating to 3.7 ml per month for a 350 g marmoset (Poole *et al.* 1999). However, this must be monitored closely to check for normal cell composition and haemoglobin concentration, and iron supplements should be given (Poole *et al.* 1999).

Greig and co-workers (2006) describe the procedure for blood collection from the femoral vein. The leg should be held straight by curling fingers around the length of the leg to ensure that the animal cannot bend at the knee or kick. The thumb provides extra restraint and support to the syringe. The syringe needle should be inserted at an angle of approximately 15° into the groove midway down the leg, the thumb can be used as a guide. The vein or the groove is not always visible in heavier animals so the midpoint should be used. The syringe plunger should be slowly pulled back just after insertion of the needle point, to ensure that it has entered the vein. If correctly inserted blood should flow back into the syringe, if not then the needle should be inserted further until blood is seen entering the needle hub. There should be no further insertion of the needle at this point. The plunger should be pulled slowly until the appropriate volume is acquired. Schultz-Darken (2003) also provides details of blood sampling from a restraint device, and advice on an intravenous femoral catheter for repeated blood sampling and a jugular vein catheter for longer-term sampling over several hours.

A restraint device can also be used for collection of semen from mated females (details in Greig *et al.* 2006), and is seen as a refinement over other methods of sperm collection such as electro-ejaculation. Schultz-Darken (2003) describes a

procedure for collecting semen using vibratory stimulation whilst the male marmoset is restrained.

### Administration of substances

The substance to be administered and the route of its administration are determined to a great extent by the objectives of the experimental procedure concerned. A thorough review of refinement techniques for administration of substances has been provided by the BVAAWF/FRAME/RSPCA/UFAW working party (JWGR 2001). Oral administration by gavage requires careful restraint because poor placement of the tube (into the trachea rather than the oesophagus or the top of the stomach) has the potential to harm or kill the subject animal, and marmoset teeth are delicate and easily damaged. A small soft plastic tube can be used to keep the mouth open. It is preferable to incorporate substances into treat feeds (such as marshmallows) or favoured fluids, a method considered to have minimal impact on the animal (JWGR 2001). If the callitrichine will not eat, the solution can be fed into the mouth with syringe. Subcutaneous injections are best administered into the loose skin above the shoulders, and the upper thigh is suitable for intramuscular injection (Poole *et al.* 1999). Intravenous injections should be performed into the saphenous vein (or caudal vein) which are preferred over the femoral vein as the neighbouring femoral artery can be injected accidentally; Bakker, personal communication).

### Anaesthesia/analgesia

Ketamine (a dissociative anaesthetic) is the most commonly used anaesthetic agent for marmosets and tamarins. Dosage depends upon depth of anaesthesia required. Poole and colleagues (1999) recommend 5–15 mg/kg by intramuscular injection for mild restraint such as fitting identity collars, although muscle relaxation is often poor. Rensing and Oerke (2005 and Rensing, personal communication), recommend up to 50 mg/kg for surgical procedures (combined with a potent analgesic) with a maximum of 25 mg/animal due to myotoxicity. To improve muscle relaxation, Poole and colleagues (1999) recommend a combination of ketamine and xylazine at a dose rate of 10–15 mg/kg ketamine and 1.5 mg/kg xylazine. Further they and Rensing (personal communication) recommend a ketamine/medetomidine mixture (3 mg/kg ketamine with 0.05 mg/kg medetomidine given intramuscularly) as this has the advantage of being reversed by administration of atipamezole intravenously or intramuscularly. In order to maintain general anaesthesia, inhalation of the narcotic gaseous anaesthetic isoflurane can be used, delivered via a modified endotracheal tube (2.0 mm) or with a face mask (Rensing & Oerke 2005). Recovery time is fast (Morris, personal communication).

Rensing and Oerke (2005) recommend Saffan® (new trade name is Alfaxan-CD RTU), of which the active constituents are alphaxalone and alphadolone, as a safer alternative to ketamine (dose rate: 18 mg/kg) to induce anaesthesia. Poole and co-authors (1999) note this has to be incremented at 30–60-minute intervals to maintain effect. For longer surgery

**Figure 36.8** A marmoset in a restraint device, showing the plastic tube and Velcro straps, having a blood sample taken from the femoral vein. (Photo: by Keith Morris, from Greig *et al.* 2006.)

Rensing and Oerke (2005) note that a combination of Saffan® (8 mg/kg) and diazepam (0.25 mg/animal) is reliable in *C. jacchus*; and ketamine (25 mg/kg) and midazolam (25 mg/kg) can be used for *S. oedipus*. Morris (personal communication) recommends buprenorphine (10–20 µg/kg or 0.03–0.06 ml/kg) for longer analgesia and post-operative pain relief and carprofen (4 mg/kg administered subcutaneously) for short-term analgesia before surgery. It is important to keep the monkey warm during anaesthesia and surgery. This can be achieved using heat lamps or heat pads, or using an operating table with a built-in thermoregulator in the table surface. It is critical to monitor anaesthesia carefully to prevent deaths and ensure safe recovery. For further advice see Flecknell (2009).

## Euthanasia

Euthanasia is required if animals are found to experience an unacceptable level of pain or suffering (specified humane endpoints), when the project requires pathology or histology examination of organs or tissues, or at the end of an experiment if they cannot be re-used (as outlined in the project licence). An overdose of an anaesthetic agent, pentobarbital (also known as sodium pentobarbital, a barbiturate formulated for euthanasia) by intravenous injection is the only acceptable method for the euthanasia of marmosets and tamarins (Poole *et al.* 1999; Rennie & Buchanan-Smith 2006c; IPS 2007). It is recommended that animals lose consciousness rapidly following injection, prior to the loss of motor function, and that no signs of pain, distress or panic should be observed (JWGR 2009). This is the case when using intravenously injected pentobarbital. Poole and co-workers (1999) and Morris (personal communication) recommend that ketamine is injected intramuscularly, to induce anaesthesia, and to mitigate the stress of handling for intravenous injection of pentobarbital. Suitable prior anaesthesia will facilitate accurate administration of pentobarbital, as extravascular injection causes irritation and may be painful. Under certain circumstances such as severe cardiac or circulatory deficiencies (eg, shock, intensive blood sampling prior to euthanasia), intracardiac injection on a deeply sedated animal may be preferred to intravenous injection (Bakker, personal communication).

## Common welfare problems

### Health

If kept permanently indoors, immunoprophylaxis is generally not required for animals if housing and husbandry are appropriate and they are provided with nutritionally balanced diets. If callitrichines have access to outside runs, they will require protection against *Yersinia* and *Salmonella* bacteria and other infections which can be carried in bird droppings (Poole *et al.* 1999).

Signs of illness include changes in activity, often listlessness including lack of alertness, a reduction in body weight, poor coat condition, diarrhoea and withdrawal from group mates. In relation to body weight, in a study of the effects

of chronic psychosocial stress in *C. jacchus*, Johnson and colleagues (1996) observed a 10% drop in body weight in individuals taken from stable pairings and placed in isolation and considered this to be indicative of considerable social stress. This was accompanied by an increase in locomotion and cringing behaviours and in crying vocalisations. Acceptable boundaries of weight loss or gain, within which the welfare of the individual is protected have not been deduced specifically for marmosets. However, persistent anorexia resulting in a loss of 10% or more of the animal's original weight is considered to signify unacceptable suffering and has been used as a humane endpoint in parasitological studies in baboons (Farah *et al.* 2001). Fluctuating body weight (in contrast to a stable body weight) in adults is also a useful indicator of poor welfare.

Callitrichines can be infected with a range of parasites, gut bacterial and viral infections and well as non-infections diseases. A very brief summary of the main diseases is provided here; further details can be found in Bennett *et al.* (1998) and Potkay (1992). Rensing and Oerke (2005) provide a summary of symptoms and details of treatment.

In the wild, callitrichines may have several parasitic infections, but these are rarely seen in captivity. Acanthocephala (*Prosthenorchis* spp.) is an exception, in colonies where cockroaches are present. It can be fatal. Other parasites reported include *Rictulria nycticebus*, *Giardia lamblia*, *Balantidium* and *Entamoeba* spp., and *Toxoplasma gondii*. Of the bacterial diseases, *Shigella*, *Yersinia pseudotuberculosis* and *Y. enterocolitica*, *Klebsiella* spp. and *Bordetella bronchiseptica* are those that cause the greatest concern. *Campylobacter* spp., *Salmonella* spp. and *Escherichia coli* can also have severe consequences. As mentioned above, the viral infection of the human herpes simplex or hominis virus can be fatal. Herpes saimiri and tamarinus have squirrel monkeys (*Saimiri*) as reservoir hosts and great care should be taken to avoid exposure (eg, though saliva, bite wounds, and on capture nets and gloves).

Wasting marmoset syndrome (WMS) used to be a common killer of captive marmosets, but is no longer frequently observed. Its aetiology is still poorly understood but it may be associated with stress, malnutrition (too much fruit, protein deficiency), parasitic, bacterial, viral infections or colitis (Sainsbury *et al.* 1987; Rensing & Oerke 2005). Haemosiderosis (a deposit of iron pigment haemosiderin in the liver) has been found in marmosets with WMS (Miller *et al.* 1997).

### Behavioural

If physical and social housing conditions are good, callitrichines rarely behave abnormally. However, hand-rearing may lead to a variety of behavioural abnormalities (Kirkwood & Stathatos 1992), and single housing may lead to locomotor stereotypies such as circling or weaving in *C. jacchus* (Hubrecht 1995). Prescott and Buchanan-Smith (2004) argue that *Saguinus* may be more predisposed to develop such abnormal behaviour than marmosets; head bobbing and self-inflicted trauma has been reported in *S. oedipus* (Box & Rohrhuber 1993; Savage 1995) and *S. labiatus* (Buchanan-Smith, personal observation).

## Reproductive problems

The increase in triplet and quadruplet births in captivity is potentially problematic. The increase in multiple births is related to weight gain in *C. jacchus* although the mechanism is not understood (Tardif & Jaquish 1997). Multiple births can lead to problems during pregnancy and birth complications (such as transverse presentation of the foetus, lameness in the pregnant female, hydrocephalus or a dead embryo blocking the cervix) (Poole *et al.* 1999). Infanticide rarely occurs in captivity, although occasionally part of an infant's tail will be bitten off. Breeding should cease from tail-biters as this behaviour appears to be passed from generation to generation.

Although, occasionally, the family will rear triplets without human intervention, often this is not the case and the weakest may fall to the floor. Hand rearing of infants is possible but the infants must be reintroduced into a conspecific group as soon as possible to minimise the serious adverse effects of separation from their natal groups. The practice of rotational hand rearing, when two infants are reared by the family group and one is human reared, has been used to reduce mortality. However it requires the animal care staff to disturb the group on a regular basis, to replace and remove an infant, and each offspring will be subjected to period of separation, which is known to influence behaviour and physiology (Dettling *et al.* 2002a, 2002b). The impact of this practice on future reproductive success, and on the suitability as models for scientific research has not been determined but it is likely to have an adverse effect (Buchanan-Smith 2006). A better practice for successfully rearing triplets may be to provide supplementary feeding to the infants whilst they remain in the family group, or to cross-foster the infants to surrogate *C. jacchus* parents, who are well experienced and on contraception. This latter practice has proved highly successful in one laboratory, reducing mortality (Morris, personal communication).

## Acknowledgments

The author would like to thank the many people who have discussed issues concerning keeping marmosets and tamarins in captivity, but in particular Hilary Box, Robert Hubrecht, Mark Prescott, Rob Rumble, Herbert Brok, Jaco Bakker, Susanne Rensing, Jean McKinley, Lois Bassett and Keith Morris and his staff at the MRC Human Reproductive Sciences Unit, Edinburgh, where several of the photos were taken. The author is most grateful to Anthony Rylands who provided to most up-to-date advice on taxonomy and to the anonymous reviewers whose constructive comments improved the chapter. Thanks also go to Lou Tasker and Inbal Badihi for their excellent editorial help.

## Squirrel monkeys

Lawrence E. Williams, Alan G. Brady and Christian R. Abee

### Biological overview

#### Taxonomy

All squirrel monkeys were once considered to be a single species (*Saimiri sciureus*) with several geographically separated subspecies. However, karyotypic and phenotypic information gathered in the early 1980s led Hershkovitz (1984) to the conclusion that squirrel monkeys should be classified as a single genus with four species (*Saimiri boliviensis*, *S. oerstedii*, *S. sciureus* and *S. ustus*) and nine subspecies. Studies conducted by Assis and Barros (1987), da Silva *et al.* (1987), VandeBerg *et al.* (1990) and Cropp and Boinski (2000) support the taxonomic classification of Hershkovitz. Ayres (1985) has described a fifth species, *Saimiri vanzolinii* that is found in central Brazil along the south bank of the Amazon River. Cropp and Boinski (2000) present evidence that *Saimiri oerstedii*, indigenous to parts of Central America (primarily Costa Rica), is a genetically distinct population and not the result of human introduction.

Squirrel monkeys are divided into two groups based on the shape of the patch of nonpigmented hair above the eyes (Figure 37.1). The use of this phenotypic characteristic for identifying species and subspecies of squirrel monkeys was first described by MacLean (1964) and later by Cooper (1968), and its usefulness confirmed by Hershkovitz (1984). Monkeys belonging to the *S. sciureus* and *vanzolinii* groups are classified as 'gothic arch' squirrel monkeys and possess a pointed arch of whitish hair above each eye. Those belonging to the *S. boliviensis* group are referred to as 'roman arch' squirrel monkeys and are characterised by more shallow semicircular patterns above the eyes. Additional phenotypic characteristics include differences in coloration of the hair on the head and body, which can range from subtle to obvious. Squirrel monkeys of the roman arch variety usually have black hair crowning their heads, although exceptions exist (Hershkovitz 1984); and gothic arch squirrel monkeys usually have a grey-green agouti coloration. *S. sciureus sciureus*, the Guyanese squirrel monkey, also possesses a pattern of pigmented hairs within the patch of whitish hair above each eye, resembling an eyebrow (Ariga *et al.* 1978).

Precise identification of squirrel monkeys often requires both phenotypic and karyotypic examination. All squirrel monkey species and subspecies that have been examined, thus far, have 44 (diploid) chromosomes; however, they vary in their number of acrocentric autosomes from five to

seven. More certain identification can be made by counting the number of acrocentric autosomes and observing the pericircular patches (Ariga *et al.* 1978). Squirrel monkeys are sexually dimorphic, although sex differences are less distinct than in many Old World primates. Male squirrel monkeys weigh 25–30% more than females, and canine teeth are larger and longer in males. In Table 37.1, the species and subspecies of squirrel monkeys are listed using the nomenclature suggested by Hershkovitz (1984).

Taxonomy is an important issue for those using squirrel monkeys in research, as a substantial body of information has accumulated over the past 30 years, providing convincing evidence that species and subspecies of squirrel monkeys vary in their susceptibility to both naturally occurring and experimentally induced diseases (Portman *et al.* 1980; Martin & McNease, 1982; Ausman *et al.* 1985; Coe *et al.* 1985).

The karyotypic variations observed in squirrel monkeys are thought to be due to pericentric inversions in the ancestral karyotype (Jones *et al.* 1973). Failure to identify and separate Peruvian, Bolivian and Guyanese squirrel monkeys in breeding colonies may result in interbreeding. Progeny of squirrel monkeys that interbreed will be heterozygous for the inversion, which may lead to the production of non-viable gametes due to crossovers at the inversion loop during meiosis. Theoretically, 50% of conceptions in hybrid squirrel monkeys may be non-viable, reducing reproductive efficiency in breeding colonies that mix species and subspecies. Furthermore, mixing species and subspecies within experimental groups may create confounding variables. There are, therefore good reasons to carefully identify and separate species and subspecies of squirrel monkeys in both breeding and experimental colonies.

#### Ecology

In the wild, squirrel monkeys inhabit most types of tropical forest including both wet and dry forest, continuous and secondary forest, mangrove swamps, riparian habitat and forest fragments (Hernandez-Camacho & Cooper 1976; Terborgh 1983; Baldwin 1985; Boinski 1987b). They appear highly flexible in their ability to adapt to different environments, and in some geographic areas appear to prefer disturbed habitats (Konstant & Mittermeier 1982; Boinski 1987b). They are omnivores, eating insects when they are available but also include fruit, flowers, bird eggs, and

**Figure 37.1** Photograph of the faces of three types of squirrel monkeys; *Saimiri sciureus sciureus* (Guyanese) top, *Saimiri boliviensis peruviansis* (Peruvian) middle and *Saimiri boliviensis boliviensis* (Bolivian) bottom. The Peruvian and Bolivian squirrel monkeys have 'Roman' or rounded periorbital arches, while the Guyanese has the 'gothic' or peaked arches.

<i>Saimiri vanzolinii</i>	44	Roman	?

occasionally vertebrates in their diet when necessary or readily available (Thorington 1967; Baldwin & Baldwin 1972; Jones *et al.* 1973; Izawa 1975; Mittermeier & van Roosmalen 1981; Scollay & Judge 1981; Mitchell *et al.* 1991). Lima & Ferrari (2003) reported that the diet of *Saimiri sciureus* in eastern Brazil shifted from 80% animal to 80% plant depending on the availability of insects.

### Social structure

In the wild, squirrel monkeys are found in large multi-male/multi-female social groups of between 20 and 50 animals, with unconfirmed reports of up to 300 monkeys in a group (Thorington 1967; Baldwin & Baldwin 1971a; Baldwin 1985; Boinski 1987b). Group size may vary somewhat depending on habitat type (Baldwin & Baldwin 1971b; Scollay & Judge 1981). In the 1960s it was thought that groups tended to break into smaller groups for foraging, rejoined for a time during the day for a rest period, and then continued foraging separately until coming back together for the night (Thorington 1967). More recent studies have found that members of social groups tend to forage as a unit, and the earlier reports are explained as observations of one troop using several large fruiting trees (Mitchell 1990). Boinski (1987b) found that Costa Rican squirrel monkeys tend to forage more widely and rest less when food is scarce during the peak wet season and travel least during the birth season.

In captivity, age/sex ratio differs depending on the type of social grouping that can be maintained in the available

housing. Generally, social groups are maintained in captivity with only one or two males per group; as male–male aggression has occurred when more than two males are maintained within a social group. Groups which have access to a more semi-natural living situation within a larger living space are able to accommodate more males within the same groupings due to the increased complexity of the environment and the possibility of escape from social conflicts. In captivity, social group size can range from a single pair up to 35–50 animals per group depending on available housing. For smaller populations, one male for every three to four females is recommended. Squirrel monkeys are very social animals and should be maintained in species-typical social groupings as much as possible.

Female squirrel monkeys reach maturity and begin breeding at around 2.5–3 years of age. In the wild, the frequency of female inter-troop transfer differs among groups from differing geographical regions. A high rate of female transfer occurs in *Saimiri oerstedii* with males remaining in their natal groups, compared to a low rate of female transfer in *Saimiri sciureus* and *boliviensis* spp., which have relatively high rates of male transfer (Boinski 1987c). Males reach sub-adult age by the time they are 2.5–3 years old and generally transfer from the natal group at that time. They may then join an all male group of juveniles and sub-adults until they become fully adult at about the age of 5 years and are able to work their way into the male dominance hierarchy of an established group (Roder & Timmermans 2002). Both social patterns provide a mechanism for maintaining genetic variability in wild populations.

### Social organisation

Squirrel monkey societies are generally kept stable by the adult females. All age–sex classes except fully adult males have been shown to be more attracted to adult females than to any other age–sex class (Baldwin 1969, 1985; Strayer & Harris 1979; Scollay & Judge 1981). Sexual segregation occurs on a seasonal basis as a unique feature of social organisation in this species. Males remain near the periphery of the group in the non-breeding season, and the majority of social interactions between the sexes take place during the breeding season (Du Mond 1967; Baldwin 1968; Mason & Epple 1969; Baldwin & Baldwin 1972; Candland *et al.* 1973; Coe & Rosenblum 1974, 1978; Strayer *et al.* 1975; Kaplan 1977; Vaitl 1977b; Vaitl *et al.* 1978; Hopf 1978; Mendoza *et al.* 1978b; Leger *et al.* 1981; Lyons *et al.* 1992; Boinski & Mitchell 1994).

The behaviour of populations from different geographical regions appears to differ (Mendoza *et al.* 1978a; Gonzalez *et al.* 1981; Mitchell *et al.* 1991). There is strong sexual segregation in *Saimiri boliviensis*, whereas *Saimiri sciureus* spp. and *Saimiri oerstedii* spp. societies are more sexually integrated (Mendoza *et al.* 1978a; Boinski 1987c). Some studies have found evidence that this sexual segregation may be female initiated through active exclusion of the males (Du Mond 1968; Baldwin & Baldwin 1972; Fairbanks 1974; Vaitl 1977a; Mendoza *et al.* 1978a). Other studies have found that the segregation may be due to inter-male social dynamics instead of female agonism (Strayer and Harris 1979; Lyons

*et al.* 1992). Boinski *et al.* (2002) suggests that the amount of female–female bonding within *Saimiri* species is related to their ecology. *Saimiri sciureus* in Suriname exhibited weaker social bonds and rarely formed coalitions with other females, when compared to *Saimiri boliviensis boliviensis*. They relate this difference to the fact that in Suriname the food patches are small and dense unlike the western South American forest. Hence, one female can dominate the food patch making any coalition unstable.

Dominance hierarchies within squirrel monkey groups differ between species. *Saimiri boliviensis boliviensis* have a high degree of sexual segregation, and also possess linear male dominance hierarchies, in which dominance is associated with higher testosterone levels and copulatory frequency. A less distinct dominance hierarchy is seen among females of this species (Mendoza *et al.* 1978a). The linear dominance hierarchies of *Saimiri sciureus* spp., which are more sexually integrated within social groups, include both sexes, with all males being dominant over all females (Mendoza *et al.* 1978a; Mitchell *et al.* 1991). *Saimiri oerstedii* spp. in the wild do not have dominance hierarchies amongst either sex; and males may co-operatively mob females to establish their state of oestrus from olfactory cues during the breeding season (Boinski 1987c; Mitchell *et al.* 1991).

Allomaternal care, or infant care by social group members other than the birth mother, has been documented in field studies (Ploog 1967; Du Mond 1968; Baldwin 1969; Hunt *et al.* 1978; Morton 2000) and in the laboratory (Williams *et al.* 1988, 1994; Soltis *et al.* 2005). Infant squirrel monkeys may spend as much as 30% of their time on allomothers during the first 6 months of their lives (Baldwin 1969; Williams *et al.* 1994). Allomothering usually begins during the first 2 weeks of life (Williams *et al.* 1994). In the wild, allomothers are usually juvenile females (Du Mond 1968). In captivity, reports have shown that one half (53%) of the allomothering is performed by young adult females, aged 4–6 years, whereas adult females, age 7–9 years, provided about 20% of the allomaternal care (Williams *et al.* 1994). Females which have experienced a reproductive failure during the year (Williams *et al.* 1988) performed almost all of the allomothering. This proclivity can be used to foster orphan infants in captivity.

### Breeding and reproduction

Squirrel monkeys have an annual reproductive cycle, with a distinct 3-month breeding season followed about 5 months later by a birth season (Du Mond 1967, 1968; Goss *et al.* 1968; Rosenblum & Cooper 1968; Baldwin 1969; Michael & Zumpe 1971; Coe & Rosenblum 1978; Boinski 1987c; Trevino 2007). A feature of this yearly cycle is reproductive seasonality in breeding males as well as the females (Du Mond 1967; Du Mond & Hutchinson 1967; Baldwin 1969; Kaplan 1977; Coe & Rosenblum 1978; Mendoza 1987; Williams *et al.* 1986b; Boinski 1987c). The 'fatted male' condition is a component of this reproductive cycle. Both sexes gain weight throughout the pre-breeding season, attaining peak weights prior to breeding. Weight gain in males is associated with increased spermatogenesis in preparation for breeding (Du Mond &

Hutchinson 1967; Coe & Rosenblum 1978; Williams *et al.* 1986b). Nadler and Rosenblum (1972) and Chen *et al.* (1981) demonstrated that male fattening is closely related to circulating levels of testosterone.

The yearly cycle has been shown, in some field studies, to be related to seasonal food availability (Du Mond & Hutchinson 1967; Baldwin 1968; Du Mond 1968; Thorington 1968; Baldwin & Baldwin 1981; Boinski 1987a). Changes in light cycles have also been shown to be associated with the timing of the reproductive cycle (Rosenblum & Cooper 1968) as has humidity level (Du Mond 1968). Boinski (1987a), in her field studies in Costa Rica, found a strong tendency towards birth synchrony in *Saimiri oerstedii* which she suggested might be an anti-predator adaptation.

Oestrous cycle lengths have been estimated to be around 8–12 days (Rosenblum & Cooper 1968; Wolf *et al.* 1975; Kaplan 1977; Diamond *et al.* 1984; Yeoman *et al.* 2000). Cycle length can be affected by social conditions (Hutchinson 1970; Wolf *et al.* 1975) and light cycles (Rosenblum & Cooper 1968).

The breeding season in squirrel monkeys shows a shift when animals are moved into the northern hemisphere (Lehner *et al.* 1967; Du Mond 1968; Rosenblum & Cooper 1968; Kaplan 1977). Several studies have linked this breeding season shift to humidity factors (Du Mond 1968; Baldwin & Baldwin 1971a; Harrison & Dukelow 1973). It has also been linked to the photoperiod by other authors (Coe & Levine 1981; Trevino 2007). The breeding season in captive squirrel monkeys is probably controlled by a combination of environmental factors, including photoperiod and humidity, that correspond with environmental changes experienced by the monkeys in their natural habitat (Dukelow 1985; Trevino 2007).

## Sources and conservation

Once plentiful and available at modest cost, squirrel monkeys were imported to the United States and Europe in large numbers in the 1960s (Cooper 1968). However, the governments of South America began banning export of primates indigenous to their countries in the 1970s. The exportation of the Bolivian squirrel monkey (*S. boliviensis boliviensis*), a species considered especially suitable for malaria vaccine studies, was banned by the Bolivian government in 1983. Thus, by the late 1980s, only Peruvian squirrel monkeys (*S. boliviensis peruviensis*) were available from the wild.

*Saimiri oerstedii citrinellus* is an endangered subspecies of which fewer than 1000 are believed to exist in the wild (Boinski 1985). These animals are not available for export; however, non-invasive field research and research aimed at improving their chances for survival are possible (Rodriguez-Vargas 2003; Sierra *et al.* 2003). Wild-caught Guyanese squirrel monkeys (*S. sciureus*) are available from Guyana and Suriname through commercial exporters. Also, Peruvian squirrel monkeys (*S. boliviensis peruviensis*) continue to be available through the Peruvian Primatology Project (PPP) in Iquitos, Peru.

There are major disadvantages to using feral-origin squirrel monkeys in research: they are of unknown age, medical

history, genetic background and reproductive history. Wild-caught animals are likely to be stressed by the process of capture and captive housing (Joint Working Group on Refinement (JWGR) 2009). Furthermore, feral animals frequently have parasitic infections, which reduce their desirability for some types of research (Abee 1985). For example, squirrel monkeys naturally infected with malaria, are not suitable for malaria vaccine development studies.

## Uses in the laboratory

### The squirrel monkey as a research subject

Squirrel monkeys (*Saimiri* spp.) are the most commonly used neotropical primates in biomedical research in the United States, whereas in Europe the predominant New World monkey used in research is the marmoset. Squirrel monkeys and marmosets share many physical characteristics, including small size and ease of handling that contribute to their desirability as research subjects. The mean body weight of adult squirrel monkeys is less than 1 kg compared with female rhesus monkeys, which usually weigh 4–5 kg. As a result, much smaller doses of synthesised compounds are necessary when using squirrel monkeys to test new drugs. This can be an important advantage when studies require administration of expensive compounds. Squirrel monkeys easily adapt to laboratory housing and can be maintained in smaller spaces and less expensive cages than larger primates, such as macaques and baboons. This characteristic is especially important in facilities with space limitations.

Interest in using squirrel monkeys instead of macaques has increased following the tragic deaths of laboratory workers after exposure to macaques shedding Cercopithecine herpesvirus 1 (B virus) in Florida (Centers for Disease Control and Prevention (CDC) 1987), Michigan (CDC 1989) Texas and Georgia (CDC 1998). There is less risk of serious zoonotic disease transmission with squirrel monkeys and other neotropical primates than with macaques and other Old World primates. Additionally, accidental exposures from bites and scratches can be managed in a manner similar to those from dogs and cats, and personal protective equipment required for handling squirrel monkeys is less extensive. The reduced risk to laboratory workers combined with ease of handling, allow more procedures to be carried out without chemical restraint or expensive handling equipment. In addition, squirrel monkeys are easily habituated to handling, which further reduces stress from manipulation. For these reasons, experimental procedures that must be performed without sedation can be carried out relatively easily in squirrel monkeys.

### Research models

The squirrel monkey has proven to be valuable in a number of areas of biomedical research as demonstrated by the publication of two textbooks devoted entirely to the squirrel monkey (Rosenblum & Cooper 1968; Rosenblum & Coe 1985). See also reviews by Brady (2000); Galland (2000);

Scammell (2000); Williams and Glasgow (2000) on further important uses of the squirrel monkey.

Although the virtues of the squirrel monkey as a research subject were described as early as the 1930s (Kliver 1933), it was not until the late 1950s that interest in its use in biomedical science really started to develop. Their small size, ease of handling and ability to tolerate high gravitational forces resulted in their use for physiological studies of the effects of space flight (Beischer 1968). The findings that squirrel monkeys maintained under laboratory conditions had fatty streaks and plaques in their aortas resembling human atherosclerosis (Middleton, *et al.* 1964), and that wild squirrel monkeys also have naturally occurring atherosclerotic lesions (Middleton *et al.* 1967), has led to their use in atherosclerosis research (reviewed by Strickland & Clarkson 1985).

Squirrel monkeys have been the subject of research involving the experimental induction of cholelithiasis (Lofland 1975; Osuga and Portman 1971) and into reproductive biology (Bennett 1967a, 1967b). The squirrel monkey is an important animal model for malaria vaccine development studies. *Plasmodium* spp. are host specific; therefore the animals used for studies of human malaria must be susceptible to the same strains of *Plasmodium* that cause disease in humans. The Bolivian squirrel monkey has been shown to be a superior model than the Guyanese squirrel monkeys (*S. sciureus sciureus*) for studies of the pathogenesis of *Plasmodium falciparum* Indochina I (Whiteley *et al.* 1987). Differences in susceptibility to experimental malaria infections emphasise the importance of species identification when using squirrel monkeys.

The squirrel monkey is one of the most susceptible non-human primate species to experimental infection with Creutzfeldt-Jakob disease (CJD) and other transmissible spongiform encephalopathies (Zlotnik *et al.* 1974; Brown *et al.* 1994; Schätzl *et al.* 1995; Marsh *et al.* 2005). Williams *et al.* (2007) reported on behavioural changes seen in squirrel monkeys that were associated with experimental transmission of both variant CJD and sporadic CJD.

Foetal rotation resembling that seen during labour and delivery in women has been observed in the squirrel monkey. The implications of this for obstetric evaluation of fossil hominid pelvises may prompt re-evaluation of currently accepted views of labour and delivery in these species (Stoller 1995). A report of lesions consistent with pelvic organ prolapse (POP) in a small group of aged squirrel monkeys from the Scott & White Clinic and Hospital in Temple, Texas (Coates *et al.* 1995), suggested that the squirrel monkey might be a model for the disease. (Shull *et al.* 1992). It was subsequently confirmed that multiparous squirrel monkeys develop lesions resembling POP in women.

## Laboratory management

### General husbandry

#### Housing, food and water

General advice on husbandry, care and common procedures for non-human primates can be found in JWGR (2009).

Squirrel monkeys are social animals and all efforts should be made to house them in social groups or, at least, in pairs. Figures 37.2 and 37.3 illustrate a large social group pen and smaller cages that can be used for single- or pair-housed animals. The European standard for squirrel monkey caging calls for a minimum floor space of 2 m<sup>2</sup> for up to two animals, with an additional 0.5 m<sup>2</sup> for each additional animal (European Commission 2007). The US standards classify squirrel monkeys as type 2 primates, requiring 3 ft<sup>2</sup> (0.28 m<sup>2</sup>) for each animal (National Research Council 1996). All squirrel monkeys should be housed with a temperature range of around 24–27°C (75–82°F) and with a relative humidity of 40–60%. Lower temperatures or humidity levels can lead to upper respiratory problems (Abee 1985).

Squirrel monkeys do well when exposed to natural lighting (Srivastava *et al.* 1970; Williams *et al.* 1986a) with the breeding season shifted toward the period of short days. A 12h light–dark cycle is appropriate for indoor-housed animals, although light cycles can vary somewhat. There is anecdotal evidence that when housed indoors for extended periods, time-limited exposure to UV lamps may be helpful for vitamin D3 synthesis.

Squirrel monkeys should be fed a nutritionally balanced diet such as commercially available monkey chows, specifically formulated for New World primates. *Ad libitum* feeding should be supplemented with fresh vegetables, fruit slices and mealworms periodically. Non-carbonated sports drinks and yogurt should be considered for animals that are ill or debilitated. Feeding each morning following completion of the cage sanitation procedures and again in the afternoon will ensure food is continuously available.

**Figure 37.2** Socially housed squirrel monkeys in an indoor facility. Note the use of vertical space and multiple travel paths throughout the cage. The animal on the middle-right is coming through a doorway from a second cage.

**Figure 37.3** Individually housed squirrel monkeys in enriched cages. There are multiple levels of perching and plastic chain used to increase access to the vertical space in the cage. Small enrichment devices are hung either in the cage or on the outside wire mesh. These cages conform to the US standard of 3 ft<sup>2</sup> (0.28 m<sup>2</sup>) per animal floor space with 30 inches (0.76 m) minimum height. The European standard is 2 m<sup>2</sup> for either one or two animals (an additional 0.5 m<sup>2</sup> for each animal over two) with 1.8 m<sup>2</sup> minimum height.

Animal feeds should be stored on pallets in a clean, dry, vermin-free environment. Milling dates should be monitored as a standard procedure to make certain that fresh feed is used. Those commercial diets made in the US with milling dates of more than 90 days (180 days for feeds certified to maintain vitamin C levels for that period of time) should be discarded. Since group-housed animals may fight over feed, sufficient food should be provided at multiple sites in the cage to allow *ad libitum* feeding throughout the daylight hours. Broadcasting diet pellets within group pens will encourage foraging behaviour and discourage food guarding by dominant animals (see general recommendations for feeding primates in European Commission 2007). This method should be considered for larger pens with solid floors.

Water may be provided from bottles with sipper tubes or by automatic watering devices, which consist of low-pressure water pipes equipped with watering valves. Monkeys unaccustomed to these devices may need to be shown how they operate to avoid dehydration. Animals housed in pens or cage/rack units should be provided with water continuously. Watering bottles should be changed no less than three times per week and should always contain water.

### Environmental provisions

In nature, squirrel monkeys live in large social groups containing 20–200 animals (Baldwin & Baldwin 1971a) with multiple males and females of different ages. Efforts should be made to house them in social groups where possible. Animals born into a social group should be maintained within their social group as long as possible. In the South American species of squirrel monkeys, females typically stay within the social group and males emigrate after age 1.5–2 years. Squirrel monkeys will fight with unfamiliar conspecifics (Williams & Abee 1988) so frequent movement of animals between social groups should be avoided. Squirrel monkeys that must be held separate from their social group for experimental or clinical purposes should be pair-housed. If that is not possible they should be given visual or auditory access to other animals (Schuler & Abee 2005).

Since squirrel monkeys are arboreal, perch arrangements can be used to vary the cage environments and increase the activity of the animals. Figures 37.2 and 37.3 illustrate caging and enrichment. Rearranging the perches and providing new materials is an easy way to provide novelty. Notice the extensive use of three-dimensional spaces. Squirrel monkeys are arboreal and will use vertical space if it is available.

Squirrel monkeys are naturally curious and will manually probe objects hung in their cages. Hanging objects such as practice golf balls, infant toys, and polyvinyl chloride (PVC) plumbing joints can be used with or without food enrichment to increase activity rates. However, using foraging (Fekete *et al.* 2000) and other devices (Spring *et al.* 1997) to ameliorate stereotypical behaviour has not been successful. See also Chapter 10.

### Cleaning, sanitation and personnel hygiene

The maintenance of monkeys in cages limits their living space to a relatively small area. This results in concentration of faeces and urine within the animals' immediate living area. Many pathogens in otherwise healthy animals are shed in large numbers in faeces. Therefore, daily cleaning of cages and contact surfaces is an essential part of the preventive medicine programme. Animal husbandry and cage sanitation schedules should include routine sanitising of contact surface areas consistent with guidelines, such as those provided in National Research Council (1996). For squirrel monkeys maintained in Europe, the Commission Recommendations (European Commission 2007) serve as guidelines for the accommodation and care of animals for experimental and other scientific purposes, and may shortly become mandatory.

Group pens should be cleaned daily. Pens should be scrubbed every 2 weeks with a detergent-disinfectant. Cages and racks should be changed and sanitised every 2 weeks. Excreta pans should be flushed daily. Accessory items, such as catch gloves, should be dedicated to specific areas to prevent fomite transmission of pathogens and should be cleaned or replaced regularly. Bedding materials, when used, should be emptied into plastic bin liners.

Technicians and other personnel working with monkeys should be provided with clean protective clothing daily.

Personnel should be required to wear a surgical mask or respirator and gloves when handling primates. Persons developing positive tuberculin reactions should not be permitted to work with monkeys until a sufficient period of treatment has elapsed or medical evaluation has been carried out. Examination gloves, leather catch gloves, face masks, dedicated uniforms and head covers should be worn whenever animals or their wastes are handled. Staff showers and locker rooms should be provided for bathing and staff should change into street clothes before leaving the facility.

### Identification of animals

Several methods are available for identification of squirrel monkeys. When properly applied, tattoos provide a durable method of identification. Recommended tattoo sites are on the chest, abdomen, or the medial thigh. Neck tags that can be read from a distance are advantageous when animals are group-housed. Modified livestock tags, cut down in size or coloured beads (Soltis *et al.* 2005) can be used to identify individuals. Neck chains for identification tags must be carefully fitted. A chain that is too loose may slip over the animal's mandible or catch on parts of the cage. If it fits too tightly, it may cause skin lesions or, in extreme cases, impede respiration. Neck chains should be rechecked for proper fit whenever animals are handled because weight loss or gain may mean that they need resizing.

Implantable microchip transponders that broadcast a unique identifying number to an external receiver provide a reliable means of identification. When choosing a method of identification consideration should be given to using the least invasive technique.

### Age determination

One major advantage of using purpose-bred squirrel monkeys for research is that the age of an animal will be known. If animals with unknown birthdates are used, an estimate of the animal's age may be made by examining dentition and general physical appearance (Galliari & Colillas 1985; Long and Cooper 1968; Smith *et al.* 1994; Tappen & Severson 1971). Williams and Gibson (2004) provide a useful chart for aging female Guyanese squirrel monkeys (*Saimiri sciureus*) using the length of the black 'sideburns' seen only on the females. There is a high correlation ( $r = 0.97$ ) between the length of the sideburn and the age of the female.

### Health monitoring

Daily observation of all squirrel monkeys is an important husbandry and veterinary support procedure. Serious health problems can progress rapidly in squirrel monkeys so that an animal overlooked during the morning observations could die before being discovered later in the day. Observations of all animals should be carried out at least twice daily. The first observation should be made before cages are cleaned in the morning. The floor of the cage should be observed for signs of blood, aborted or stillborn fetuses (during the birth season), and for animals sitting or

lying on the floor of the cage. An estimation of the feed consumed should also be made at this time. If water bottles are being used, the water consumed should be also estimated. A second observation is made late in the day. Animals that do not appear interested in eating should be observed for signs of injury or disease. During the birth season, observations are often useful in determining which females are nearing parturition and whether labour is beginning or whether there is an abnormal foetal presentation. The veterinary staff should be consulted immediately if unproductive labour is observed. Unproductive labour exceeding 1 h requires immediate veterinary attention.

### Biosafety considerations

Squirrel monkeys are carriers of herpesvirus saimiri 2, which is known to be oncogenic in other primates and can infect and transform human T-lymphocytes *in vitro* (Mansfield & King 1998). Although there are no data which would indicate that Herpesvirus saimiri 2 can cause disease in humans, its ability to cause disease in other animals and to replicate in human issues is sufficient reason to counsel persons who work with squirrel monkeys to use appropriate procedures to minimise potential risk of transmission of the virus from the animals to themselves.

They are also carriers for herpesvirus saimiri 1, which is known to cause fatal disease in *Aotus* and some other species of New World primates (Mansfield & King 1998). Biosafety precautions should always be followed with squirrel monkeys. A sensible approach is to follow the *Update: Universal Precautions for Workers Handling Human Blood, Body Fluids and Tissue in the Workplace* (CDC 1988) when working with squirrel monkeys, their tissues and their body fluids.

Squirrel monkeys are not considered to be carriers of Cercopithecine herpesvirus 1, CHV-1 (also known as B virus), which can cause deadly central nervous system disease in humans. Therefore, the stringent testing and treatment techniques required for bites, scratches and splashes on humans when inflicted by macaques from B-virus positive colonies are not required for cases involving squirrel monkeys (Holmes *et al.* 1995). Squirrel monkeys are also thought to be less likely to contract tuberculosis than macaques (Osborn & Lowenstine 1998).

### Laboratory procedures

#### Restraint techniques

Manual and chair restraint methods may be used for squirrel monkeys. Techniques of restraint may have important effects on certain types of studies. Both capture and chair restraint can cause adrenal cortical activation and growth hormone release (Brown *et al.* 1971b, 1971a). Manual restraint can cause elevation in glucagon (Myers *et al.* 1988). Ketamine anaesthesia has been postulated to cause changes in glucose tolerance test results in other non-human primates (Streett & Jonas 1982); however, this belief has been disputed by others (Brady & Koritnik 1985; Castro *et al.* 1981); Kemnitz & Kraemer 1982). The ultrashort-acting barbiturate anaes-

thetic sodium thiopental can cause premature ventricular contractions in squirrel monkeys (Wolf *et al.* 1969) and should be used with caution.

### Gastric intubation and vascular access

Gastric intubation and vascular access techniques are useful for a variety of studies. Gastric intubation may be performed by the orogastric or nasogastric route. Both may be performed using a number 5 French infant feeding tube (Abee 1985). Orogastric intubation requires the use of a speculum in awake animals to prevent the animal from chewing the tube. Nasogastric intubation requires some practice to be performed properly in the squirrel monkey. After marking the distance to the stomach on the tube, a small amount of sterile lubricant jelly is applied to the tip, and the tube is gently inserted into the nares. The tube must be directed medially to avoid the blind pouch in the nasal cavity (Abee 1985). When the tube has been inserted to the previously made mark, it should be dipped in water to form a meniscus on the luer adapter. This meniscus should then be observed for respiratory movement because such movement suggests that the tube may have been inserted into the trachea and it should be repositioned before use to prevent accidental aspiration. Epistaxis may occasionally occur as a result of nasogastric intubation, but it is usually mild and self-limiting when the technique is performed properly.

### Blood sampling and parenteral injections

General advice on blood sampling techniques can be obtained from JWGR (1993). Venous sampling and intravenous injection are best performed with 23–27G needles. Large samples (>0.25 ml) may be taken from the femoral vein at the femoral triangle or the lateral tail vein. These sites are also suitable for injection. The saphenous veins located on the dorsal surface of the leg below the knee may be used for intravenous injections and small blood volume collections. These sites are generally suitable only for smaller samples because veins at these sites collapse easily. Blood sample volumes are limited by the size of squirrel monkeys. As a general rule, no more than 3–4 ml of blood per kilogram of body weight should be obtained at one time. Animals from which samples are taken repeatedly should have periodic haematocrits to monitor for anaemia. The following protocol can be used to treat adult squirrel monkeys that have anaemia associated with blood loss or that are included on experimental protocols requiring frequent blood sampling: (1) iron as iron dextran: 50 mg intramuscularly, once; (2) folic acid: 2.5 mg subcutaneously, twice weekly; and (3) vitamin B complex includes cyanocobalamin, riboflavin (B2), and pyridoxine (B6): dose depends on formulation, subcutaneously, twice weekly. Once the hematocrit reaches 40%, treatment should stop.

General advice on the administration of substances can be found in JWGR (2001). Subcutaneous injections in squirrel monkeys may be performed dorsally between the scapulae. Caution should be used when intramuscular injections into the thigh are performed because the ischiatic nerve is easily damaged by needle penetration of the leg (Abee 1985).

### Anaesthesia and analgesia

Anaesthesia may be performed in squirrel monkeys with many of the same agents used in other primate species (Brady 2000; Horne 2001). The discussions later in the chapter, regarding hypothermia and hypoglycaemia in squirrel monkeys, are directly applicable to animals that are anaesthetised, and especially those animals anaesthetised for prolonged periods. Appropriate precautions should be taken to prevent hypothermia and hypoglycaemia.

The use of a long-acting barbiturate such as sodium pentobarbital is recommended in squirrel monkeys only for terminal procedures because long-acting barbiturates cause respiratory depression (Flecknell 2009) and prolonged recovery in squirrel monkeys. If sodium pentobarbital is used at the standard 50 mg/ml concentration, it should be diluted 1:1 with saline before use.

Isoflurane is an excellent agent for inhalation anaesthesia of squirrel monkeys. Mask induction may be rapidly performed in animals that are manually restrained, or animals may be induced with an injectable agent, intubated, and maintained under anaesthesia with isoflurane. Morris *et al.* (1997) have described a technique for intubation of squirrel monkeys. Dead space, resistance to flow, and heat and humidity loss in anaesthesia circuits are important considerations due to the small size of the squirrel monkey (Hartsfield 1996). A non-rebreathing anaesthesia circuit is recommended for inhalation anaesthesia.

Experimental work with pregnant squirrel monkeys anaesthetised for extended periods has shown the value of careful anaesthesia monitoring, and 'balanced anaesthesia' technique, where multiple drugs are used with each agent directed at a different component of the anaesthetic state (consciousness, analgesia, autonomic reflexes, muscle relaxation) (Thurmon *et al.* 1996). End-tidal carbon dioxide and blood pressure/heart rate are especially useful parameters for managing squirrel monkeys during anaesthesia. Drugs to consider for this balanced approach may include isoflurane, nitrous oxide and thiopental (Avidan, personal communication).

Mechanical ventilation can be performed in squirrel monkeys under anaesthesia. A neurophysiology study of five adult squirrel monkeys used an estimated tidal volume of 6–8 ml/kg with a respiratory rate of 70/minute as initial settings. These volumes were then adjusted to give an end-tidal carbon dioxide (collected through a catheter inserted through the endotracheal tube to midtrachea) of 3.5–3.8% (Maier *et al.* 1997; Morris, personal communication).

Analgesics should be used in squirrel monkeys during and after recovery from surgical procedures unless specifically contraindicated by experimental protocol or the medical condition of the animal. Buprenorphine at a dose of 0.01 mg/kg intramuscularly or intravenously causes little sedation in squirrel monkeys and is an effective analgesic that may be given every 12 h (Jenkins, 1987).

### Euthanasia

Euthanasia should be performed in accordance with established humane procedures (American Veterinary Medical

Association (AVMA) 2007) in the US. European laboratories with squirrel monkeys should comply with the principles set by the European Commission Recommendations for euthanasia of experimental animals (Part 1 and Part 2) (European Commission 2007) or local national regulations.

## Common welfare problems

### Hypothermia and hypoglycaemia

Investigators accustomed to using rodents and larger primates in their research should be aware of squirrel monkey characteristics that may require alteration of experimental procedures. Their small size, low body fat reserve and long extremities all contribute to rapid heat loss when they are anaesthetised or debilitated. At-risk animals should be monitored for body temperature on a regular basis. Awake, restrained squirrel monkeys normally have a temperature of 38–39.5°C. Healthy, active, struggling animals may rapidly increase their body temperatures as high as 41°C. Temperatures of less than 37.7°C are seen with seriously ill animals and should be investigated immediately. In general, electronic thermometers designed for use on humans and animals may be used with squirrel monkeys. Tympanic membrane thermometers register temperatures much faster than most rectal thermometers, and can be used with adult squirrel monkeys. These thermometers are especially useful for rapidly estimating temperatures on multiple animals. Williams (unpublished data) has found an 85% correlation between the two methods, with the tympanic membrane thermometer registering 0.2–0.6°C lower than the mercury rectal thermometer. Careful positioning of these thermometers over the tympanic membrane is important. These thermometers may not work well for infant or smaller juvenile squirrel monkeys.

For hypothermic animals, supplemental heat may be provided in a variety of ways. Awake animals may be housed in incubator-type enclosures or on warm water recirculating pads. Recirculating pads may also be used for anaesthetised animals. Heat packs that use a controlled exothermic chemical reaction can provide a convenient, portable, temporary source of warmth for anaesthetised and recovering animals. Electrical heating pads should not be used with squirrel monkeys due to the danger of burns and electrical shock. Convection warmers are effective for maintaining body temperature in anaesthetised squirrel monkeys.

Squirrel monkeys are predisposed to hypoglycaemia (Abee 1985; Brady *et al.* 1990, 1991). The normal blood glucose concentration for adult squirrel monkeys is 80 ± 28 mg/dL (Loeb & Quimby 1989). Prolonged research procedures, fasting, or debilitating conditions that result in anorexia may place animals at risk for a hypoglycaemic crisis. Dry reagent strips for determining blood glucose concentration and meters that accurately read these strips are available from most pharmacies. These strips are inexpensive and useful tools for monitoring squirrel monkeys. Hypoglycaemic animals that are still conscious should be given glucose or sucrose solution orally. Unconscious animals should be given sterile 20% dextrose solution by

nasogastric tube (discussed earlier in this chapter). Infants should be given 1 ml, juveniles 3–5 ml, and adults 10 ml. Use of concentrated intravenous glucose solutions to treat hypoglycaemia is not recommended.

### Selected diseases and injuries

Infection of squirrel monkeys with herpesvirus saimiri 1 and 2 (HS-1 and -2) is widespread, with most infected animals having no clinical signs. Squirrel monkeys infected with HS-1 that are stressed or immunosuppressed may have oral-pharyngeal lesions that resemble human cold sores. The lesions usually resolve within a few days without treatment, but animals may require hand-feeding during this period due to difficulty eating. (Gibson, personal communication).

*Yersinia enterocolitica* and *Yersinia pseudotuberculosis* are aetiological agents for the disease known as pseudotuberculosis in squirrel monkeys and other non-human primates. Infection can result in septicaemia. Animals are often not diagnosed until the disease is severe, or animals are simply found dead with no prior clinical signs. This makes treatment of pseudotuberculosis difficult. Visceral abscesses are commonly seen at necropsy. Feral rodents and birds are reservoirs for the causative agents. Squirrel monkeys can also be silent carriers. Cultures of rectal swabs under the required conditions may identify monkeys that carry these agents (Brady & Morton 1998). *Pasteurella*, *Bordetella*, *Staphylococcus* and *Klebsiella* have caused bacterial disease in squirrel monkeys.

Heart disease is frequent in older squirrel monkeys (Brady *et al.* 2003). In one study, 23 of 88 adult squirrel monkeys necropsied over a 4-year period had a diagnosis of heart failure or had lesions consistent with heart disease. Heart disease is most often seen in multiparous older females, but may also be seen in peripartum females of any age and in older males (Gibson, personal communication). Most heart disease in squirrel monkeys is cardiomyopathic. Clinical signs may include laboured respiration, ascites, hepatomegaly and cyanosis. Diagnosis is best accomplished by echocardiography. Although successful protocols have been developed for treatment of other New World primates (Brady *et al.* 2005), squirrel monkeys with cardiomyopathy have been relatively refractory to treatment.

### Renal disease

Renal disease has long been recognised as a major cause of morbidity and mortality in older squirrel monkeys, especially those of feral origin. Glomerulonephritis, pyelonephritis and renal lithiasis have been reported (Stills & Bullock 1981). Affected animals may have weight loss, lethargy, a characteristic foul odour and, in advanced cases, subcutaneous oedema (Abee 1985). Serum chemistry generally demonstrates elevated blood urea nitrogen (BUN) and creatinine with low serum albumen. Haematology test results may reveal anaemia (see Tables 37.2 and 37.3). Animals with acute renal disease may respond to supportive care and fluid therapy. However, chronic renal disease with clinical signs noted above is often refractory to treat-

**Table 37.2** Reference haematology values taken at the Center for Neotropical Primate Research and Resources. Assays were performed on blood collected in EDTA. Blood samples were collected from juvenile and adult Bolivian squirrel monkeys, most of which were colony born. Values from pregnant monkeys were included. \*Albumin levels are low due to test methodology (dry substrate bromidene green) and under-represent actual values.

ment. Ensuring adequate hydration at all times is the best method for preventing and managing renal disease.

#### Periodontal disease

Dental disease, especially periodontal disease, has been reported in captive colonies of squirrel monkeys (Clark *et al.* 1988; Brady *et al.* 2000). Periodontal disease can lead to dental abscesses and reduced food intake due to painful

eating, especially in older animals. It can also cause systemic bacteraemia, with associated health problems. Increased diet supplementation with vegetables as opposed to fruits may be of some benefit in preventing periodontal disease (Williams *et al.* 1992). Sodium hexametaphosphate as a feed additive has been proposed as a means to prevent dental calculus formation that is thought to predispose squirrel monkeys to periodontal disease. Unfortunately, the diet with this additive does not appear to be effective in reducing

existing calculus (Brady *et al.* 2000). All squirrel monkey colonies should have programmes for routine dental examination and cleaning and be equipped to treat dental problems such as dental abscesses.

### Fight-related injuries

Although social housing of squirrel monkeys is desirable, fight-related injuries are common in such housing, especially when social groups are first established. Close attention to group compatibility, careful supervision of newly established groups and provision of hiding places in animal enclosures can help reduce such injuries or prevent them altogether (Williams & Abee 1988). When wounds do occur, they can usually be divided into crushing-type injuries (more commonly inflicted by female squirrel monkeys) or lacerations (commonly inflicted by males) (Ruiz *et al.* 2005). To treat wounds, surrounding hair should be clipped, the wound cleaned and debrided as needed and the wound dressed and/or sutured at the discretion of the attending veterinarian. Care should be used when deciding to suture fight wounds, especially the crushing-type of injuries. Many of these wounds will heal better by second intention rather than suturing. Absorbent dressings may be useful with suppurative wounds as these dressings will serve as a wick to draw the infection out of the wound.

### Failure-to-thrive syndrome

A syndrome resembling human failure-to-thrive syndrome (FTT) has been described in squirrel monkey infants. In one colony, 3% of live-born infants showed signs of FTT. It was characterised by premature thymic involution, poor weight gain and increased number of opportunist infections. Most of the infants died before they reached 6 months of age (Gibson *et al.* 1998). No effective treatment has been developed for FTT in squirrel monkeys.

## Capuchin monkeys

James R. Anderson and Elisabetta Visalberghi

### Biological overview

Recent revisions of the taxonomy of the genus *Cebus* have identified between 7 and 11 species (see overview in Fragaszy *et al.* 2004b). In addition to the long-recognised four species (white-fronted capuchin, *C. albifrons*; black-capped, brown or tufted capuchin, *C. apella*; white-faced or white-throated capuchin, *C. capucinus*; and weeper or wedge-capped capuchin, *C. olivaceus*), the following are now increasingly accorded full species status: the yellow-breasted capuchin (*C. xanthosternos*), the Ka'apor capuchin (*Cebus kaapori*), the black-striped or bearded capuchin (*C. libidinosus*), and the black or black horned capuchin (*C. nigrinus*). However, more systematic and comprehensive studies of morphology, anatomy and molecular biology are needed in order to base taxonomic revisions on solid evidence.

Notwithstanding the new revisions, almost all the literature concerning capuchin monkeys follows the 'traditional' taxonomic four-species split. This is especially true for studies carried out in captivity on the tufted species, the former *C. apella*; most researchers have not known the geographical origin of the founders of the colony and it is likely that interbreeding of *C. apella*, *C. libidinosus* and *C. nigrinus* has occurred. In this chapter we refer to the four traditional species except in cases where one of the recently designated species (such as *C. xanthosternos*) has been explicitly identified.

It is clear that the genus *Cebus* is a successful and adaptable one, with representatives widely distributed throughout Central and South America. Capuchin monkeys are not particularly rare; in fact *C. xanthosternos* is the only species listed as 'critically endangered' in the 2007 International Union for the Conservation of Nature and Natural Resources (IUCN) Red list, but this probably reflects a lack of adequate information on some of the other species; see Rylands *et al.* (1995, 2005) for discussions of taxonomy and distribution of capuchin monkeys). Most information about behavioural biology, and how best to keep capuchins in captivity, comes from studies of *C. albifrons*, *C. capucinus* and *C. olivaceus*, and especially *C. apella*, but taxonomic misidentifications seem likely throughout much of the earlier literature.

### Social organisation

Capuchins live in groups, typically ranging in size from around 12–35 individuals (Fragaszy *et al.* 2004b). Although

group size is variable across populations and species, groups typically contain at least one adult male and several adult females, juveniles and infants. Males, but not females, typically emigrate from their natal group, and they may emigrate more than once in their lifetime. Some aspects of social organisation may vary across species, but there is usually a clearly dominant male (often larger and stronger than the other males, but in captivity at least it is not always so) and a dominant female.

Although group members can be categorised into different dominance classes, this can be difficult below alpha status, as social relations are characterised by a high degree of inter-individual tolerance and low rates of aggression. In captive groups of *C. apella*, sometimes one individual can become the target of harassment or aggression by many of the other group members, thus becoming a scapegoat. In the wild, such a subordinate would be better able to avoid others by staying on the periphery of the group, possibly even leaving the group altogether. Agonistic interactions do not usually escalate to involve two competing factions, but instead consist of one or more individuals pitted against another individual. Agonistic coalitions may occur, reflecting kinship or rank relations (Ferreira *et al.* 2006). The extent of post-conflict reconciliation in the different species remains an open question, but the behaviour may be more common in captivity (*C. capucinus*, Leca *et al.* 2002), and influenced by early experience (*C. apella*, Weaver & de Waal 2003).

### Feeding habits

Capuchins live in a wide variety of habitats from sea level to above 2500m altitude, mostly but not exclusively in forests (Fragaszy *et al.* 2004b). Some groups inhabit forest patches surrounded by large open areas and secondary vegetation, and some may be commensal with humans, living close to urban areas and coming into daily contact with people (Sabbatini *et al.* 2006). They spend most of their time in trees, especially in middle layers of the canopy, but depending on local habitat conditions they also exploit resources on the ground, for feeding (including crop raiding), drinking, playing, or crossing gaps between patches of forest.

Capuchins are omnivores. They eat mostly fruits, but include varying proportions of other vegetable items (shoots, flowers, buds, leaves etc), invertebrates (molluscs, insects,

worms, etc) and vertebrates (for example, birds and their eggs, snakes, lizards, small mammals including bats) in their diet. Some groups also exploit human garbage. Many other South American monkeys eat the same items as capuchins, but the latter are distinguished by their 'destructive' manner of foraging. They are 'extractive' foragers, meaning that they exploit hidden and encased foods. Fragaszy and Boinski (1995) describe the wide diversity of capuchins' foraging styles, including the following 'strenuous' foraging actions, which may be combined: dig, rip, bite, bang, grab, break, carry, tap, roll, scrape, chase. 'Quiet' foraging actions, which may also be combined, include pick, visually examine, lick, mouth, sniff, manually examine, sift, take, feel, scoop, turn over, masticate, open by peeling.

One particular combination of strenuous foraging activities typifies wild capuchins: breaking open hard-shelled fruits or nuts. For example, *C. apella* pluck hard-shelled cumare fruits by biting through the stem, then repeatedly bang the fruit against the tree trunk or a branch until cracks appear on the fruit. They then peel the cracked rind with their teeth and then bang the nut again until the husk breaks and the kernels can be extracted. Combined foraging actions are also evident in searching for edible items among the debris to be found in palm fronds, and in breaking off palm leaves and peeling off the stems. Another foraging category, long known in captive groups but recently confirmed in the wild, is tool-assisted extractive foraging, notably using sticks to dig, and nut cracking using natural hammers and anvils (*C. libidinosus*, Fragaszy *et al.* 2004a; Moura & Lee 2004).

### Standard biological data

Table 38.1 presents information on a number of important aspects of growth and development of *C. apella*. Data are provided on this species because it is by far the most commonly studied species in captivity. Blood biochemistry, haematological and serum protein parameters for adult males and females, and juveniles, are reported in Appendix III of Fragaszy *et al.* (2004b). Recent information on reproductive biology (including hormonal profiles) can be found in Carosi *et al.* (2005) and Carnegie *et al.* (2005a). Ankel-Simons (2007) presents anatomical data.

In addition to some distinctive physical biological traits (see later), a number of behavioural features combine to make capuchins unique among New World monkeys. They have the same variety of facial displays as Old World monkeys, with displays emerging at different points in development (Visalberghi *et al.* 2006; De Marco & Visalberghi 2007) (Figure 38.1). Lip-smacking (an affiliative display) appears near the end of the first month; the open-mouth threat face is the last to emerge, between 4.5 and 10 months of age. Capuchins also possess a rich vocal repertoire – still to be thoroughly studied – and great manual dexterity that includes precision grips and diverse tool-using behaviours (Fragaszy *et al.* 2004a, 2004b; Spinozzi & Truppa 1999; Visalberghi 1990).

*C. apella* show highly elaborate sexual behaviour. Females in oestrus actively solicit males, who may be at least initially reluctant (Phillips *et al.* 1994; Carosi & Visalberghi 2002;

**Table 38.1** Reproduction, growth and development of *Cebus apella*.

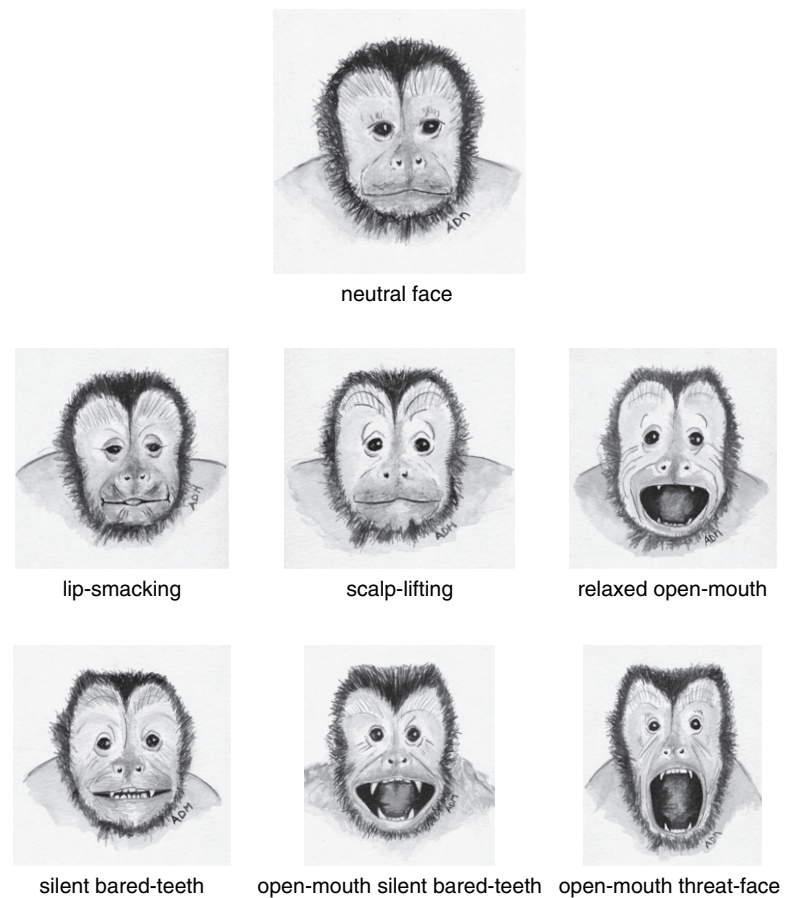

Parameter	Normal value	Source
Gestation	Captive capuchins, 160 days	Fragaszy & Adams-Curtis, 1998
Birth seasonality	Not marked. Peak birth period may coincide with increased availability of food	Di Bitetti & Janson, 2000
Interbirth interval	Captive capuchins, 20.6 months	Fragaszy & Adams-Curtis, 1998

combination it signals that she is in the periovulatory phase. Although copulation is mostly dorso-ventral, ventro-ventral posturing with mutual gaze is common. The sexual behaviour of the other *Cebus* species has not been so closely investigated, but good field data exist for *C. capucinus* (Manson *et al.* 1997; Carnegie *et al.* 2005b). In this species chemical communication has a greater role, as indicated by male interest in females' urine.

It is easy to mistake male and female newborns and infants because the external sex organ of the female resembles that of the male in size, general shape and mobility (Figure 38.2); only close examination allows detection in females of a fissure instead of a hole at the tip of the genitalia and sex differences in shape. For good illustrations of the genitalia of both sexes, see Fragaszy *et al.* (2004b).

Like other New World primates, capuchins show sex-linked colour vision polymorphism. Some females have trichromatic vision, whereas all other individuals have dichromatic vision. Several studies have attempted to link this polymorphism to differences in wild monkeys' foraging strategies or efficiency, with little overall success. However, a recent study on wild *C. capucinus* reported differential success in preying upon camouflaged insects (Melin *et al.* 2007). A study on captive *C. apella* also reported an advantage of dichromacy compared to trichromacy for detecting camouflaged stimuli (Saito *et al.* 2005). The fact that there will probably be different colour vision abilities within a given captive group should always be borne in mind, as this

may influence choice of enrichment devices and feeding techniques.

### Sources of supply

Capuchins are widely distributed in the wild and breed very well in captive conditions. They are quite hardy and resistant to disease (see later), although intestinal parasites

(worms) may be present. Laboratories and zoos have often a surplus of animals, leading to the use of birth control methods. Captive-bred specimens can be found through the Primate Resource Referral Service (Washington National Primate Research Center, USA).

## Uses in the laboratory

Due to their fascinating biological and behavioural features, capuchins have become very popular in behavioural studies both in the wild and captivity. This popularity seems likely to increase, with the first *in vivo* brain imaging study a notable recent development (eg, Phillips *et al.* 2007). They are also used in biomedical research; for example, pharmacology, *Trypanosoma cruzi* infection, genital herpes II, reproductive biology and neuroscience, but to a much lesser extent than other New World monkeys such as *Aotus*, *Callithrix* or *Saimiri*. Capuchins (especially *C. apella* and *C. albifrons*) have been used to provide 'simian helpers' to paraplegics in North America, Israel and France, but the cost effectiveness and welfare implications of these projects are debatable.

However, capuchins are probably considered especially interesting for their cognitive abilities. Their psychological traits are currently studied from many perspectives including tool use (Anderson 2002; Fujita *et al.* 2003; Visalberghi & Fragaszy 2006); visual perception and visuo-spatial learning (Fragaszy *et al.* 2003; Anderson *et al.* 2005; Fujita & Giersch 2005; Rosengart & Fragaszy 2005), visual search, memory, and metacognition, (Tavares & Tomaz 2002; Spinozzi *et al.* 2003; Paukner *et al.* 2006; De Lillo *et al.* 2007), co-operation, exchange, and symbolic representation (Brosnan & de Waal 2004; Addessi *et al.* 2007a, 2007b), judgements of quantity (Addessi *et al.* 2007b; Beran *et al.* 2007), use of social and non-social cues for finding food (Vick & Anderson 2000; Visalberghi & Neel 2003; Hattori *et al.* 2007; Sabbatini & Visalberghi 2008), face processing (Dufour *et al.* 2006) and self-recognition (Paukner *et al.* 2004; de Waal *et al.* 2005; Roma *et al.* 2007). Despite the fact that fieldwork has been done on all four traditionally recognised *Cebus* species and is now extending to other species, the laboratory population consists almost entirely of tufted capuchins (*C. apella*), while zoos host also *C. capucinus*, *C. albifrons*, *C. olivaceus* and *C. xanthosternos*. It should be noted that captive capuchins may live for well over 40 years, and one specimen reportedly lived up to 53 years (Bartus, personal communication). Any planning of research should take this extended longevity into consideration.

## Laboratory management and breeding

### General husbandry

General advice on husbandry, care, and common procedures for non-human primates can be found in a report by the Joint Working Group on Refinement (JWGR) (2009). Many of the safety- and hygiene-related requirements for the transportation, housing and handling of capuchins are identical to those that apply when dealing with other non-

human primate species (see the Primate Info Net website<sup>1</sup>). In this chapter we focus particularly on aspects of welfare that might concern capuchins more specifically, given their somewhat unique biological and behavioural profiles.

Although they may spend much time on the ground, capuchins are primarily arboreal, and they employ their semi-prehensile tail during above ground locomotion and posturing. The height of cages or enclosures should reflect these adaptations and, for example, allow the monkeys to perch above human eye level. Prior to its revision in June 2007, Annex II to the European Directive 86/609 EEC specified a minimum floor area of 0.5 m<sup>2</sup> for individual capuchin-sized monkeys and a cage height of 0.8 m. This and the corresponding US stipulations are, in the authors' views, over-restrictive (Reinhardt *et al.* 1996a). The revised Annex II (European Commission 2007) does not provide specific recommendations for capuchins but does provide general performance standards that can be applied for this species. There are not yet any published guidelines regarding increasing space requirements as a function of group size. For example, the ISTC-CNR, Rome, keeps groups of five to ten capuchins in indoor/outdoor enclosures of 374 m<sup>3</sup> (outdoors) and 25.3 m<sup>3</sup> (indoors), and 106.5 m<sup>3</sup> (outdoors) and 24.4 m<sup>3</sup> (indoors), respectively. In the Strasbourg Primate Centre, different groups of 14+ *C. apella* and *C. capucinus* thrived in a complex three-structure indoor/outdoor facility of approximately 180 m<sup>2</sup> (height 3 m). In a recent study, when capuchins' normal indoor area was reduced by approximately half, the monkeys coped by avoiding social encounters and by increasing self-grooming, which may reduce arousal (van Wolkenten *et al.* 2006). In laboratories, where space is more restricted, the following minimum cage dimensions are suitable for capuchins: each monkey should have at least 1 m<sup>2</sup> floor area, and the cage should be at least 2 m high. If a capuchin needs to be housed singly, the minimum available floor area should be 2 m<sup>2</sup>, and the height, 2 m. For a typical captive group of 10 individuals, the recommended minimum space allowances (floor area 10 m<sup>2</sup>, height 2 m) will allow expression of the full locomotor repertoire (including leaping, running and climbing) and sitting or hanging by the tail above human eye level.

### Environmental provisions

Promoting the psychological well-being of captive primates is important for ethical and scientific as well as legal reasons. Of course, it is not feasible, nor indeed desirable for a laboratory or zoo to attempt to meticulously reproduce all aspects of natural settings. However, appropriate compromises are feasible. This involves focusing on features of the environment that can be either recreated or simulated in order to elicit a similar range of social and non-social activities as seen in the wild. For example, it would be hopeless to try to provide exactly the same foods as capuchins eat in the wild, but it is important to give adequate proportions of proteins, carbohydrates, vitamins, minerals, etc, as well as variety, and to do so through situations that encourage the kinds of

<sup>1</sup><http://pin.primate.wisc.edu/research/vet/>

manipulatory, locomotor and temporal patterns of feeding-related activities seen in wild capuchins (see later in this chapter).

In view of their highly developed manipulatory propensities, broad repertoire of object-orientated actions and their curiosity and sustained interest in objects, providing capuchins with a stimulating environment is not only a requisite of good husbandry, but also relatively easy and gratifying to do. Many potential enrichment techniques exist, ranging from increasing the diversity and processing requirements of food (to simulate aspects of foraging), improving furnishing of the cage or enclosure (to improve locomotor possibilities and provide cover) and providing stimulating sensory events including objects to explore, play with or destroy. Recommendations given here are based upon species-typical behaviour in the wild or, in a few cases, outcomes of enrichment studies in captivity.

One important goal of the care and management of captive primates is the reduction of excessive inactivity in the animals, that is, to reduce boredom and its negative consequences, such as lethargy and abnormal behaviours. The following aspects are addressed from this perspective in the rest of this chapter: the social and physical environment, and routine capture and handling techniques.

Capuchins are arboreal quadrupedalists that locomote on surfaces which are vertical and horizontal, but mostly oblique. Therefore, capuchins should be provided with oblique structures in addition to the more obvious vertical and horizontal ones. Panels, hanging screens, branches, slides, swings, ropes, crates, frames, poles and PVC pipes and plastic mats are all potentially suitable structures. Some such structures should be selected to allow monkeys to avoid others if they so choose, as well as to provide shade and shelter (if outdoors) and appropriate substrates for resting and sleeping. See Anderson (2000), for environmental factors influencing sleep. Visalberghi, (personal observation) has seen wild capuchins use caves to shelter from inclement weather. Such structures can also be excellent stimuli for promoting physical exercise and play and for better exploiting available cage space.

Another effective way of increasing use of available cage space is to make the floor more attractive. Plants may be a feasible addition to some enclosures (Figure 38.3), although in relatively small spaces capuchins are likely to eventually destroy all or most of them, except for stinging nettles or toxic varieties (eg, Solanaceae). (Note: the authors do not advocate giving captive animals access to toxic plants.) More plants are likely to survive in very large enclosures, especially if they are already well established before the capuchins arrive. Many laboratories and zoos use deep litter such as woodchips, woodwool, straw, or bark chips (eg, Ludes & Anderson 1996); there is adequate scope for trying other potentially suitable materials. The best litters encourage locomotion and foraging activities and sometimes play; they also afford some protection if an animal falls from an elevated position. Furthermore, concerns regarding possible hygienic disadvantages of using deep litter have so far proved to be unfounded; litter may be safely left for several weeks without hosing or disinfecting. However, the removal of heavily soiled parts of the litter or rotten food is advisable, especially if there is the chance that rodents might be attracted.

Capuchins will readily manipulate and do their best to break open almost any object given. (They can learn to open cage doors or partitions that are secured only by simple latches or dog clips, so padlocks are advised.) Discarded children's toys, tennis balls, plastic and cardboard boxes, wooden blocks, rubber tubing, plastic mirrors are all examples of good, readily available and affordable enrichment objects. They must be checked carefully and all potentially dangerous parts (protruding wires, nails, sharp edges etc) removed. The most effective strategy for maintaining the monkeys' interest is to replace objects every few days. Certain types of objects (eg, a puppet) may initially elicit alarm and mobbing by the capuchins, especially upon first introduction. It has been suggested that occasional brief challenging events of this type may be beneficial to the animals, allowing them to express natural behavioural and physiological responses without undue risk. Capuchins do not readily enter deep

**Figure 38.3** Outdoor enclosure in the Primate Center of the Istituto di Scienze e Tecnologie della Cognizione hosted by the Bioparco of Rome (Italy). Members of the public (in the background) can observe the capuchin monkeys; the latter are also used for research. (Photo: Valentina Truppa)

water, but a plastic container filled with shallow water undoubtedly stimulates exploratory and playful activities, especially in hot weather.

In summary, there are many different ways in which the physical environment can be enriched. The choices need not be mutually exclusive. For example, simple objects can be baited with food treats to elicit specific feeding techniques. When deep litters contain buried food, animals devote much time to sifting and searching through the litter (Westergaard & Fragaszy 1985). Finally, furnishings may well include structures with holes or openings containing treats (syrup, honey, raisins, etc) to encourage extractive techniques, including tool use.

In the wild, capuchin monkeys have been observed rubbing leaves, fruits and even ants and millipedes into their fur (sometimes referred to as 'anointing') (see Baker 1996). The monkeys sometimes appear highly motivated to do this and the significance of the behaviour may be related to skin/pelage maintenance, and to repel insects. Captive capuchins also readily engage in this behaviour. There may be species and individual preferences for which substances may be rubbed into the fur, but the authors have seen onions, citrus fruits, garlic, peat, tobacco, and even tobacco smoke used for this purpose (the authors do not advocate the use of tobacco products). At least two independent observations have suggested that such fur-rubbing activities may reduce the incidence of skin sores (Ludes and Anderson 1995a). Given the high motivation of capuchins for this activity, the authors recommend that trial and error be used to identify appropriate fur-rubbing-eliciting objects or substances, and that the capuchins are allowed to perform this behaviour periodically. It should be noted that both wild and captive capuchin monkeys also frequently rub their bodies with urine, which they collect on the hands and feet and tip of the tail. The functions of 'urine washing' are not fully understood, but it is a normal behaviour, possibly with a thermoregulatory function (Roeder & Anderson 1991).

### Social grouping

Capuchin monkeys demonstrably prefer to be in contact with at least one familiar social partner (Dettmer & Fragaszy 2000). The optimal social grouping for captive capuchins is undoubtedly one that would contain proportions of age- and sex-classes as seen in natural conditions. However, capuchins' social structure is quite variable, so this principle can be implemented with some flexibility, depending on space limitations and on the purpose for which the monkeys are maintained. In any case, except under truly exceptional circumstances, capuchin monkeys should be kept socially, as social companions are excellent sources of interactive and ever-changing stimulation (Visalberghi & Anderson 1993).

As already mentioned, in some groups the lowest-ranking individual can become the target of repeated aggression. This is obviously a stressful situation for the victim, and in extreme cases removal of the unfortunate individual may be the best solution. However, unless serious injury or depression results from such bullying, removal can have some considerable drawbacks: it results in isolation and possible problematic (re-)integration for a socially rejected individ-

ual. Furthermore, there is no guarantee that the remaining group members will not start to redirect their aggression upon another individual. The physical and psychological health of the victimised individual should be carefully monitored, and temporary relief and food supplements provided during temporary separations, if necessary. The authors are not aware of any cases in which a subordinate individual has been harassed to the point of death; indeed, they have noticed that not only physical but also social wounds usually heal with time. For example, in the Rome colony a female who was a scapegoat at 3 years of age rose to become the dominant female of her group a few years later. It should be ensured that subordinates have adequate access to resources, including shelter. Facilities should be designed such that subordinates cannot easily be trapped or cornered during aggression. It should also be noted that haematological, physiological and immunological parameters of severely bullied or otherwise stressed animals might be outside the normal range of values.

If two or more groups are housed in the same facility, care should be taken to prevent direct physical contact between them. A single wire mesh partition is not sufficient for separating neighbouring groups; fingers, toes, and tips of tails can easily be bitten off. Groups in visual or auditory contact may react to each other, but if managed properly this should give rise to no negative consequences. Several zoos have successfully kept capuchins in mixed-species exhibits; compatible mixed-species groups can be enriching not only for the species involved but also for visitors.

It is advisable to allow animals some choice regarding whom to be with in the group, and whether to be in visual contact with a neighbouring group (International Primatological Society 2007). This can be achieved by providing 'privacy' panels or other structures inside the cage(s) or, even better, housing groups in interconnecting rooms or cages, preferably with more than one connecting door or hatch between them.

Experimental testing sometimes requires working with a single subject at a time, leading to the question of how to separate the subject from the group while minimising stress. A tried and tested solution is to have the test apparatus in or alongside a cage or room connected to the colony quarters by sliding doors. The authors strongly recommend the use of horizontally or upward sliding doors instead of the traditional guillotine door, to reduce the risk of injury to monkeys. For most individuals, gradual habituation to increasingly long periods of separation associated with positive reinforcement, inherent interest of the tasks (using only positive reinforcement, never punishment) and subsequent reunion, are sufficient to overcome the initial reluctance to be separated.

As a general rule, a well established stable group will pose fewer problems than the process of forming a new group or of introducing unfamiliar individuals into an established group. The latter two scenarios are focused upon in the next section, drawing upon the authors' personal experiences and those of colleagues to suggest some procedures, as well as some pitfalls to avoid. It should be noted that most of the authors' knowledge on how to form or modify capuchin groups comes not from systematic experimental manipulations but from experience gained through husbandry challenges faced occasionally by laboratories and zoos. Overall,

group formation is a stressful procedure both for the animals and the care staff, and although cumulative experience may help to reduce the risks of failure, the outcome can never be predicted with absolute certainty (Visalberghi & Anderson 1993).

### Introduction and re-introduction

Since an individually housed monkey is *de facto* living in impoverished conditions and therefore psychologically deprived, all efforts should be made towards compatible social housing. Sometimes, this may be feasible even shortly after major veterinary treatment; for an example with a newborn infant see Anderson *et al.* (1995). Hand-reared (ages ranging from 5–9 months) and mother-reared (8–12 months) infants were successfully introduced to a group when full integration was preceded by a period of visual contact, allowing mutual familiarisation at a safe distance (Visalberghi & Riviello 1987; Riviello 1992). In order to integrate single adult females, initial visual contact was followed by periods in which the female was together with the dominant male and then together with him and each of the other group members, before being housed permanently with the entire group (Anderson *et al.* 1991; Ludes & Anderson 1995b). In the most extensive report on introduction and integration of strangers into captive groups of tufted capuchins, Fragaszy *et al.* (1994) describe the successful introduction of two to four individuals (adult males, females and juveniles) into three established groups of six to nine capuchins. This report is useful as it provides several behavioural categories that can be employed in both monitoring and predicting the success of introductions. First, the newcomers were familiarised with the resident group's living quarters, and only then were residents and newcomers mixed. No serious aggression-related injuries occurred at the time of introductions or during the following months. When one or more individuals persistently chased a new female, partial separations were used to form mixed subgroups of newcomers and residents for overnight housing.

Concerning the introduction of adult males, one adult male (more than 10 years old), previously kept in a zoo, was successfully introduced to a group in which the dominant male was only 4 years old. The procedure included a quicker progression through stages similar to those just described for adult females, and with contact between the newcomer and the dominant resident male left until last. Strikingly, these two males immediately came into contact and performed joint threats, towards no particular target. They quickly developed a positive relationship, the newcomer being alpha male. Although all introductions are likely to involve some degree of stress, in none of the above cases did the introduced monkey need to be removed from the group due to aggression or stress-related ill-health. Two introduction scenarios did result in severe aggression: unfamiliar adult males going into a group with no resident adult male, and males familiar with each other going into a group containing an elderly resident male (Cooper *et al.* 2001). In contrast, moving two males familiar with each other into a group with no resident male was peaceful.

Overall, the risks associated with introductions appear greatly outweighed by the disadvantages of solitary housing. No foolproof recipe is yet available for group formation or introduction procedures, but the chances of success can be increased by having a good knowledge of the animals involved, careful monitoring before and after the introduction, and by taking into account factors such as sex, age and experience of the newcomers (Visalberghi & Anderson 1993). Given a few recent reports of male-perpetrated infanticide in the wild (Fragaszy *et al.* 2004b), introduction of a fully adult male into a group containing neonates should be considered risky. Also, the introduction of an adult female in a group containing more than one adult male may lead to a violent attempt by a subordinate to overthrow the dominant male, especially if the latter is old.

### Identification

Tattooing with an electric pen and ink is still the most commonly used method, and the authors are aware of no ill effects. Identification collars are not advised, as capuchins will try their best to destroy them. Implanted microchips are becoming increasingly popular for individual identification of captive New World primates (Savastano *et al.* 2003), including some pet capuchins. However, the use of microchips is not problem-free; cost, equipment incompatibility and possible migration of the microchip are all potential compromising factors (Rennie & Buchanan-Smith 2006). The authors know of no published reports on their use in capuchins kept in laboratories or zoos.

### The physical environment

Capuchins are quite hardy animals provided that they have constant access to heated indoor quarters. They may occasionally venture outdoors in temperatures close to freezing; however, they do not appear to enjoy walking on frozen surfaces. In enclosed environments, a temperature of around 23 °C, humidity of 50–60% and a ventilation rate of 4–5 air changes per hour are recommended. Rooms without natural light are typically kept on a 12h–12h artificial light cycle. Although no scientific data are available, gradual light changes to simulate natural changes at dawn and dusk may be beneficial. Natural light from windows or skylights will provide low levels of light at night, similar to the situation in the wild. There is little systematic work on the influence of auditory environments on captive primates, but excessive noise should be avoided.

### Quarantine

Quarantine procedures are broadly similar to those for other primates. Duration ranges from 40–90 days, during which time repeated tuberculin skin tests, serology and stool analyses are performed. Prophylactic treatment varies across institutions; for groups with access to outdoor areas vaccination against tetanus is recommended. A zoo-housed colony was successfully protected against rabies using a human

non-vaccinated exposure protocol consisting of periodic intramuscular doses of killed rabies (between possible post-exposure days 2–33) and a single dose of human rabies immune globulin (at possible post-exposure day 5) (Kenny *et al.* 2001).

## Breeding

### Pregnancy and newborns

The authors do not recommend separating pregnant females from their group, even though dead neonates are occasionally recovered. Greater importance is attached to maintaining the complex network of intra-group social relations than to episodic breeding success if the latter implies stress due to lengthy separation and later reintegration of the mother-infant pair into the group. As in other primates, most births occur at night. Also as in other primates, maternal performance may differ between primiparous and multiparous mothers, and the former may abandon their infants. Conceivably, delivery for primiparous females is particularly long and/or tiring, and the infant may be compromised after a lengthy delivery. Some females with inadequate early social experience might kill their newborn. If an abandoned or abused neonate is recovered in time, hand rearing is a viable possibility (see below). However, after initial incompetence, capuchin females may become competent mothers with subsequent offspring. While it is not clear why this improvement occurs, age, previous experience of hormonal changes, higher social status of the female and the presence of other mothers with infants may be contributing factors.

In a recent analysis of breeding records of four American and European colonies of tufted capuchins, 2.4% of pregnancies gave rise to twins, a higher incidence than previously estimated, and not dissimilar to human twinning rates (Leighty *et al.* 2004). If twins survived the first day of post-natal life (45% did not, compared to 16% of singletons), then subsequent survival was similar to that of singletons. Three complete sets of twins out of 10 sets recorded survived beyond 30 days, while another three individuals whose twin died survived beyond the first month.

Infant transfer is common in capuchins. Young infants, even newborns, may be held or transported (and, rarely, nursed) by individuals other than their mother. Infant white-faced and tufted capuchins may be carried by adult males for long periods. This is usually safe, but it may carry risks if the infant is very young and/or when the mother does not retrieve it. The infant may take the initiative in transferring from the mother onto a nearby individual, or the other individual may solicit the transfer by adopting an inviting posture. The non-maternal carrier is rarely aggressive, but infants up to about 8 weeks run the risk of dehydration/starvation if they are unable to transfer back to the mother, so surveillance is recommended. Some mothers do not attempt to get their infant back; sometimes, but not always, this is due to the mother's subordinate status. In such cases intervention may become necessary. This can involve either bringing the mother and the carrier into close proximity, for example by offering a non-transportable treat

such as juice, or by restraining them in a restricted space. If these procedures fail, the carrier may need to be captured and the infant returned to its mother, with follow-up monitoring for adequacy of maternal care. Sometimes during this process the carrier (even the mother) will forcefully dislodge the infant by rough pulling or even biting. Care should be taken to keep the capture process calm so as not to endanger the infant.

### Hand rearing

Viable infants abandoned at birth can be successfully hand reared. Commercially available human infant milk formulas generally work well for common laboratory primate species. Following an initial few feeds consisting of warmed rehydration fluid or 5% glucose, the authors recommend bottle-feeding newborns every 3 h with artificial milk, for example, Similac (Ross Laboratories, Columbus, OH), SMA (Wyeth Laboratories), or S-26 powdered baby milk. The interval between feedings can be gradually increased, especially during the night. The concentration of the milk substitute can also be progressively increased, until full strength is reached by 24–36 h. Usually the infant vocalises when hungry. The hole in the nipple should be small enough to prevent excessively fast ingestion. The monkey stops drinking when satiated and it is advisable to keep it upright for a few minutes to facilitate burping and avoid regurgitation. Based on what happens in the wild, the authors recommend giving small pieces of solid foods (eg, cookies, banana or apple) to infant capuchins as early as 3–4 weeks. Not much is consumed at this age, but the animals lick or mouth it.

According to Lehner (1984) nursery-reared infants ingest about 175 kcal/kg per day during the first week. The amount peaks at around 400 kcal/kg per day at 2 months, then declines to a stable level of around 300 kcal/kg for rest of the first year. They grow rapidly, gaining about 100 g per month for the first 10 months. By 1 year of age, the infant will have reached more than 50% of the mother's non-pregnant body weight (Fragaszy & Adams-Curtis 1998). Like other New World monkeys, capuchins require vitamin D3 for adequate skeletal growth, especially if the monkeys have no access to unfiltered sunlight. Vitamin D3 is available in pelleted diets and vitamin/mineral supplements. Sainsbury (1991) gives 100 IU/kg body weight as sufficient for young animals.

## Feeding

Mann (1970) traces the development of diets for captive *Cebus*, and describes some common nutritional deficiency states including rickets. For a recent detailed overview of primate nutrition see National Research Council of the National Academies (2003). Commercially available New World monkey food supplemented with fresh vegetables and fruits satisfies the general requirements of captive capuchins. However, pellets are not among capuchins' preferred foods (Addessi *et al.* 2005), despite containing all the requirements for physical health. Furthermore, given wild capuchins' wide variety of foods and feeding techniques (see overview earlier in this chapter), it is highly recom-

mended to attempt to simulate some aspects of this diversity. For example, capuchins like to break open and peel fruits, so it is rarely necessary to peel and chop such items into fine pieces. Whole fruits allow them to spend more time in species-typical feeding behaviour. Food can be placed in locations to encourage arboreality and increase search time; for example if the top of the cage or enclosure is of wire mesh, foods big enough not to drop directly through the holes can be spread there to encourage a variety of food-gathering techniques. Food can also be hidden in a variety of ways and locations so as to stimulate searching. For example, when capuchins were presented with food treats dispersed in bins full of sawdust or water (the food could be reached only by inserting an arm through holes in the bins), they spent considerable time engaged in tactile search. Specially constructed containers containing straw or woodchips and food treats can be used to elicit a range of species-typical foraging activities. Extensive picking activities including fine precision grips are easily elicited by synthetic 'grass' secured to a board outside the cage and filled with grains or other small edible items. Variability can also be made a feature of the timing of feeding, although whether this has observable beneficial effects for capuchins requires confirmation.

Raw and unprocessed foods are an obvious way of challenging capuchins' natural extractive propensities. Unshelled nuts can be made even more of a challenge to manual or tool-assisted cracking techniques by increasing the resistance of their shells (Visalberghi & Vitale 1990). Every region has products suitable for capuchin 'treatment': corn on the cob, unshelled beans and nuts, coconuts and unhusked cereals are good examples, and all are excellent supplements to the staple balanced diet. Raw eggs are a preferred treat, although there may be an associated risk of salmonellosis, and of restricted biotin uptake due to the uncooked avidin. Commercial pellets for South American monkeys appear nutritionally ideal, although as mentioned above, they are not particularly appreciated (Addessi *et al.* 2005). Such diets are prepared to include requisite proportions of proteins, amino acids and minerals, etc. Especially when commercial food is not given, mealworms, cheese, yoghurt etc, should be added to the regime to provide animal proteins. Obese capuchins are rare, even among those known to eat rich, processed human foods, therefore some food can be given almost *ad libitum*. It is advisable to provide a highly preferred mixture (cottage cheese, eggs, cereals, etc) a few times a week and to use this occasion to administer medicines by mixing them with the food.

## Laboratory procedures

### Handling and training

The traditional way of capturing group-living capuchins is with a net and/or protective gloves. The chasing involved in this method is extremely stressful, and the method is not without risk of injury to the animal(s). Some of the stress and most of the risk of injury can be eliminated by herding the animal through a system of tunnels that lead the animal into a squeeze cage where it can be restrained for

examination or treatment. In either case, the expertise of the person doing the capture is paramount. Since stress increases over time if its source persists, rapid, efficient netting may be preferable to a prolonged wait for a frightened animal to enter the tunnel (Linn *et al.* 1995). Nets should have padded rims to prevent injury to the animal (especially to its teeth) during capture. Capture-related stress can be reduced by giving piece of banana or grape containing a few drops of diazepam (2 mg/kg, C. Tomaz, personal communication).

Capture may be made less stressful by habituating the monkeys to sights and sounds associated with capture from an early age. Even so, capture typically results in the colony being highly aroused for some time afterward, although this may be alleviated by providing distracting foraging opportunities immediately after the event (Landau & Fragaszy, unpublished, cited in Fragaszy *et al.* 2004b). The authors have noticed that events typically occurring on capture days often become associated with the stressful experience. For example the arrival of the veterinarian, or the sight or noise of capture equipment (gloves, tunnel-cages, etc), give rise to tension and/or fear. Therefore, it may be advisable for those whose research activity involves direct observation of spontaneous behaviour not to be involved in capturing the animals. Capuchins have extremely powerful jaws and can inflict serious bite wounds, so personnel should guard against being bitten (or scratched), for example by wearing protective gloves.

Transport boxes are commonly used to take individual monkeys from their home cage to an experimental room, for example to administer Wisconsin General Test Apparatus- or video-based tasks. Initial coaxing of the animal to enter the box may require any of a number of stratagems of varying forcefulness, ranging from attracting it into the box using treats to chasing it in by blocking all escape routes except the entrance to the box. Capuchins can distinguish between different tones of voice and possibly words; this can be used in training. However, positive reinforcement is essential. Once the transport procedure becomes routine, the monkeys often start to enter the transport cage spontaneously, sometimes even in absence of food reward. Indeed it is common for a reliable order to emerge, often dominance-related, in which group members vie to be given access to the test apparatus.

### Physiological monitoring

For general advice see JWGR (1993, 2009). In zoos and laboratories, positive reinforcement training is becoming popular as an alternative to capturing monkeys for collecting vaginal swabs or blood (Prescott *et al.* 2005). However, there are still very few examples with capuchins; it is possible that capuchins are harder to train than macaques for such procedures (see Fragaszy *et al.* 2004b). Drug treatments can also be administered to co-operative animals in this way, thus circumventing the problem of rejection of food or liquid laced with the substance to be administered. Females can be trained to sit on a plastic bin for increasingly long periods and to urinate while seated. It took less than 1 month to fully train a female to urinate on the bin within a few minutes of

taking up position. However, such training does not succeed with all animals.

It is increasingly common for physiological data to be collected by implantation of telemetry devices that weigh only a few grams or by equipping the subject with a jacket containing a measuring device. Jackets have been also used with *Cebus apella* (Vitale *et al.* 1994). However, those that fitted well were bitten and torn apart by the animals, and tighter jackets appeared to restrict the animal's locomotor behaviour; currently available jackets are not well suited to the body shape or the behavioural tendencies of this species.

### Administration of medicines

For general advice see JWGR (2001, 2009). Oral doses can readily be given either in fruit juice or concealed in a preferred small fruit, such as a grape. Intravenous injections should be given in either the femoral or saphenous veins, although the latter may be more difficult.

### Diseases and treatments

As in other primates, behavioural changes may be the last signs of underlying illness to appear, so regular careful monitoring (including weighing) is advised. Lehner (1984) and Sainsbury (1991) give summaries of diseases to which capuchins and other members of the Cebidae are susceptible. These include the common human cold and other viral diseases (eg, measles, chicken pox). Tuberculosis appears to be the most important of the bacterial diseases, although capuchins are quite resistant and diagnosis may be difficult. Among parasitic diseases, malarial infection (*Plasmodium brazilianum*) and haemo-flagellate infection (*Trypanosoma cruzi*) have sometimes been fatal. Lehner (1984) describes the various signs of these diseases and others, such as rickettsial and viral, along with treatments and prognoses.

Three cases of tetanus have occurred in Italian colonies and two of them were successfully treated. The animals (all adults) were found rigid and presented marked locomotor impairment and 'lockjaw'. One died after several hours; the others were treated as humans with the same disease. Medical care consisted of immunoglobulin, diazepam, antibiotics and rehydration therapy with physiological solution, and vitamins were administered in doses appropriate for the monkeys' body weights. They were kept in a warm, dimly lit environment and fed by hand four times a day. Treatment lasted between 20 and 30 days, after which the animal slowly recovered and was able to return to its group (Lorenzo De Marco, Massimiliano Bianchi and Fabio Faiola, personal communication). A 32-year-old *C. capucinus* was successfully treated for *Toxoplasma* meningitis using clindamycin and trimethoprim-sulfamethoxazole (Fiorello *et al.* 2006).

Diarrhoea may occur in response to stress, incorrect diet, or infection. Sainsbury (1991) indicates fenbendazole, mebendazole and ivermectin for the treatment of nematode parasites, and dichlorophen and niclosamide for the treatment of cestodes. Nagle and Denari (1983) describe the treatment of respiratory tract infections and diarrhoea in recently

captured capuchins using penicillin, chloramphenicol and electrolytes with 5% dextrose solution. They state that thia-bendazole is effective against nematodes. Wolff (1990) provides an extensive table of internal and external parasites of cebid monkeys, along with host location, disease signs and diagnostic and treatment procedures. Information on miscellaneous health problems including fractures, dental disease and soft tissue injuries can be found in Sainsbury (1991).

### Anaesthesia

Short-term sedation can be induced with ketamine (10 mg/kg). In order to treat a sick infant every 2–3 days, the authors first lightly anaesthetised the mother with intramuscular ketamine 10 mg/kg. Inhalation anaesthetics and endotracheal techniques are indicated for surgical procedures. Specialised information on anaesthesia and analgesia can be found in Sedgwick (1986), Sainsbury (1991), Flecknell (2009) and Popilskis and Kohn (1997); the last authors also address intra-operative monitoring and support, and special anaesthetic considerations, although no specific recommendations are made for capuchin monkeys.

Care must be taken to ensure that a captured animal is unable to reach the needle of the syringe. Capuchins are extremely swift and capable of exploiting any possibility to prevent capture, injections and so on, unless specifically trained. Training, however, may require patience. Dettmer *et al.* (1996) reported that repeated capture and venepuncture procedures in *C. apella* resulted in raised cortisol levels, before a reduction in week 7 brought them back down to week 1 levels. After this phase, however, behaviourally habituated animals no longer showed this physiological stress response to venepuncture, whereas non-habituated animals did.

The post-anaesthesia recovery period should follow standard monitoring and hygiene-related protocols, ensuring adequate warmth, freedom from potential injury, and rapid return to the social group as soon as possible.

### Euthanasia

If euthanasia is necessary, the animal should be anaesthetised and then injected intravenously with an overdose of pentobarbital. See also Chapter 17.

# 39 Old World monkeys

Sarah Wolfensohn

## General biology

### Natural history

St. George Mivart (1873) defined the order Primates as

*Unguiculate clavicate placental mammals, with orbits encircled by bone; three kinds of teeth, at least at one time of life; brain always with a posterior lobe and calcarine fissure; the innermost digits of at least one pair of extremities opposable; hallux with a flat nail or none; a well-developed caecum; penis pendulous, testes scrotal; always two pectoral mammae.*

Primate taxonomy and definitions of particular species now go beyond simple anatomical parameters and includes considerations such as: genetics, population biology, ecology and biodiversity. There is disagreement over precisely what constitutes a particular species and definitions shift slightly over time. A more modern, lengthy definition of primate may be found in Martin (1990). However, a simplified classification of living primates is shown in Figure 39.1 (adapted from Wolfensohn & Honess 2005). The term 'Old World monkeys', indicates a geographical origin from Asia and Africa, as opposed to the Americas. They are generally accepted to be monkeys from the superfamily Cercopithecoidea; all lack prehensile tails and have some degree of callus over the ischial tuberosities. Many have cheek pouches, all have a narrow nasal septum and opposable thumbs. They may be divided into two subfamilies – the *Cercopithecine* and the *Colobinae*. The genera in the *Cercopithecine* subfamily fall more or less into two groups – the African long-tailed monkeys (such as vervets, guenons, talapoin and patas monkeys), and the macaques, baboons and mangabeys. The genera of the *Colobine* subfamily are the colobine monkeys, langurs and other leaf eaters.

This chapter will only deal with selected species from the *Cercopithecine* subfamily which are commonly used in research programmes, that is *Macaca mulatta* (rhesus macaque), *Macaca fascicularis* (long-tailed, crab-eating or cynomolgus macaque), *Chlorocebus* sp. (formerly *Cercopithecus* sp. (Groves 2001)) (sometimes called the African green monkey or the vervet monkey) and *Papio* species (baboons). Old World primates includes many species that vary widely in social structure, ecology, reproduction, etc. It would be cumbersome in this chapter to continually refer to the rhesus, cynomolgus, vervet and baboon either as a list or as 'Old World primates commonly used in research'. Therefore,

in this chapter the term Old World primates is used to refer only to these species, except where otherwise stated. Moreover, the emphasis of this chapter is on the rhesus and cynomolgus macaque as these are, by far, the most commonly used Old World primates.

### Biological data

See Table 39.1 (reproduced from Wolfensohn and Lloyd 1998 and 2003).

### Social organisation and normal behaviour

The literature on primate biology, ecology and behaviour is extensive from both field and laboratory studies, eg, Smuts *et al.* (1987); Mittermeier *et al.* (1988); Lindburg (1991); Bennett *et al.* (1995); Fa and Lindburg (1996); Fleagle (1999); Cowlshaw and Dunbar (2000); Strier (2000); Röder and Timmermans (2002).

The primate species commonly used in research are highly social animals. There are both costs and benefits from living in a group (Lee 1994; Strier 2000). The potential negative consequences of group living such as competition for food or mates, or increased likelihood of parasitism or predation, are offset by co-operation resulting in the improved survival of individuals with shared genes (Krebs & Davies 1993). This is achieved by living with close relatives, described as kin-bonded groups, which in Old World primates are typically female kin-bonded groups with the distribution of males superimposed on to that of the females. Group structure varies according to differences in the quality and density of resources and incidence of disease and level of predation. An excellent treatment of the variation in primate societies and the different strategies adopted by different species in balancing the costs and benefits of group living with attempts to maximise individual reproductive success and inclusive fitness is presented by the authors in Smuts *et al.* (1987).

The macaque genus has a wide range, extending from Morocco and Gibraltar through the Indian subcontinent up through China and Japan and down through the Philippines, Java and Sumatra. This range includes a wide variation in environmental temperatures and diets, and the macaques have adapted to a variety of ecological niches. This is

## TAXONOMIC LEVEL

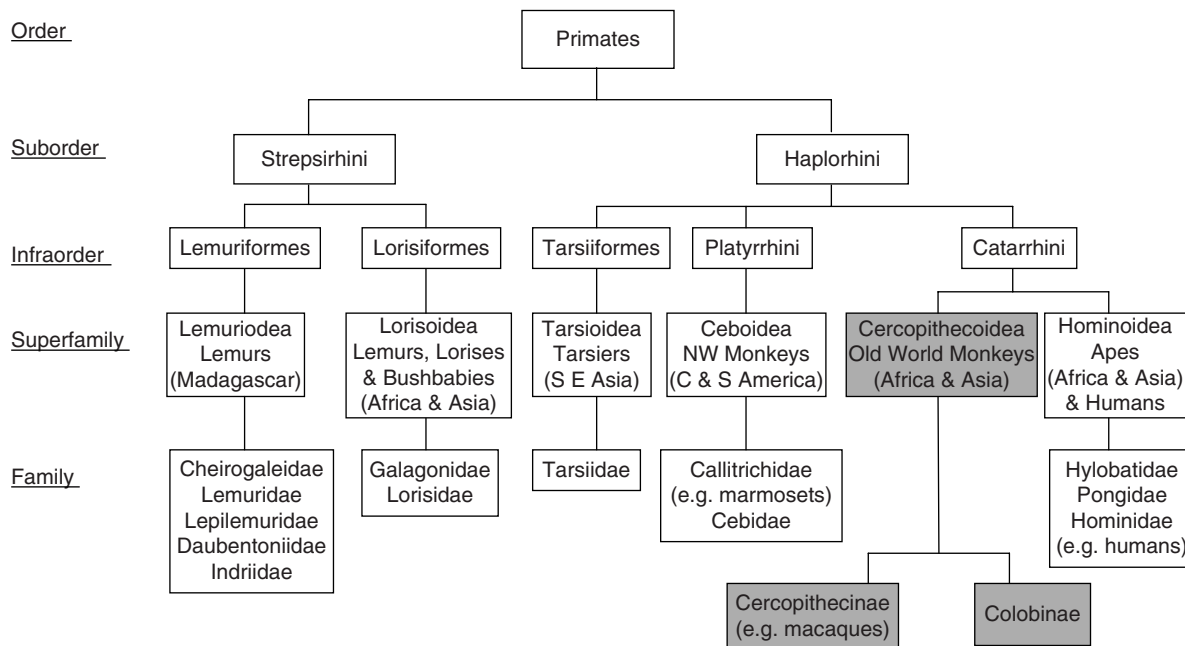

Figure 39.1 A simplified classification of primates.

reflected in normal variations in patterns of behaviour and interactions with humans, for example foraging around urban environments (Honest *et al.* 2006) to foraging in remote areas. The components of a wild macaque's diet typically come in small aliquots (eg, seeds, buds and flowers), dispersed over a wide area, so the process of gathering them is very time consuming and demands much energy. The daily activity cycle reflects this as a macaque troop typically spends the morning foraging, followed by a rest period, then another bout of food gathering through the afternoon, finally moving to a sleeping site for grooming and sleep. Of the two macaque species commonly used in research, the cynomolgus monkey spends more of its time in the trees whereas the rhesus is a ground-dwelling monkey that forages on the floor and takes to the trees for safety and to sleep. Macaques also appear to enjoy playing in water and, although they do not actively swim, they will forage for food in shallow water and use water for thermoregulation.

### Reproduction and rearing

There are a several types of captive breeding systems for primates including free-ranging island colonies, semi-free-ranging corral colonies and enclosure or pen pairs or harems. A description of each is provided in a report by the Scientific Committee on Animal Health and Welfare (SCAHAW) (2002). Kirkwood and Stathatos (1992) provide a list of primate reproduction parameters such as the duration of events, adult and neonate weights, growth curves, infant feeding, weaning and physical and behavioural development.

Reproductive success depends on four key elements. Firstly, the individual must be able to survive to breeding age, which depends on the health and condition of the mother, the growth rate of the infant and the incidence of predation, disease and accidental death. Second, is the duration of the reproductive lifespan. Thirdly, productivity depends on fertility which can be affected by environmental, social, lactational and genetic factors. Finally, to ensure their genetic contribution to succeeding generations any offspring produced must, themselves, be able to survive to reproductive age.

Assuming that resources are sufficient, the major recurring influence on female fertility is lactation through the inhibition of ovulation and the negative effect on maternal condition (Lee 1987). There are also social influences on the fertility of primate species that live in groups, since Old World primates moderate the potentially negative process of competing for resources, such as food, nest sites or mates, through the development of dominance hierarchies. Dominance rank is maintained through displays of strength, or in some macaque species through the inheritance of maternal rank thus reducing the incidence of aggressive competition for limited resources. A number of primate species use social dominance and status to improve their reproductive success and females with higher dominance rank breed earlier and produce more offspring per year (Harcourt 1987).

The period of oestrus is indicated by changes in the female's behaviour; olfactory cues and swelling and reddening of the perineal skin may occur to a varying degree. Sexual activity peaks around the time of ovulation and the frequency of aggressive episodes also increases during mating periods. Fraser and Lunn (1999) present a detailed

**Table 39.1** Biological data.

	<i>Rhesus macaque</i> ( <i>Macaca mulatta</i> )	<i>Cynomolgus macaque</i> ( <i>Macaca fascicularis</i> )	<i>Baboon</i> ( <i>Papio sp.</i> )
<i>Biological data</i>			
Adult weight (kg)	Male 6–11 Female 4–9	Male 4–8 Female 2–6	Male 22–30 Female 11–15
Diploid number	42	42	42
Food intake	420J/kg for maintenance, 525–630J/kg for production, 840J/kg for neonates		
Water intake	<i>Ad libitum</i> , 40–80 ml/kg daily		
Natural lifespan (years)	20–30	15–25	Up to 28
Temperature (°C)	36–40	37–40	36–39

description of the physiological features of reproduction in female primates. Data on primate ovarian cycle length are given in Hendrickx and Dukelow (1995a). Dixson (1998) describes in detail the differences between primate taxa in reproductive anatomy, both internal and external, and also provides detail on the menstrual cycle of the rhesus macaque. The size and colour of the sexual skin in Old World primates may not only indicate the occurrence of ovulation but may also be associated with attractiveness in the context of mate choice, both of females to males and *vice versa*, eg, in rhesus macaques (Waitt *et al.* 2003). In females the anogenital region is frequently the primary site of sexual skin, but it may occur in other areas, such as the side of the thigh in rhesus macaques. The presence of sexual skin in male primates may also be dramatic and brightly coloured, eg, the blue of the scrotum of the vervet monkey (*Chlorocebus aethiops*). In addition to visual signals of reproductive state, communication via auditory and olfactory routes is extremely important in many primate species.

Primate groups are not simply convenient aggregations of individuals for breeding purposes (Dixson 1998); even seasonal breeders will form groups all year-round, so it is necessary to distinguish between grouping or social systems, and breeding or mating systems. The reproductive behaviour of male and female primates may vary considerably with the stage of the ovarian cycle, for example in the frequency of ejaculatory mounts in males and the proceptiveness and receptiveness of females. Evidence suggests that changes in the proceptivity behaviour of females, in initiating copulations, may serve as a useful predictor of the day of conception in some species (eg, rhesus macaque, *Macaca mulatta* (Zehr *et al.* 2000)), and this may be very valuable for studies where accurate aging of embryos is required. The rhesus macaque is a seasonal breeder in which reproduction appears to be triggered by changes in day length. The importance of day length in this context is supported by observations of a captive rhesus population in Brazil, in the southern hemisphere, outside the natural range of this species which is totally in the northern hemisphere. In this colony there is an inversion of the breeding season, with births occurring between October and April compared to March to September in the northern hemisphere (Gomes & Bicca-Marques 2003).

In some cases contraceptive strategies may be required. Permanent sterility can be ensured by surgical means, but a reversible solution may be preferred. Useful information on contraception can be found in the 2003 AZA Contraception Advisory Group Recommendations<sup>1</sup>. There can be complications associated with the use of contraceptives. Implants may be lost, or new ones may not be administered soon enough, resulting in pregnancies. In some cases there can be permanent sterility; and a predisposition to simian immunodeficiency virus (SIV) infection by sexual transmission, possibly due to a thinning of the vaginal epithelium, has been associated with the use of progesterone implants in macaques (Marx *et al.* 1996). Contraceptive strategies for some primates are aimed at prevention of implantation (Sengupta *et al.* 2003).

<sup>1</sup><http://www.stlzoo.org/animals/scienceresearch/contraceptioncenter/>

Artificial insemination is generally unnecessary as part of a breeding management strategy in the normal captive breeding of primates. It has been undertaken successfully in various Old World primate species (Gould & Martin 1986), including the rhesus macaque (Dede & Plentl 1966). The diagnosis of pregnancy in primates can be made by manual palpation, detection of hormonal changes in the urine and serum (Kirkwood & Stathatos 1992; Hendrickx & Dukelow 1995b) and the use of ultrasound imaging. Data on embryonic and foetal development of commonly used Old World species are given by Fortman *et al.* (2002). Morphological and endocrine diagnosis can be used to determine the early loss of pregnancy (Hendrickx *et al.* 1999). See Table 39.1 for data on duration of gestation.

Hendrickx & Dukelow (1995a) detail many of the hormonal changes that occur during pregnancy and parturition. In most primates, parturition takes place at night or in the early morning. If delivery takes in excess of three hours it will require careful monitoring and may need veterinary intervention (Kirkwood & Stathatos 1992). Multiple births are rare in Old World Monkeys (0.06% to 0.5% of births in macaques (Canfield *et al.* 2000)), though twins are known to occur (eg, in the stump-tailed macaque, *Macaca arctoides*; (Schrier & Povar 1984)). Complications such as the production of conjoined twins are even rarer, but reports do exist (eg, in the rhesus macaque (Canfield *et al.* 2000)).

The production of milk and suckling behaviour is a vital part of the reproductive cycle of primates. It performs several important functions, providing nourishment and early immune protection of the infant; establishing and maintaining the maternal–infant bond; and causing lactational amenorrhoea – a period after the birth which impedes the ovarian cycle and prevents the mother becoming pregnant again for a period after the birth. Data on the length of the lactation period, as well as information on milk composition for many species are presented in Hendrickx and Dukelow (1995a).

Sometimes it is necessary to consider hand rearing of infants, due to human interference by taking neonatal primates for scientific procedures, or due to maternal neglect or death or because the mother has an inadequate supply of milk. In the latter case it may be possible to leave the infant with the mother for nurturing and care, and simply provide supplementary feeding until the infant is able to take food for itself. This is the preferred option since it will develop within its natal and peer group and the risk of any consequential behavioural abnormalities will be reduced. However, if it is established that an infant should be removed from its mother for hand rearing, it should be placed in a cage with some type of surrogate mother. This should be soft to touch, warm and, if possible, should move gently. Each day the infant's body weight is recorded and its physical state monitored. Other parameters to be monitored include level of activity and general alertness, body tone, quality and quantity of faecal output, peripheral perfusion and weight gain. Hand feeding is not a precise activity and the timing of feeds and quantity of feed given may be varied according to the viability of the infant, but all information on the infant's food intake should be recorded. It may sometimes be necessary to foster or hand rear young primates but

they should not be maintained in isolation. For a protocol for hand rearing see Wolfensohn and Honess (2005).

Lactation in the macaque has all but finished by 10–11 months so that the infants would be fully weaned before the birth of the next, and at this stage they do not depend on their mother for nutrition. Confusion arises over the use of the term ‘weaning’ to describe both the cessation of suckling by the mother, in unmanaged populations, as well as the removal of offspring in captive populations as part of a breeding management or supply strategy. The conflicting interests of the mother (to accelerate weaning) and offspring (to prolong suckling) result in the mother terminating suckling at a point determined by the metabolic independence of the offspring, this being a factor of the offspring’s body weight at birth and at weaning – the ‘metabolic weaning weight’. In rhesus macaques the threshold weaning weight is 1.34 kg (with a range of 1.0–1.6 kg), which reflects a constant multiple 3.4 times the neonate’s birth weight (Lee 1999).

Natural weaning is not an abrupt event but a process lasting several months. Most infants can feed themselves at 6 months but remain socially dependent on their mothers and return to them when disturbed and to sleep. This period of suckling and gradual increasing independence is an important time in the development of the infants. It is during this time, and shortly after, that they begin to learn from their mother and to refine food selection, acquisition and processing skills (Altmann 1980; Janson & van Schaik 2002). After the first year, juvenile animals, especially males, become more and more involved in peer group activities. Stimulus deprivation in infancy has a dramatic impact on the development of young macaques, making them less active, more withdrawn, with more stereotypic behaviour (Harlow *et al.* 1965), higher basal cortisol levels and showing more fear–disturbance–emotional behaviour than non-deprived control animals (Sacket *et al.* 1973). The importance of social stimulation during infancy is well established, but considerably less is known about the influence of social contact during juvenile and adolescent stages of development (National Research Council (NRC) 1998). It is therefore important to monitor each animal and if the assessments indicate an incidence of behavioural problems, then management regimes, such as age of separation from the natal group, should be reviewed. Continual assessment of behaviour and welfare is more important than sticking to rigid temporal criteria, and each animal should be considered individually.

Since many managers have tried to use temporal criteria for separating infants from mothers in captive breeding colonies, opinions differ on the ideal time (Goo & Fugate 1984; Home Office 1995; Wallis & Valentine 2001; Reinhardt 2002; International Primatological Society (IPS) 2007). However, forced weaning appears to have no appreciable benefit in terms of increased production, and account must be taken of the welfare aspects on the psychological well-being of the mother and the infant. If young monkeys are reared with an inappropriate social background they will show indicators of poor welfare such as a restricted repertoire of behaviours, an abnormal activity pattern, inadequate social behaviour and/or abnormal behaviours such as self-injury. Monkeys raised without appropriate social stim-

ulation tend to be dysfunctional in their reproductive behaviour (Goldfoot 1977). Socially deprived male rhesus do not develop the full double foot-clasp mating stance adopted by undeprived animals (Goy *et al.* 1974) and there is a higher rate of rejection of infants in primiparous socially deprived females (Suomi 1986).

Sufficient outbreeding helps to avoid some hereditary conditions or familial predispositions to diseases such as metabolic bone disease (Wolfensohn 2003). Researchers working in immunology may prefer animals of a specific type of major histocompatibility complex (MHC) but those individuals with a greater variety of MHC alleles will have more protection from a corresponding diversity of possible diseases (Strier 2000). Knapp *et al.* (1996) demonstrated, in pig-tailed macaques (*Macaca nemestrina*), that mates sharing the same MHC type suffered significantly more spontaneous abortions than those with different MHC types, and the olfactory recognition of MHC type among animals (Brown & Eklund 1994) avoids this kind of reproductive wastage, while at the same time maximising MHC allele diversity. In addition to considering genetic profile, breeding facilities that supply animals for research may wish to select animals based on aspects of their behaviour, such as temperament or learning ability. Tracking the performance of animals during training within both the breeding facility and the experimental facility will help to identify individuals that produce offspring that are more likely to be easily trainable and to co-operate with research protocols. This will contribute, when coupled with the highest welfare standards in housing and husbandry, to a reduction in the stress of primates maintained for research.

### Sources, supply, conservation status, transportation

In the USA and Europe, although there are some facilities for breeding macaques for research use, these do not yet supply adequate numbers to match the demand in these countries. Most jurisdictions either do not permit, or discourage the use of wild-caught primates in research and some are encouraging moves to the use of F2 animals (ie, ones that are second-generation captive bred). The current text of article 7(3) of EU Directive 86/609/EEC states, ‘*experiments on animals taken from the wild may not be carried out unless experiments on other animals would not suffice for the aims of the experiment*’ (European Council 1986).

A substantial number of macaques are, therefore, imported into the USA and Europe from countries of origin where they are purpose-bred. *Cynomolgus* macaques may be sourced from China, the Philippines, Mauritius, Indonesia and Israel; and rhesus macaques may be sourced from China, Vietnam and Cambodia. The majority of primates used in scientific procedures are purpose bred, but at present a number of the breeding animals from which they are derived are still sourced from the wild in some facilities. Some breeding establishments are now introducing programmes to move to use of F1 or subsequent generation animals for breeding, with the aim of avoiding the need over the next decade or so to take animals from the wild and enabling them to supply F2 or subsequent generation

animals for use in research from self-sustaining captive colonies. However, ongoing pilot projects evaluating the impact of self-sustaining breeding and inbreeding show there may be a significant impact on fertility rates and other physiological parameters. At this time, it is not yet possible to assess the impact of these changes on availability of animals for research. The feasibility and impact of these moves towards self-sustaining breeding is being monitored to inform future decisions about moving exclusively to use of self-sustaining breeding colonies.

When breeding stock is sourced from the wild conservation status has to be carefully taken into account. However, there is no evidence that the trapping of the cynomolgus macaque in controlled conditions for breeding purposes, is necessarily a conservation issue and in Mauritius the cynomolgus macaque has been implicated as a predator of other species that are endangered (Carter & Bright 2002). Indeed, in some areas the cynomolgus monkey is considered a pest, causing significant damage to agricultural crop production. Sourcing from the wild is also associated with potential health risks and these must be controlled by appropriate quarantine procedures.

There is debate about the merits of obtaining primates from overseas breeding centres rather than from national breeding centres. This has been prompted partly by findings about the stress that primates respond to during international air transport (Wolfensohn 1997; Prescott 2001; SCAHAW 2002; Honess *et al.* 2004).

Macaques come from a wide range of natural habitats, and it seems likely that the genetic backgrounds and responses to experimental procedures may also be variable for macaques from different populations. For example, rhesus macaques from India and China can show very different responses to experimental infections (Smith 2005). However, without better knowledge of this variation it is possible that crucial characteristics for future experimental models may be lost if they are not present in the limited number of parents from which self-sustaining colonies are derived. Therefore, wild animals are an important reservoir of genetic characteristics that may be of prime importance for the study of diseases in the future. For other species, recent legislation against the exportation of wildlife in a number of source countries has affected supply. Even where the export of captive-bred representatives of indigenous species is permitted, this is often under a quota system. Wild-caught olive baboons (*Papio hamadryas anubis*) have been exported from African countries (eg, Kenya) for research use, but the trade in this species from Tanzania and Ethiopia is now subject to CITES export quotas (Prescott 2001).

The Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) regulates international trade in endangered species, live or dead, or any parts or products of them. Species listed in Appendix I are considered the most endangered. Currently, all primates are listed as being in either Appendix I (threatened with extinction) or Appendix II (could become endangered without control of trade). CITES permits must be obtained for all movements (import and export) of CITES listed species between countries that have signed the Convention. These CITES management authorities are listed in the International Air Transport Association (IATA) Live Animal Regulations

which are published annually in several languages (English, Spanish and French). The IATA regulations set out minimum conditions for the air transport of live animals and provide essential information for all those seeking to transport live primates. Further information relating to transport has been provided by the Laboratory Animal Science Association (LASA) (2005), IPS (2007) and see also Chapter 13.

When primates are transported to research facilities, they are usually shipped while still juvenile, so that the total weight and cost of the consignment is reduced. Juvenile animals may be shipped in pairs within the transport container, and pairing animals allows for mutual support during stressful events. Evidence suggests that when primates are subjected to a stressful event, such as transportation, signs of physiological stress are markedly reduced when in the presence of other individuals (Honess & Marin 2006a). The compatibility of paired animals can be ensured by studying the interactions of the animals in their social groups prior to being transported; animals which show affiliation can be assigned to travel together. This approach should extend beyond the transport phase and efforts should be made to ensure that groups which will be housed together at their destination are socially stable and, where possible, from the same breeding group. In this way, relationships and social status will have already been established in natal groups, reducing the likelihood and intensity of conflict. This makes future veterinary and behavioural management of the animals easier.

A change in diet can affect the gut flora and, with all the other changes involved in transportation, will add to the animals' stress. A gradual change to a new diet over 4–5 days will reduce the incidence of diarrhoea. Communication between shipper and recipient, prior to shipping, should ensure that a list of the animals' favoured and acceptable foods is passed on so that these can be available on arrival.

There may also be disease risks associated with the transportation of primates, both between the animals and handling staff and between consignments of animals, particularly if the health status of the animals is unknown. They may be carrying zoonotic diseases, and disease could also pass from the shipment handlers to the primates. Rhesus, long-tailed, bonnet and pig-tailed macaques show distinct and consistent differences in behavioural and adrenocortical responses to stress induced by confinement in a transport cage, and by a cage and room change (Clarke *et al.* 1988; Crockett *et al.* 1995, 2000). It is frequently difficult, if not impossible, to separate the effect of the transport element of their journey from the effect on the animals of other changes that may accompany this: changes in accommodation, animal care staff, diet, climatic conditions etc. (Honess *et al.* 2004).

## General husbandry

### Enclosures

The physical environment in which captive primates are housed is an essential element of the conditions that contribute to the physical and psychological health of the animals. When designing accommodation in which to keep primates, the starting point is to examine the ecological requirements

of the species, consider its habitat in the wild and what features of that environment can be replicated in the captive setting. Not all features of the wild environment are in the animal's welfare interest; for example, food resources may be scarce, competition from conspecifics and prevalence of predation and disease may be high in the wild. In captivity, on the other hand, there may be plentiful provision of food and effective disease control; but there may be a reduction in activity leading to boredom and obesity with resultant poor health, both physical and psychological. Replication of the natural environment in the captive situation must be balanced to ensure that the animals' health is maximised.

While there may be similar trends in many species, the details may differ for some with variation in social relationships, anatomical and ecological adaptations, use of space, level of activity and time and energy budgets, and in aspects of infant rearing, feeding and foraging (Honest & Marin 2006b). Thus, some practices suitable for one species may have unforeseen and potentially disastrous consequences when applied to another. Recommendations for captive maintenance, therefore, need to take into account knowledge of species-specific behavioural responses, life history patterns and clinical tendencies.

There are many imperfections in current guidelines on the housing of primates kept for research, and there are inconsistencies between countries in regulations (Poole 1995). Sometimes, specific space guidelines (eg, NRC 1996) may be incompatible with the recommendation that behavioural needs should be met (NRC 1998) and the wide discrepancies in the recommended space allowances (Terao 2005) can throw doubt on their credibility. It is, therefore, important that these guidelines should be scrutinised and revised regularly, using a harmonised approach that will best serve the interests of the animals. The most recent recommendations are those published by the European Commission (2007).

Existing recommendations for primate housing, particularly in research facilities, are generally inadequate from the animal welfare perspective. Most are based solely on the weight of an animal without reference to linear dimensions. This can result in recommended cage sizes which are actually smaller in the vertical dimension than the head to tail length of the monkey so that the animals cannot perch in the cage with the tail freely suspended, as they do in nature. The sizes of cages are sometimes too small to meet the behavioural needs of the animals; providing neither adequate space for exercise nor room for environmental enrichment (Crockett *et al.* 1995). The assumption is made that heavier individuals require more space than lighter ones, although in practice light, young animals are usually more active than the heavier adults (Wolfensohn & Honest 2005). Rather than basing cage size on parameters such as body weight or crown to rump length, it is better to use performance standards which assess the ability of the animal to express its species-typical behaviours and which will vary depending on species, age, sex, individual temperament, group composition and dynamics (Honest & Marin 2006b). It is important to appreciate that most recommendations for cage sizes represent *minimum* dimensions for animals of all ages. The duration of stay of the animal is also relevant. Where primates are to be kept for a period of years, the necessity for housing them in an environment that better satisfies their

needs is even more important than for those animals which will only stay for a short while.

Cages are frequently constructed of metal with wire mesh walls, or parallel metal bars. Such cages are not only expensive but cold to touch, noisy and not very animal friendly. Metal is easy to clean but materials that are warmer to the touch, chewable, and which provide a quieter environment than the clanking of metal cages are preferable. The structural division of space in primate enclosures is of paramount importance. It is essential that the animals should be able to utilise as much of the volume as possible because, being arboreal, they occupy a three-dimensional space. To make this possible, perches, swings and climbing structures should be provided. Visual barriers, which allow the animals to be out of sight of one another, are important in group housing and multiple escape routes provide opportunities to avoid attacks and also prevent dominant individuals from restricting access of subordinates to other parts of the cage (National Centre for the Replacement, Refinement and Reduction of Animals used in Research (NC3Rs) 2007). Where individuals may need to be treated individually, as in some toxicology experiments, areas with a partition to allow separation or varying degrees of social contact is required. Flexibility of use should be incorporated into the design of the housing.

In a research setting, a design that combines cages with a larger enclosed area is a flexible and useful solution to the conflict between wishing to give the animal free access to space and wishing to keep it in a cage to make it more accessible. This permits the retention of a number of standard cages allowing the animals to be removed into transport chairs for testing, dosing or sampling; but at the same time allowing them access to a much larger and more complex space when not in use. In this setting, the animals will show an extensive range of natural behaviours, little aggression and will move readily into chairs or boxes. There is an ethical obligation to house and maintain animals used in research in the best conditions that can be provided. So, as 'best practice' evolves it is necessary to continually re-evaluate whether the facilities and their operation and management can be improved.

Foraging is a natural and desirable behaviour which can occupy a significant period of time, reducing boredom and the incidence of stereotypic behaviours. Therefore, a substrate such as woodchips, hemp or shavings should be provided in which forage can be scattered. Hay, straw or other material such as shredded paper may be provided for environmental enrichment. Careful design and positioning of drains and air vents are required to ensure they do not become blocked, or can be readily cleared.

In addition to animal holding areas, a primate facility should be equipped with many functional support areas (see Chapter 9). The kinds of support areas needed will depend on the purpose of the facility and the use to which the primates are put, but all should receive due consideration in the planning stages.

## Social housing

All species of primates used in the laboratory are social animals that live in family groups or large troops and it is

widely accepted that housing individuals on their own is a major stressor (Joint Working Group on Refinement (JWGR) 2009). Knowledge of the normal social structure (including how groups are constituted and dominance hierarchies established) should be used to inform how they should be group-housed in captivity. This is important in determining group size and structure, defining socialisation programmes, managing aggression, promoting natural behaviour, optimising reproductive success, where appropriate, and of course initially in the design of housing and husbandry systems (Wolfensohn 2004).

The Old World primates described in this chapter live in social hierarchies in which there are inevitable conflicts and fights which may result in some animals being injured or even killed. A singly housed animal may be in excellent physical health because it is not exposed to the risk of infections from other animals, there is no competition for food and no chance of wounding by companions. Furthermore, although it will suffer the stress of social deprivation, it will not have to try to maintain its position in a social hierarchy. However, such animals frequently show a poor behavioural repertoire with abnormal and even self-harming behaviours and do not have well developed coping skills. The benefit of social housing is that the environment is dynamic, variable and unpredictable so there is little habituation, but on the other hand, there may be increased risks of infection, wounding and competition for food. With good management strategies these risks can be minimised but not altogether removed. Because of the overall welfare benefits, it is widely accepted that monkeys should be kept in groups. There will, however, be the occasional social misfit who will have to be removed either for their own safety or for the benefit of the remainder of that group. It is important to maintain a flexible approach to the management and use of monkey colonies to ensure that such individuals are used to maximum benefit, and are neither wasted nor left to suffer social deprivation simply because they do not fit in. The size of the group is important, and arguably more important than the amount of space per animal. In nature, many primates live in fairly large groups (for macaques around 50 in a troop) and while putting a small group of animals or a pair together will give them company, there appears to be a higher incidence of fights and unsettled behaviour in these than in larger groups, even if floor space per monkey is lower in the latter case.

Provision of foraging opportunities in an adequate amount of space is a way of offering a socially sanctioned method of establishing the hierarchy that does not result in significant wounding and injury. The damage caused to an animal by individual housing may not be immediately apparent as the changes in behaviour may at first be very subtle, but in the long term there may be self-mutilation and more obvious damage. The animal's individual experiences will modify its development since there is a dynamic process that determines its later behaviour. For example, sucking and clinging, which should be directed toward the mother, may become directed toward other available objects or even the individual's own body. Although this does not provide the nutrition and contact that should come from the natural mother-directed behaviour, it continues to provide a state of a psycho-physiological arousal. Thus digit sucking or self-hugging will occur when an individual is anxious or

distressed; the same circumstances in which an animal will return to its mother. Stimulation-seeking behaviours manifest themselves in a variety of ways depending on the available options afforded by the environment.

Evaluation of the psychological condition of the animal should take into account its physical health, its behavioural repertoire and an assessment of its coping skills when presented with novelty. The latter will evaluate normal inquisitive and explorative behaviour or any abnormal response and how long the animal takes to return to baseline level of behavioural repertoire.

### Environmental enrichment

Establishments wishing to demonstrate best practice should endeavour to produce conditions for their animals which provide key safe features of a naturalistic environment that will contribute to encouraging as natural a range and rate of behaviours as possible. Environmental enrichment is essential for captive non-human primates to meet their ethological and psychological needs (Young 2003). It should provide the animals with the opportunity to carry out a sufficiently varied daily programme of activity (see Chapter 10). The actual enrichment provided will vary, but there is now a large literature offering a wide variety of options. The effectiveness of many is reviewed in Honess and Marin (2006b).

Opportunities for the animals to exercise a full locomotory repertoire should be provided in the living area. To allow this, the cage must be sufficiently large and contain adequate furnishings. Cage furniture itself can provide opportunities for a wide repertoire of behaviour. Perches, ladders, swings, plastic chains, car tyres etc. are all of value, and allow the animals plenty of places to sit without having to squabble. This allows a social hierarchy to develop with less aggressive encounters. Devices to encourage foraging (ranging from food scattered in the substrate to puzzle feeders) have also proved effective. Some practical methods include the use of wire grids over food hoppers rather than expensive manufactured food puzzles, ice cubes of frozen juice, frozen grapes or melon cubes, food on top of the enclosure to encourage animals to forage upwards through the mesh, wrapping or boxing of treats, empty diet bags or cardboard boxes, and foraging boxes full of hay or sawdust (Dean 1999). Novelty is important so the items should be changed frequently to avoid habituation and a programme of rotation of items of environmental enrichment should be recorded.

Reducing the incidence of aggressive encounters by resorting to long-term single housing of animals is not acceptable; the environment and the group composition need to be actively managed to ensure maintenance of social stability. A key component in a successful strategy is to start with the right compatible grouping, which may require coordination and effective communication with the source breeding colony which establishes the groups at weaning. Training animals to co-operate with carers and experimenters also helps to enrich the animals' lives and reduces handling stress (Reinhardt & Reinhardt 2000). It is vital to remember that the animal's principal purpose is for a scien-

tific procedure and the animal model must be valid in terms of normality and reproducibility. The environmental enrichment programme should be reviewed to consider of any effect (positive or negative) on the quality of the scientific data generated.

### Physical environment

The environmental sensitivity of primates varies considerably between species, some being more tolerant of environmental change than others. In the wild, rhesus macaques (*M. mulatta*) occur across a wide range of altitudes from sea level to 3000 metres (Rowe 1996) indicating a tolerance of a substantial temperature range. Long-tailed macaques (*M. fascicularis*), on the other hand, may be less tolerant, being found in habitats from sea level to 2000 metres.

### Temperature

The recommended temperature regimes for Old World primates relate to differences in the natural habitats to which they have adapted. In the UK codes of practice for users and breeders, 15–24°C is required for Old World monkeys reflecting their tropical to subtropical natural habitat (Home Office 1989, 1995). In the USA the recommended temperature range is 18–24°C for all primates (NRC 1996). Depending on the location and ambient temperature of the facility housing primates these recommended temperatures will be achieved and maintained either through a system of heating or cooling. Stocking density will affect the temperature in each room, so leading to significant temperature variation between rooms with the same heating/cooling system where stocking density varies significantly. Rapid fluctuations in housing temperature are undesirable, but appropriate dampened temperature fluctuation on a 24h cycle that mimics natural temperature may help encourage natural behaviour, such as taking a siesta during the hot part of the day and huddling at nights when it is cooler (Honest *et al.* 2004).

Where no indoor housing is provided, it is vital that sufficient shelter is available to protect animals from climatic extremes. If an outside run is provided, the interior accommodation should be sufficiently attractive that animals do not seek all their stimulation outside, particularly during periods of inclement weather. Outside caging can be protected with natural vegetation or roofing; during seasonally bad weather, sides and a ceiling can be attached to the caging for extra shelter and to allow heating of the interior. Where excessive heat may be a problem, this can be alleviated by providing a pool for recreational use and behavioural thermoregulation or by thermostatically controlled spraying of a fine mist of water droplets that can reduce the ambient temperature by about 5°C (Honest *et al.* 2004). Under certain experimental regimes and containment levels it may be important to ensure negative air pressure in the animal rooms. In the UK 10–12 air changes per hour are required (Home Office 1989, 1995) while 10–15 air changes per hour are recommended in the USA and recycled air should contain at least 50% fresh air (NRC 1996). It is important, however, to prevent draughts.

### Relative humidity

In the UK relative humidity levels are required to be 45–65% in areas where primates are used in scientific procedures (Home Office 1989); or 40–70% where they are kept for breeding (Home Office 1995). In the USA the recommended range is 30–70% for all primates (NRC 1996). Efforts should be made to reduce the impact of husbandry practices, such as extensive cage/housing washing, on conditions such as humidity levels. Extensive daily washing, such as pressure-hosing, may result in surfaces which remain permanently wet, resulting in elevated humidity levels and also presenting a potential health risk to the animals as many pathogens remain viable in a warm, wet environment.

### Lighting

Where animals have access to daylight and are not maintained in a region where day lengths are the same as, or very similar to, those in the natural geographical range of the species it will be necessary to regulate lighting regimes. Where access to daylight is not available a lighting regime of 12h light, 12h dark is typically provided, in which case efforts should be made to replicate dawn and dusk gradations in light intensity. In the wild, primates rely on the ultra violet (UV) in daylight to produce vitamin D<sub>3</sub>. Care should be taken to ensure that, particularly in the absence of natural light, artificial light is provided using daylight spectrum tubes or bulbs, rather than standard fluorescent lighting. This is of particular importance where there may be a familial predisposition to metabolic bone disease or an even minor deficit in dietary vitamin D<sub>3</sub> (Wolfensohn 2003). Artificial lighting typically lacks a UV component; where this is the case and access to daylight is limited, specific provision of UV light is recommended, and vitamin D<sub>3</sub> should be supplied as a supplement in the animals' diet.

Care should be taken in the positioning and intensity of artificial lighting in interior accommodation. Highly engineered caging, such as that found in experimental facilities, is frequently made of galvanised steel. Poorly positioned and overly intense lighting can intensify the glare from highly polished metal surfaces. This can be reduced by using more sympathetic, better placed lighting and the use of more natural caging materials such as wood and wire. The lighting system is also important in preventing the creation of dark areas of the caging, such as the lower levels or corners of shelved caging, in which animals may hide from view. A facility can be designed to maximise daylight by the incorporation of windows; and if the configuration of the building offers a choice between a place in a sunny/cool window region and a more controlled environment within the inner confines of the building this will allow the animals to select their own thermal environment.

### Noise

There are four primary sources of noise: the primates themselves (eg, vocalisations); the physical environment (eg, caging, extractors, pumps, doors); the staff (overshoes, shouting, husbandry procedures); alarms, public address and entertainment systems (for staff and animals). High

noise levels may intimidate many animals and have a negative effect on their psychological well-being. Primates are highly social animals and one of their primary modes of communication is vocal. Dominance can be asserted through vocalisations and therefore care needs to be taken in placement of overly assertive animals in proximity to those that may be negatively affected by vocal bullying.

The design of the physical environment and materials used in its construction can be responsible for substantial noise pollution. If cages are constructed using metal sheeting and heavy meshing with metal furniture, such as swings, noise production can be substantial particularly when larger primates display. The use of more natural caging construction and furnishing materials such as wood will help reduce noise, as will the provision of a solid, rather than grid, floor covered with sound dampening forage substrate such as wood chips. Other sources such as air extractors and pumps also need to be considered when trying to minimise noise.

The people working around the primates, as well as those who visit the facility, can generate considerable noise. It may be reassuring for the animals to hear the voices of familiar care staff but not all staff are viewed as friendly by the animals and their voices may, particularly when loud, produce a response suggesting stress or anxiety. Staff should be encouraged to keep voices down and to work around the animals in a way that reduces unnecessary loud noises. Heavy metal modular caging is noisy to manipulate during cleaning or when catching animals for treatment, research procedures or husbandry changes. Trolleys that are used to move animals, food and bedding can be noisy especially if they collide with walls and doors. Other noise-generating factors such as slamming doors and clothing, including plastic overshoes, should be included in reviews of noise production and its prevention around captive primates.

### Accommodation design

Laboratory primates are often kept in cages or rooms, but some larger species may be kept in outside pens or corrals, with free access to a heated indoor area. There is a perception that there is a welfare advantage to all primates associated with the provision of external accommodation. However, it is the quality of the accommodation and the handling of the animals which matters most in terms of animal welfare and outdoor accommodation is not necessarily in itself a benefit. External accommodation carries with it risks from exposure to wildlife (small birds, rodents, insects), disease transmission from outside vectors (eg, *Mycobacterium*, *Salmonella*, *Yersinia*), and damage due to adverse climate conditions (eg, frost injuries). In the laboratory setting where disease-free animals are required, these factors may reduce the supposed welfare gain of external accommodation over a good quality internal exercise area.

The choice of internal accommodation will also facilitate animal handling and may influence the extent to which the primates become accustomed to human contact and socialisation. Achieving this with a potentially aggressive species depends not only on staff education and training, but also on the configuration of the facilities, including plentiful enrichment, and accommodation which allows the animal refuge points from where it can interact with humans

without feeling threatened. In the development of non-stressful and safe means of capture, and in the training of animals, there should be dual emphasis on animal welfare and staff health and safety. These developments are only practicable in a building which allows for the seclusion of the occasional aggressive animal (sub-division of areas) for the protection of staff and other animals, and within which it is possible to train animals to come forward for capture and for simple interventions. Capture by means of netting (as is often used in large outside runs) is both stressful for the animals and may be source of minor injuries. The stress of handling for minor procedures can be greatly reduced by training, and monkeys are capable of learning to volunteer for these interventions (see Chapter 16). The extent of the human-monkey interaction bears directly on intended end-use; familiarity with human handling is valuable in preparing animals for work in some studies. Initial profiling and training has potential benefits in selecting animals for different end-uses. This is more difficult to deliver without the kind of close contact which is possible in an internal facility. However, for other types of study (such as studies of natural behaviour) it is necessary to have large naturalistic social groups (depending on the species) with diversity of demography and social and genetic relationships which are more achievable in a parkland type setting. The final decision on whether to choose an internal, external or mixed facility will depend on factors including the use of the animals (laboratory, zoo, sanctuary, conservation study prior to returning to the wild), the species, the local climate and cost. The facility must be 'fit for purpose' but there should be no underlying assumption that outside living areas are somehow automatically better. A well designed facility is critical to be able to deliver a successful animal care programme and behavioural management.

Building a new facility takes a long time from conception to completion and there will be many factors and details to consider (see Chapter 9). Cost, design, materials and utilities will be high on the list of priorities for the build management team, however the species-specific behaviours of the animals to be housed in it should take an equally high priority in the design criteria. Finally, managers will often require husbandry duties to be carried out in a way that optimises the efficient use of staff time and as a result it is easy to overlook the effect their methods of working have on the animals. Wherever possible, husbandry duties should be carried out to minimise the impact on the animals being cared for, even if this may be at the cost of working efficiency. Husbandry regimes that may be more labour-intensive but have a reduced impact on the animals should be used. It may well be that there will be cost savings elsewhere; for example, through less aggression leading to less traumatic injuries, easier training producing a more valid research model and ultimately a more effective use of research funds.

### Feeding/watering

#### Food

Analysis of wild primate activity budgets has shown that more time is given to foraging than to any other activity

(Lindburg 1991), and arguably food gathering is the most profoundly affected activity of a captive existence. Since many primates choose to spend a substantial amount of their time foraging, anything that may restrict this should be regarded as potentially detrimental to their welfare. In captivity, providing food removes the need to forage and food tends to be presented to a predictable schedule. It is better to provide small portions and with an unpredictable schedule to satisfy the animal's behavioural needs than to provide the quantity required to satisfy the daily nutritional requirements in just one feed.

Nutrient intake cannot be assessed adequately just in terms of grams of food taken. It is necessary to consider the metabolisable energy (ME) value and the nutrient content of the food so as to take into account variations in water content and digestibility. Macaques require approximately 420 kJ ME/kg daily for maintenance, 525–630 kJ/kg if pregnant or lactating, and 840 kJ/kg for neonatal growth. Commercial Old World monkey diets that have a protein density of 15–25% are used, with supplements of fruit and nuts. Foraging mix can be scattered through the substrate of the enclosure adding interest to the diet as well as providing environmental enrichment. Very useful tables of the nutrient contents of foods commonly used to feed primates are published by the NRC (2003).

Dietary intake is affected by the colour, smell and taste of the food. Most species prefer sweet foods, but its hardness and density will also affect intake. The food pieces need to be of a size such as to be held easily so the primate can manipulate its food, but it is not necessary to chop foods into very small pieces. Food may be offered *ad libitum* or given in a fixed amount. If fed *ad libitum*, primates eat to their energy requirements but can become obese if fed on palatable foods, this applies especially to dominant animals who may monopolise favoured foods.

An overview of energy requirements and how these are calculated is given in Chapter 4 of Wolfensohn and Honess (2005). This energy requirement is met by a combination of commercial primate diet, a selection of fruit and vegetables and forage mix, but variety is essential and, when adding any supplements such as fruit, care must be taken not to upset the nutrient balance. Amounts fed will also need to be adjusted according to levels of activity and weight gain/loss must be evaluated regularly. Recommended dietary levels of minerals and vitamins are given in Table 39.2.

Supplements are generally given for environmental enrichment or as part of positive reinforcement training, rather than primarily for nutrition, but they may have the undesired effect of distorting the balance of the nutrition provided. It is therefore important to use items that are nutritionally complete or which are high in moisture and low in calories – such as fresh fruit and vegetables – rather than offering energy-dense but nutritionally incomplete foods such as nuts and raisins. Since fresh fruit and vegetables are 80–90% moisture, if these make up less than 40% of the wet weight of the diet, they will be providing less than 10% of the total dietary dry matter and therefore will minimally distort the nutrient balance.

Data on composition of foods and feed ingredients, including details of dry matter, energy, protein and other nutrient densities are essential for formulating feeds and

**Table 39.2** Recommended dietary concentration and levels of minerals and vitamins.

Mineral	Concentration
Calcium	0.8%
Phosphorus	0.6%
Magnesium	0.08%
Potassium	0.4%
Sodium	0.2%
Chloride	0.2%
Iron	100 mg/kg
Copper	20 mg/kg
Manganese	20 mg/kg
Zinc	100 mg/kg
Iodine	0.35 mg/kg
Selenium	0.3 mg/kg
Vitamin	Level
Vitamin A	12 000 IU/kg DM
Vitamin D	1000–3000 IU/kg DM
Vitamin E: ( $\alpha$ -tocopherol)	50 mg/kg DM
Vitamin K	2 $\mu$ g/kg body weight/day
Thiamine	1.1 mg/kg DM
Riboflavin	1.7 mg/kg DM
Niacin	16–56 mg/kg DM
Vitamin B6	4.4 mg/kg DM
Biotin	110 $\mu$ g/kg DM
Folic acid	2.55–5.61 mg/kg DM
Vitamin B12	11 $\mu$ g/kg DM
Vitamin C	55–110 mg/kg DM

diets that meet requirements (see NRC 2003). The exact analysis of fruits will vary depending on the condition of the particular batch, the season and the source. Animals should be fed according to their individual needs, and these will depend on species, age, sex, physiological and reproductive status, health and environmental conditions. Estimates of energy requirements are usually related to the stage of life cycle – maintenance, growth, pregnancy or lactation – and are often expressed as multiples of the maintenance requirement. Over-consumption of calories by immature animals will lead to excess weight gain, affect age of sexual maturity and adult weight, and predispose to obesity. Energy requirements during pregnancy and lactation are substantially increased, with lactation being the most energetically demanding phase of reproduction (NRC 2003).

Growth can be measured in various ways such as body weight, crown–rump length, limb length, or head circumference. The linear measurements are not distorted by accumulations of body fat in the way that body weight may be. Growth rate will vary depending on genetic background, maternal nutrition in pregnancy and lactation, availability of supplementary weaning foods and rearing practices.

## Water

The amount of water drunk to satisfy physiological needs will depend on many factors such as the water and electrolyte content of the food eaten, the ambient temperature and humidity and activity level of the animal. The mean total water intake in cynomolgus monkeys has been found to be  $76 \pm 35$  ml/kg/day for males and  $100 \pm 51$  ml/kg/day for females, of which drinking water comprised  $50 \pm 33$  ml/kg/day for males and  $49 \pm 48$  ml/kg/day for females – other water being derived from food (Suzuki *et al.* 1989). Even moderate restriction of water will reduce food consumption.

## Identification

All primates should be uniquely identifiable, and this is a legal requirement in some countries (eg, European Commission 2007). In some establishments this is done by a tattoo, and some animals may receive two or more of these if they are marked at both the breeding and the using establishment. A number of other methods can be used (Honest & Macdonald 2003). Animals that are individually recognisable can be given names since this helps to increase recognition of their individuality, facilitate recall of the animal's history, and encourage appropriate attitudes to the animal (Segal 1989; Reinhardt 2003a). Names can be a useful aid in training, particularly when animals are in groups. Variations in fur colour or pattern, ridges, wrinkles, pigmentation, flaps of skin or other physical traits can be permanently recorded by photographs, drawings or written descriptions. The disadvantage of this method is that it can be difficult to identify individuals in large groups and may not comply with regulation of some studies. Coloured collars may be used, but should be monitored regularly to ensure that they do not abrade the skin or become too tight. Non-toxic dyes such as 'permanent' hair dye for human use are a useful minimally invasive method to mark animals for short-term needs but most dyes last less than 1 month and animals will have to be captured for re-application for longer-term marking. Temporary marking can be achieved by clipping patches of fur and this can last up to 4 months before re-clipping is necessary.

Microchips are electronic implants that provide unique permanent identification. However, they give no external indication of the animal's identity and so may be unsuitable for some applications. In the UK and Europe, most microchips and readers comply with ISO (International Standards Organisation) Standards (ie, ISO 11784 and 11785). The USA and Canada have different microchips that necessitate use of different readers. If animals are to be supplied microchipped to a different world region, the appropriate reader should be supplied with the animals and the location of the microchip specified. Tattoos are also permanent, though ink may diffuse over time and become unreadable. Invasive methods of identification (microchipping and tattooing) should always be carried out by competent, trained staff. Ideally, the method used should: not be painful, not cause an adverse reaction, not be uncomfortable and not be likely to cause injury, and must also be appropriate to the study.

## Health monitoring and quarantine

When new monkeys are brought into a facility, basic information about them is necessary in order to be able to design the quarantine programme and establish the health-screening programme. The first consideration is the source of the animals. The choice of where they are bought from may be imposed simply by availability, but this will have profound effects on the design of the quarantine and health-screening programmes. It is necessary to establish how the animals were kept at the source establishment, or if they were of wild origin. Details should be obtained of the groups in which they were kept (eg, peer groups or family groups) and how long they had been established. If they were weaned at an early age (less than 12 months) they will be more likely to be stressed and more likely to be carrying subclinical infections, such as shigellosis, which may then become a clinical problem when they arrive. Previous exposure to some infections, such as *Yersinia* from birds or avian mycobacteria, will depend on whether they have been housed with access to the outside, and may interfere with the interpretation of the tuberculin test. Information should be obtained on the standards of care in the source establishment and the background health status of the source colony, taking note of the time period over which this been established.

Lists of pathogens for which the animals have been tested should be examined closely, an unlisted pathogen may mean it is not tested for, rather than that the colony has a negative status. Samples from individual animals may be unhelpful without details of the full colony history. If screening results are available, it is important to determine which tests were carried out, where the laboratory processing was done, the method of quality control and whether or not any independent checks were made.

Once the source of the monkeys has been decided, they then have to be transported. If they are only coming a short distance, the impact of transportation will be much less than if they are coming half way round the world and stopping at airports in various countries where they may potentially encounter pathogens from other animals in airport holding areas. It is important to determine how they are to be transported, what will be the prevailing environmental conditions and how this may result in pathological changes in the animal affecting its health and welfare. Additional factors such as whether the monkeys travel alone, or in pairs or with another from its peer group, or with a stranger, will influence the degree of stress and the likelihood of fight wounds and of transmitting infections. All these parameters will influence the interpretation of signs that may be seen in the quarantine period.

During the quarantine period incoming monkeys need to be isolated from existing stock. This could be in a different building or in a separate area within the same building. Staff working practices must be such that they do not risk spreading infection to existing stock (or vice versa). There should be adequate provision of protective clothing and changing areas, and methods to prevent spread of disease by rodents or insects. Access to monkeys in quarantine should be limited. In research establishments, scientists may want to start work on the animal from the moment it arrives. However, it is vital to set aside enough time to allow for

observation of these new animals, building up a picture of each one's normal behavioural repertoire, so that changes due to illness or experimental stress may be spotted rapidly. The key here is good-quality staff and good technician training. It has been demonstrated that the behaviour of juvenile long-tailed macaques does not settle to pre-transport levels even 1 month after international transport and relocation to a new unit (Honest *et al.* 2004).

Quarantine can have a considerable impact on animal welfare through the way that animals are housed and handled, particularly if there is separation by single housing and a poor physical environment due to small cage sizes, lack of enrichment, isolation from former social companions, and fear of unfamiliar animals and humans in close proximity. Since some forms of quarantine or conditioning can have serious consequences for animal welfare, it is important for everyone to be clear about what is required and why, in order to avoid unnecessary constraints on the animals' husbandry and care.

The length of the quarantine period also depends on the source. In the UK, under the Rabies (Importation of dogs, cats and other mammals) Order 1974, if the animal comes from overseas it will have to be held under rabies quarantine for 6 months. If there is any risk of filovirus, then an absolute minimum of 31 days quarantine should be applied. If there are doubts about simian herpesvirus (herpesvirus simiae, B virus) and tuberculosis (TB) status then it will take 3 months to establish these. If the source is one for which there is 100% certainty of the health status of the animals then they can be moved sooner, depending on the use to which they will be put. 'Conditioning' is a particular form of quarantine which covers the processes often used in source countries. This may be used to ensure that animals are in good condition and physical health before transport and relocation, or may be to 'prepackage' and stress habituate the animals.

### Health-screening programme

It is preferable to prevent diseases than to have to deal with them when they arise. Several infectious diseases of primates are potentially zoonotic so health-screening programmes can not only improve animal health and welfare but will also contribute to the occupational health programme of the institute in which they are kept. The health programme should also take into account any necessity to screen staff to prevent spread of infections from humans to monkeys.

Monkeys can carry a number of potentially serious infectious diseases: some bacterial, ranging from salmonellosis to tuberculosis, and some viral. The UK Advisory Committee on Dangerous Pathogens has made particular recommendations with respect to simian herpesvirus (herpesvirus simiae, B virus) and simian retroviruses (Advisory Committee on Dangerous Pathogens 1998). Cohen *et al.* (2002) give recommendations for prevention of and therapy for exposure to B virus. A health-screening programme should be drawn up for every facility holding primates which should take account of the source of the animals, the use to which they are put (eg, breeding/experimental, long term/short term, immunology/neuroscience), and the resources available for testing.

A health-monitoring programme must define what samples to take (how many and how much) and how the samples will be stored and then processed. All animals that die unexpectedly for whatever reason should be subjected to full *post-mortem* examination including routine monitoring of enteric organisms, even if the cause of unexpected death is obvious, such as traumatic wounding. The cause of death should be established on the basis of facts, not based on circumstantial and anecdotal evidence from care staff. In a research environment there may be plenty of available data from animals at the end of experiments. The opportunity should be taken to use this and carry out a complete routine *post-mortem* examination on as many subjects as possible. Given the problems of false positives (and negatives) with tuberculin testing this may be an additional method for screening for tuberculosis. This opportunity can be taken to check for changing antibiotic resistance of normal gut bacterial flora, particularly if there are antibiotics used routinely post-operatively following experimental surgery.

Random sampling for haematology, clinical biochemistry and faecal bacteriology and parasitology will all yield useful background information about a colony. Ensuring full investigation of any clinical disease may reveal background health problems that might be affecting the health of the colony, such as marginal nutritional deficiencies. There should also be in place an annual screening programme for selected diseases. As an absolute minimum, the screening history for B virus should be available for Old World monkeys and faecal bacteriology/parasitology should be carried out annually. Every such primate over 12 months of age should have the following checked annually:

- clinical assessment (weight, review growth, condition score, alopecia);
- dentistry/oral examination;
- fingers/toes/tail examination;
- thoracic auscultation;
- abdominal palpation;
- assessment of psychological health;
- serum sample to check B virus serology;
- other tests as necessary.

A regular health-screening programme of a colony of animals should be maintained to cover some or all of the following:

- B virus;
- simian immunodeficiency virus (SIV);
- simian T-lymphotrophic virus (STLV-1);
- simian retroviruses;
- foamy virus;
- SV 40;
- hepatitis A;
- filoviruses;
- tuberculosis;
- faecal pathogens:
  - *Campylobacter* spp.;
  - *Salmonella* spp.;
  - *Shigella* spp.;
  - *Yersinia pseudotuberculosis*;
  - *Entamoeba histolytica*;
  - *Trichuris*.

The number of animals to be sampled (the sample size) should be as appropriate for the pathogens under investigation, taking into account that the probability of detecting infection will depend on the infection rate and other factors (ILAR 1976; Weber *et al.* 1999).

The health monitoring report should contain information on:

- species, breed and unit to which the report applies;
- date the colony was established;
- list of organisms monitored;
- date of latest investigation, diagnostic test used and identification of the testing laboratory;
- results of latest investigation, number of positive/negative animals and number tested;
- dates, test method, testing laboratory and results of the two preceding investigations;
- any additional information of other investigations not included in the standard report such as investigations of sick animals.

All animals should undergo a full *post-mortem* examination as soon as possible after death. If they are found out of normal working hours the carcass should be kept in a refrigerator at 4°C, not frozen, so as not to damage tissues that may be required for histological examination, and examined as soon as possible (within a day).

Animals used in experiments should, wherever possible, be from herpes B virus (BV)-free colonies, particularly where animals are handled under conditions of close contact, in long term studies or for neurological surgery, or for work where a latent infection may be reactivated. Examples of such procedures are those involving psychological stress or immunosuppression, the establishment of tissue culture or cell lines, surgery of the brain or oropharyngeal region, the genital region or the neural ganglia related to these areas. A comprehensive programme of testing in the source colony over many years will enable interpretation of the results in individual animals from that source colony with more confidence. Unless full background information is provided, testing of single specimens may not be diagnostic and interpretation of the result is not possible (Kalter *et al.* 1997). The animals should come from regularly monitored BV-negative stocks, from breeding colonies free of BV or by serologically testing each animal. All animals used to start a breeding colony should be screened and all Old World monkeys should be tested annually. All incidents should be taken seriously and guidelines should be in place to deal with potential transmissions of infection.

## Use in research

Primates should only be used in research programmes where there is particular need in justified research programmes and where it can be demonstrated that the benefits to society outweigh the harms inflicted on the animals that are used (Wetherall 2006). While this principle applies to the use of all animals used in research, there is a particular societal concern and uncertainty over the acceptability of using primates in research, principally because of their evolutionary proximity to human beings. It is also considered

by some that they may have a greater capacity for suffering than other animals because of their more developed cognitive abilities (Summerhoff 1990). It is therefore particularly necessary when considering the use of primates in research to consider the ethical issues as well as the merely practical ones.

The total number of primates used in research worldwide is estimated at between 100 000 and 200 000, with 64.7% involving Old World monkeys (Carlsson *et al.* 2004). Most (up to 70%) are used in regulatory toxicology.

The most common research areas for which primates are used are: infectious diseases (including HIV/AIDS) 26%, neuroscience 19%, biochemistry 12% and pharmacology/physiology 11%, in addition to their use in regulatory toxicology. The use of non-human primates in research in the UK has recently been comprehensively reviewed by Wetherall (2006).

The responses of different species of macaques to environmental stressors varies and this is reflected in their response to minor procedures such as routine capture, when compared with rhesus. *Cynomolgus* macaques tend to be more stressed (Clarke *et al.* 1988), and the animals' responses to stress can have implications for research (Boccia *et al.* 1995).

## Laboratory procedures

### Handling, restraint and training

Particular care must be taken when handling primates because of the danger of transmitting potentially zoonotic diseases. Appropriate protective clothing must be worn. For quarantine animals, this should include cap, gown, mask, boots and gloves. For other animals, gloves and protective gowns may be sufficient but there will be local safety rules for each institution which must be followed. These rules will take into account the origin of the animal and the results of health screening.

Many experimental procedures require gaining access to the individual animal but since primates are intelligent they can readily be trained to co-operate, even when they are living in social groups. Training is encouraged by the use of positive reinforcement, which may be in the form of a favourite food or drink which does not form part of their normal diet, so they are not habituated to it. Rhesus monkeys respond very well to being trained to co-operate using voice commands, which will not distort their nutrition.

In order to carry out a full examination of a primate it may be necessary to sedate it in order to reduce the risk of injury to the handler (eg, in experiments involving the use of infectious agents), to reduce the stress to the animal and also to enable the examination to be carried out thoroughly to yield the maximum possible information. A 'restraint' cage may be used for this in which the back is pulled gently forward or the front pushed gently backwards. Most animals find this procedure very stressful and there are better ways to handle most monkeys. The animal may also be netted but this is a significant stress factor and most animals will not respond well to this method of capture. It is much better to spend time training the monkey to present its hindquarters for injection of sedative, which can then be carried out

without stress to animal or handler (Wolfensohn & Finnemore 2006). Even if a macaque is sedated it should be held by the upper arms, to keep its face away from the handler. Even better is to train the animal for manual capture and restraint since sedatives themselves are stressors (Honest & Marin 2006a). The most humane method of capture for macaques is to train animals to enter a transport container. Other methods used to catch laboratory primates include net-catching (see Luttrell *et al.* 1994), catching animals in a nest box or transport container, and, for macaques, use of a pole and collar. These methods all have advantages and disadvantages and a useful discussion of the welfare implications of the various techniques is contained in Rennie and Buchanan-Smith (2006). Whatever the method of capture, macaques should be safely restrained and their body weight supported when they are carried.

It is important to recognise that restraint for any purpose and whether for short duration or longer may induce fear and stress responses, such as physical resistance to handling, alarm vocalisations, defensive threatening and aggression, urination and defecation, and that there are also likely to be physiological responses that will increase unwanted data variability (Reinhardt *et al.* 1995; Honest & Marin 2006b). These fear and stress responses should be recognised as indicative of a serious welfare problem that must be properly addressed. It may be that restraint itself can be avoided. Habituation and socialisation, together with training animals to co-operate with procedures using positive reinforcement techniques, can obviate the need for physical or chemical restraint. For example, macaques can quite quickly and easily be trained to present their hindquarters for injection or present a limb for blood sampling, and this avoids the need to catch them or to use a squeeze-back mechanism (Reinhardt *et al.* 1995; Reinhardt 2003b; Saucedo & Schmidt 2000; Wolfensohn and Finnemore 2006).

If restraint is required to control a primate during a scientific procedure, then the method used should provide the least level of restraint for the minimum frequency and duration necessary consistent with achieving the experimental aims. It should protect both primate and personnel from harm and should avoid causing unnecessary distress or discomfort.

Restraint chairs are used to support primates in a sitting position when it is deemed necessary to restrain them for prolonged periods, such as for single cell recording within the CNS or chronic infusion when they may be required to remain in one position for several hours. Chair restraint can affect the animal's physiology (Norman & Smith 1992; Norman *et al.* 1994) and can severely compromise their welfare (Klein & Murray 1995; Morton *et al.* 1987).

All primates can and will, on occasion, bite. They are very quick, surprisingly strong and will snatch and grab at such things as jewellery and loose clothing. Injuries can be prevented by knowledge of the particular species and the individual, including knowledge and interpretation of the posture and expression of the animal. Primates communicate in a variety of ways using sounds, facial expressions and postural changes. Many signals can be easily interpreted. For example, shaking a tree is a sign of aggression which, in a captive environment, translates to rattling the cage. A low-grade threat can be communicated in some

primates with a brief 'eyebrow flash' which in humans is an indication of recognition and may form part of ritualised flirting behaviour. Raised eyebrows combined with lip-smacking are used as a social appeasement signal in macaques. Other facial expressions may communicate quite different meaning to non-human primates than to humans. For example, the grimace, or silent bared-teeth face, indicates uncertainty or submission in many primates but, as a smile in humans, can be seen as an expression of friendliness. Another common source of confusion is the human 'stare'. A person may stare at an animal out of interest, but most primates will interpret this as an aggressive threat and respond accordingly. This 'miscommunication' is a common problem when people who have no experience of interacting with primates visit animal units.

One of the most effective ways to minimise stress for primates in the laboratory is to ensure that they are handled in a competent and empathetic way, and that they react well to this, without trying to assert dominance over staff members. The aim should be for the animals to feel unafraid, at ease and comfortable when they are approached, handled, carried and restrained. Major improvements in this respect have been achieved in many laboratories in recent years (JWGR 2009).

All staff-animal interactions should be based on an understanding of species-typical behaviour patterns and communication systems, such that these are interpreted correctly and responded to appropriately. Direct eye contact and potentially threatening body postures should be avoided. Animals should be adequately habituated and socialised to humans early in life, so breeders and users of primates should liaise closely to ensure that good practice in handling and restraint procedures is harmonised between facilities. Good training can enable less invasive restraint procedures to be used. All methods of capture, handling and restraint require experience and skill and should therefore be included as an integral part of staff training programmes. Methods used should safeguard the health and welfare of both animals and staff.

Training animals to co-operate with scientific, veterinary and husbandry procedures helps to reduce the stress that may be caused to both the animal and the laboratory staff (see Chapter 16). However, in order to start a programme of training with laboratory primates it is first necessary to train the people to communicate and interact positively with primates through recognition and interpretation of primate signals, and to help the primates to respond positively to humans through habituation and socialisation. Primates are not domesticated animals and contact with humans can be extremely stressful, especially where the primates are not in control of the level and intensity of that contact, which is a particular problem in the laboratory (SCAHAW 2002). Habituating and socialising captive primates to the presence (sight, sound, smell) and behaviour of humans as early as possible in their lives is essential. If the need to do this is not taken seriously, both animal welfare and the science can be seriously affected.

Early habituation reduces any fear or distress the animals may experience when confronted with new situations as adults. It can also facilitate handling and restraint and training of animals, and may reduce the need for sedation and

personal protective equipment when carrying out procedures (Reinhardt *et al.* 1995). It also allows staff to observe behaviour patterns which are relatively unaffected by their own presence, and this helps them to assess the welfare of the animals more effectively.

There should be a formal habituation and socialisation programme, based on the principles of positive reinforcement (Prescott & Buchanan-Smith 2007). In addition, all staff that come into contact with the animals should understand the need to ensure that their own actions make a positive and consistent contribution to the habituation and socialisation programme, and everyone should be trained accordingly.

Training primates has significant benefits for animal welfare, science and staff, especially when combined with appropriate socialisation, habituation and desensitisation. This is additional to the training required for primates to carry out specific tasks in some areas of research. Accordingly, training is recommended as good practice by many legislative and professional guidelines (Home Office 1989; NRC 1998; IPS 2007). Training methods should be based on positive reinforcement techniques, which reward desired behaviour, since this method of training is considered to be the most humane (see Chapter 16; Laule *et al.* 2003; Pryor 2002). Negative reinforcement should only be used when positive alternatives have been exhausted (eg, training for aversive procedures), and it should only be used in combination with positive reinforcement.

Positive reinforcement training is the preferred method of training animals. It refers to any form of training that is based on rewards rather than punishment. The animal is rewarded with some treat, such as a morsel of food, for a job well done. Negative reinforcement is the opposite of positive reinforcement and involves a punishment for less than favourable performances and usually implies some kind of fear, pain or discomfort for the animal being trained. Another way to get an animal to perform a task is to motivate it by withholding food or water and it has to perform the task in order to obtain food or water. As the intake of water is essential for survival, water deprivation is a stronger motivator than food deprivation and will achieve faster results since an animal will become physiologically compromised quicker with water deprivation than with food deprivation. Access to fluid in these conditions cannot be described as 'positive reward'.

Some research protocols require the regulation of the food or fluid intake. This regulation may simply involve strict scheduling of the access to water, or may involve restriction in which the total amount of water is strictly controlled, so that thirst becomes the motivator for performance of certain tasks. With limited access to water, food consumption also decreases and these protocols are often associated with weight loss and associated stress. Pre-screening should be conducted to determine whether the particular animal's temperament is conducive to training and to performing the tasks required. On such protocols the amount of fluid consumed and a hydration assessment should be recorded daily for each animal. Variables that can be used to assess hydration status include the body weight, food intake, skin turgor, urine output, moistness of faeces, general appearance and demeanour. It is important to evaluate the health and

welfare of each animal individually (Smith *et al.* 2006). Animals should generally be given free access to water for some period of time on days when there are no experimental sessions (NRC 2003). There is currently much debate over the use of water restriction paradigms and guidelines have been issued by the UK Home Office (2003) and Prescott *et al.* (in prep).

### Administration of substances, blood sampling

Some recent reviews have been published which provide detailed advice on refinements for the administration of substances and of sampling (JWGR 1993, 2001, 2009; Diehl *et al.* 2001).

Factors to consider include whether the particular individual or species is the most appropriate for the study or whether it is too easily stressed by handling and requires further time to acclimatise to the procedures. The use of sedatives may or may not reduce stress (Honess & Marin 2006a), but may confound the experiment and not be feasible. If possible, animals should be trained to co-operate with the procedures to avoid the need for physical restraint. Staff should be competent to carry out the procedure and post-administration monitoring.

### Telemetry

Telemetry is frequently used in studies involving primates, including those carried out to fulfil the requirements of regulatory bodies. Telemetry is widely viewed as benefiting science and animal welfare because it can reduce stress caused to animals (eg, by restraint), enable reductions in animal numbers and provide indicators of animal well-being to help implement humane endpoints. However, telemetry can require invasive procedures such as implantation surgery, single housing and use of jackets, which can cause pain and distress. Although telemetry is often described as a refinement, this will not be the case unless the technique itself has been fully refined.

Detailed advice on refinements in telemetry can be found in JWGR (2003 and 2004), including maintaining stable group housing, and behavioural pre-screening to ensure that individuals are suitable for projects and are not implanted unnecessarily. In particular, the reports explain how to pair- or group-house animals implanted with devices that transmit at the same frequency, eg, by housing an implanted animal with a naïve 'buddy' or using devices that can be turned on and off one at a time or by using developing devices which transmit at different frequencies.

### Anaesthesia, analgesia and post-operative care

A selection of drugs that may be used to sedate primates to facilitate handling are listed here. Veterinary advice should be sought on the use of these but some further information is provided by Foster *et al.* (1996); Sun *et al.* (2003) and Flecknell (2009). In the UK, all these drugs are prescription-only medicines and therefore must only be used under veterinary direction.

- Ketamine (5–25 mg/kg im) is the drug of choice to produce tranquillisation to facilitate handling. Peak effect is reached in 5–10 minutes and lasts 30–60 minutes.
- Medetomidine can be used to produce moderate sedation which can be reversed with atipamezole. Use medetomidine at 50–100 µg/kg im; reverse with atipamezole at 250–500 µg/kg im.
- Ketamine can be used in combination with medetomidine to produce anaesthesia.
- Acepromazine (0.2 mg/kg im) produces sedation but this is insufficient for safe handling.
- Diazepam (1 mg/kg im) also produces insufficient sedation for handling of larger primates, but may be used in combination with ketamine.

Once the animal can be handled, anaesthesia for surgical interventions should be of the highest standard. Induction (and maintenance) of anaesthesia can be by intravenous infusion of propofol. Barbiturates are associated with respiratory depression and resultant hypercapnia. Initial trials with Alfaxan indicate that it may be suitable for use in primates, but further work is necessary to substantiate this. Primates should be intubated, having first sprayed the larynx with local anaesthetic to prevent the occurrence of laryngospasm. Prior to intubation, administration of oxygen by face mask is advisable. Maintenance of anaesthesia using isoflurane or sevoflurane is most satisfactory and gives a good quality of recovery.

During anaesthesia, it is vital to monitor the vital signs including, temperature, blood pressure, oxygen and carbon dioxide levels and to maintain physiological stability with administration of fluids. This will assist the quality of the animal's recovery. Post-operatively, analgesia can be provided with opioids or non-steroidal anti-inflammatory drugs. Post-operative gastritis and vomiting can be controlled using metoclopramide. Selection of the appropriate regime will also depend on the area of scientific investigation as some anaesthetics may affect the area under study (Culley *et al.* 2007).

### Husbandry following surgery

Primates have traditionally been housed singly after surgery because it has been thought that otherwise animals will interfere with the other's sutures or equipment, such as cranial implants, or that animals which are slower to recover than others could be at risk of bullying or aggression. Clearly, animals need to be allowed to recover separately in the immediate post-operative period. However, it has been successfully demonstrated that surgically treated animals can be pair- or group-housed soon after recovery (Wolfensohn & Peters 2005).

Interrupted subcuticular sutures, with the possible additional use of tissue adhesives, should be sufficient to maintain the integrity of a surgical wound such that removal of sutures by the individual or cage mates is not a problem. Adequate perioperative analgesia will prevent animals from paying untoward attention to their own wound sites and attracting the attention of others. It has also been shown

that primates with surgical implants, for example cranial implants, can successfully be kept in social groups (Wolfensohn & Peters 2005). For work on extremities and limbs primates will tolerate bandaging to provide protection and support of the affected area provided the dressing is carefully applied.

When planning housing for the recovery period, it should be remembered that primates may climb before they are fully recovered from anaesthesia, and may fall and injure themselves. A purpose-built recovery enclosure may be used, or a temporary reduction in the height of the home area may be implemented. If a recovery enclosure is used, it should be constructed so that the primate does not have to be physically caught in order to be returned to the home cage, or animals should be trained to enter and leave a transport cage. Animals should be allowed to recover in proximity to others from their social group, not in social isolation. If surgery involves producing neurological lesions, the home area may need to be adapted to take account of any possible long-term side effects. If single housing following surgery can be justified, individual animals should have visual, auditory and, if possible, tactile contact with other primates.

## Welfare

### Assessment of welfare

Primates are highly intelligent, sentient and social animals with a complex range of physical as well as psychological needs. There is no doubt that they experience pain and that they experience a range of negative psychological states, such as anxiety, apprehension, fear, frustration and boredom, as well as a range of positive states (JWGR 2009). It should be assumed that procedures that cause pain and distress in humans will probably cause pain or distress in other primates (Organisation for Economic Co-operation and Development (OECD) 2001; Soulsby & Morton 2001). A monkey in pain may show a generally miserable appearance, and may adopt a huddled position or crouch with head forwards and arms across the body. It will tend to refuse food and drink and to avoid companions, although monkeys that are unwell may attract extra attention from cage mates, varying from social grooming to attack. Vocalisation is more likely to indicate anger than pain.

Good animal welfare may be defined according to the five freedoms:

1. Freedom from hunger and thirst.
2. Freedom from discomfort.
3. Freedom from pain, injury and disease.
4. Freedom to express normal behaviours.
5. Freedom from fear and distress.

Research using primates has the ability to impact on these five freedoms in some of the following ways, depending on the types of procedure being used:

- Freedom 1: use of food/fluid regulation paradigms.
- Freedom 2: keeping animals in metal cages on grid floors.

- Freedom 3: carrying out surgery, placement of implants with subsequent chronic infections.
- Freedom 4: use of single housing and restricted availability of space.
- Freedom 5: use of handling methods and procedural techniques which do not use reinforcement training but use aversive methods such as squeeze cages.

The welfare of primates will be maximised by keeping the animals in good health. This applies not just to their physical health but also to their psychological health. It has been demonstrated that cynomolgus macaques have the capacity for depression and that there is a relationship between social status and mood-related behaviours in this species (Shively 2006). The health should be evaluated regularly and records kept and a programme to review and improve physical and mental health applied where necessary. Quantitative assessment of the animal's well-being can be usefully recorded with a clinical score sheet. The animal should be reassessed at appropriate intervals in order to monitor its progress and check on the responses to any treatment given or changes in management. Good clinical score sheets remove the variation in interpretation of clinical signs which is frequently found between animal care staff and research staff; and the criteria for intervention are clearly defined before the animal's condition deteriorates (Wolfensohn & Lloyd 2003). The recognition of animals suffering pain or psychological distress is important, as it is the first step to avoiding or alleviating such conditions.

There are several parameters that can be used to assess welfare, which may be behavioural, physiological or biochemical (Table 39.3). The most readily accessible and commonly used index for assessing well-being in primates is behaviour.

**Table 39.3** Parameters used to assess welfare.

<i>Behavioural parameters</i>	<i>Physiological parameters</i>	<i>Biochemical parameters</i>
Time budgets	Body weight	Corticosteroids
Play	Condition scoring*	Reproductive hormones
Allogrooming	Alopecia scoring***	Leucocyte activity**
Locomotion	Heart rate	
Posture	Blood pressure	
Social interactions	Body temperature	
Sleep		
Self-scratching		
Stereotypical behaviours		

\*Wolfensohn & Honess (2005);

\*\*Honest *et al.* (2005a);

\*\*\*Honest *et al.* (2005b).

For general information see Novak and Suomi 1988, Boccia *et al.* (1995), Mendoza *et al.* (2000), Honess and Marin (2006a).

Clinical scoring systems are usually used for monitoring of single incidents but there should also be some assessment of the cumulative suffering and the lifetime experience of the animal. This will include direct suffering from the procedure as well as contingent suffering (Russell & Burch 1959) as a result of transport, housing, the environment and injuries from caging or conspecifics, to name just a few examples. The lifespan of primates, compared with other laboratory animal species, is relatively long. They are valuable animals, have long breeding lives and are likely to be used in long-term experiments. Some primates may therefore be housed in the laboratory for many years. In such circumstances, there are particular welfare issues that must be addressed (JWGR 2003, 2004). A welfare assessment matrix can be used to give a pictorial view of welfare and is based on Wolfensohn and Honess (2007). The matrix consist of axes relating to the following basic parameters:

- clinical condition (physical well-being);
- behavioural deviations (psychological well-being);
- the time frame of incident (duration);
- harm:benefit (justification).

This produces a basic four-axes matrix to which additional axes may be added (Wolfensohn & Honess submitted). The use of this type of matrix allows comparison of one animal at different time points or allows comparison between groups of animals. It also allows estimation of cumulative suffering and, by giving a pictorial representation, may be very useful for ethical review committees, particularly where there is lay representation.

### Behavioural monitoring

When assessing welfare using behavioural parameters it is important to assess the animals at various times. The animal's behaviour should be noted on the approach of the observer. Observations should then be repeated after the animal has had time to habituate to the presence of the observer. The use of space and structures, any self-maintenance behaviour, social behaviour, as well as the animal's disposition and interaction with observers are all recorded. An example of a behavioural assessment table is shown in Table 39.4, which demonstrates a difference in the behavioural repertoire between the two groups, the cause of which can then be investigated.

An awareness of the normal behavioural repertoire for the species is important to enable provision of appropriate care and management and for assessing their physical and psychological well-being. Knowledge of the behaviour of individual animals is also essential since primates show a high degree of individuality. Any deviations from normal must also be recognised to enable evaluation of refinements such as changes in cage design or environmental enrichment.

The advice of a primate behaviour specialist is invaluable in training both care staff and research staff to recognise and interpret deviations from normal behaviour and to assist in developing programmes to ensure good psychological health.

**Table 39.4** Example of behavioural assessment table.

Parameter	Group A	Group B
Confidence in approaching observer	Confident	Huddled at back of cage
Use of all levels of enclosure	Used all	Remained at highest level
Use of foraging	Used	Did not use
Use of environmental enrichment	Used them	Occasionally biting at objects
Manipulation of objects	Yes	No manipulation
Social interaction	Normal auto- and allogrooming	Hugging, no grooming
Dominance behaviour	No aggression	Aggression and chasing
Alopecia score	9 animals, total score 11	13 animals, total score 35

## Physical health

The first step in assessment of the monkey's physical health is to observe the animal in its home cage and evaluate its appearance, behaviour and general demeanour. In order to do this it is vital that the observer has some experience of the animal (both the species and the individual) in order to be able to judge whether the animal is exhibiting a normal behavioural repertoire. Just like humans some individual non-human primates exhibit behavioural patterns that are specific for that individual, but do not necessarily reflect poor well-being. Only after completing the examination from a distance and noting the behavioural responses, should the animal be caught in order to look at it more closely. Catching it will markedly affect its behaviour, whether or not sedatives are used, which is why it is important to make a full evaluation, before disturbing it other than by one's presence. For a full description of clinical assessment of a monkey see Wolfensohn and Honess (2005) and Smith *et al.* (2006).

The animal's weight should be recorded and its body condition noted as in Figures 39.2 and 39.3. This may be scored in a similar way to condition scoring of sheep (Ministry of Agriculture, Fisheries & Food 1994). It is assessed by palpating the monkey over its thoracic and lumbar vertebrae (at the level of the last rib) and making a judgment as to the amount of fat and muscle covering the bony prominences of the vertebrae and giving a quantitative score. Condition scoring at weaning and during the post-weaning period, combined with regular weight measurements, is important to ensure that the animal is receiving adequate nutrition and growing properly.

## Diseases

The potential of primates to carry serious zoonotic diseases should not be underestimated (Advisory Committee on

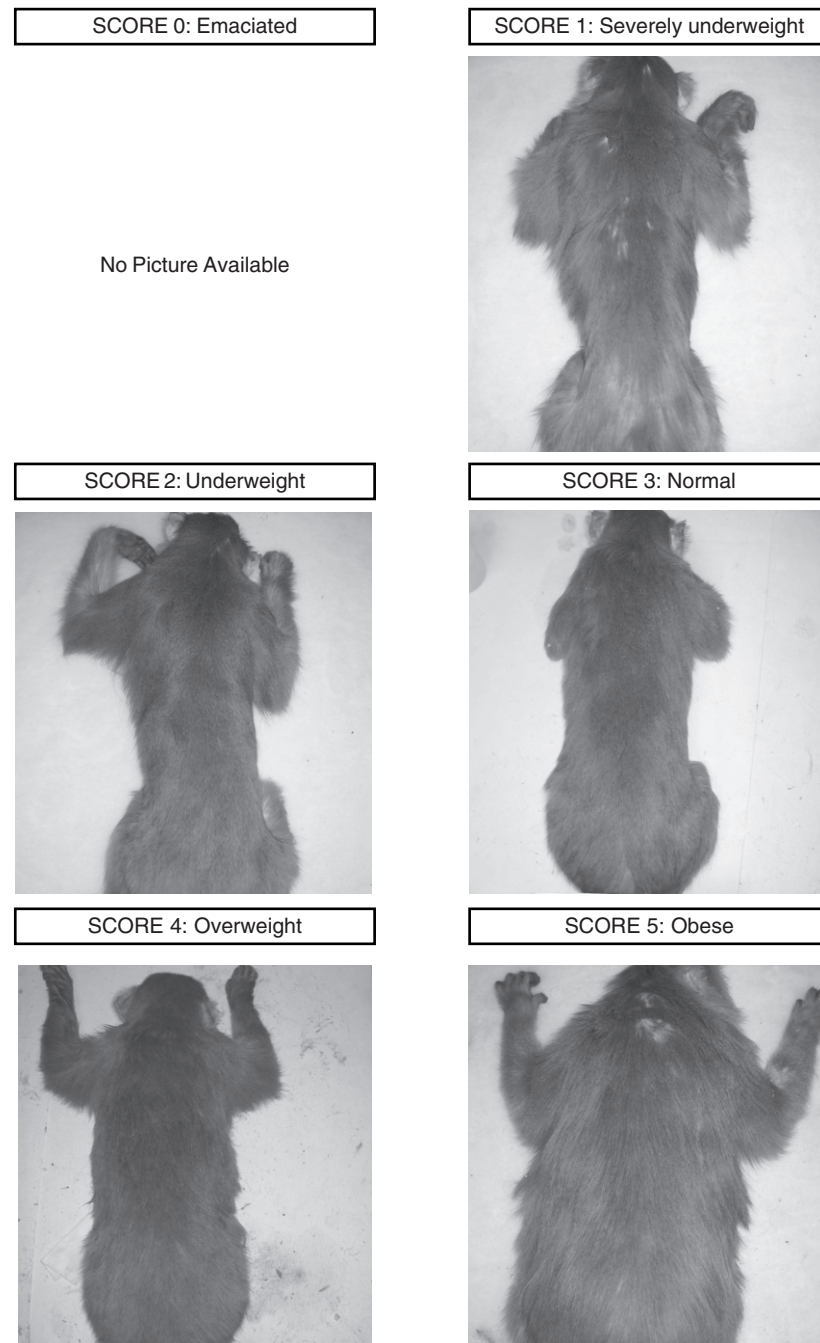

Dangerous Pathogens 1998). Captive-bred animals of known health status are less of a risk, and these should now comprise the majority of animals used. Monkeys are susceptible to many diseases carried by humans, such as colds and flu, tuberculosis, measles and many others. Therefore it is important to exclude casual visitors or at least wear a suitable face mask to reduce the risk of spreading such infections to the monkeys if appropriate occupational health surveillance has not been established. It is important to wear appropriate protective clothing and use good hygiene, to protect us from them, and them from us. Power hoses promote the formation of aerosols, which may allow transmission of zoonotic diseases, so suitable protective clothing must be worn when operating these.

There are many diseases which should be included in a regular screening programme as discussed above. Full details on the diseases of primates and their management can be found in Bennett *et al.* (1998) and Wolfe-Coote (2005); only a brief resumé is presented here.

**Tuberculosis** causes a chronic fatal disease in monkeys, and can pass from monkey to man and vice versa. It can be screened for using an intradermal skin test, commonly in the skin of the eyelid. Alternatively there are enzyme-linked immunosorbent assay (ELISA) tests available to detect antibody (Brusasca *et al.* 2003; Kanaujia *et al.* 2003). The disease in monkeys can remain subclinical for 6 months or more, and indeed may be latent until the animal is terminally ill. To prevent the disease from entering the colony, all new animals should come with a health profile which indicates they have been screened prior to arrival. Personnel intending to work with monkeys should be vaccinated or screened regularly for the disease. Any animal which has contacted a known human case should be effectively quarantined for at least 6 months until it is proved not to have contracted the disease. The important points about tuberculosis in primates are:

- skin tests are not 100% reliable;
- infectivity precedes radiographic or clinical signs or positive tuberculin test;
- radiographic signs precede clinical signs;
- coughing is the most common clinical sign;
- no single test is reliable – use combinations;
- take sequential chest X-rays of coughing monkeys;
- routine *post-mortem* examinations will add to the available screening data.

**Enteric disease** may be caused by a number of factors including pathogenic organisms. Monkeys will pass loose stools if they are frightened, or if there are changes in their environment or diet. Stress, such as after weaning, transportation, surgery or due to changes in social hierarchy, can also cause sub-clinical infections to become clinical, so any case of diarrhoea should be investigated to eliminate infectious causes. Zoonoses such as *Shigella*, *Salmonella*, *Campylobacter* and *Yersinia* are common bacterial pathogens, and protozoa such as *Entamoeba* or helminth parasites may also pose a risk. Some of these organisms can cause explosive outbreaks of disease and death if not controlled immediately. Regular screening and treatment will reduce the level of infection, and must be combined with strict hygiene and good husbandry to prevent transmission between animals and to personnel. Husbandry and environmental factors may also

**Figure 39.2** Condition scoring: whole primates.

contribute to the development of enteric disease, as will the presence of parasites or viruses such as rotavirus, retroviruses and haemorrhagic viruses. Therefore, prompt and accurate diagnosis of the aetiology of the enteritis is important so that a specific therapy can be instituted.

Eradication will depend on a prolonged programme to break the cycles of infection and transmission by improving hygiene and detecting and treating carriers (Wolfensohn 1998). In some units, the presence of *Shigella* is accepted, since with good husbandry, control is possible even with healthy carriers in the colony, provided the animals are not subjected to undue levels of stress, which may precipitate clinical disease. However, given the zoonotic potential, con-

sideration must be given to the assessment of risk to staff and, since the secondary complications possible from the type of pathology induced by shigellosis could be numerous and serious, it is important to keep animals free from disease wherever possible.

Post-weaning chronic diarrhoea is significantly associated with body weight at weaning rather than age (Munoz-Zanzi *et al.* 1999). An episode of pre-weaning diarrhoea is a good predictor for the occurrence of post-weaning diarrhoea, possibly since this may alter the function of intestinal mucosa and thus reduce the absorption of nutrients. This leads to reduced growth, smaller weight, impaired immune function and consequently post-weaning diarrhoea.

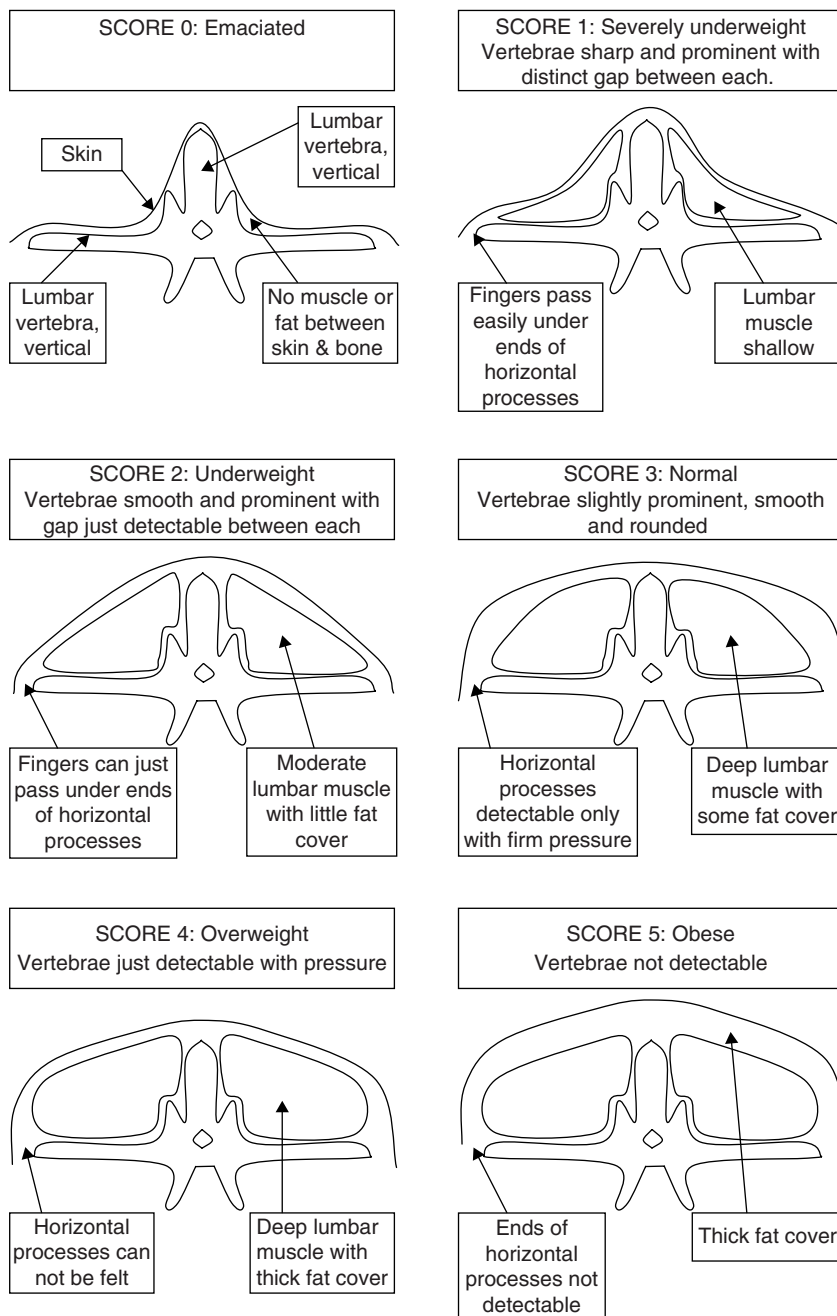

Figure 39.3 Condition scoring: vertebrae.

There are many enteric parasitic infections of primates, many are non-pathogenic, some are zoonotic, a few require diagnosis and treatment. Full details may be found in Owen (1992). The important ones to consider are the protozoans, *Giardia* spp., *Trichomonas* spp., *Entamoeba histolytica*, *Cryptosporidium* spp., *Balantidium* spp., and the metazoans, *Strongyloides* spp. and *Trichuris* spp. The protozoa may be treated with agents such as metronidazole and the metazoans with ivermectin.

For further information on screening of primate colonies see Weber *et al.* (1999).

#### Husbandry-related diseases

A management strategy for dealing with such problems as fight injuries or nutritional imbalances which may be

encountered with increasing use of foraging and group housing should be developed and built into any primate health-management programme. The benefit of social housing is that the environment is dynamic, unpredictable and variable so there is little habituation, but there are increased risks of infection, wounding and competition for food. With good management strategies, such as appropriate housing, these risks can be minimised but not altogether removed.

Clinical problems may be brought about by the increasing provision of forage mix in addition to normal pelleted diet. Although the forage mixes are all well balanced nutritionally, this assumes that the monkey will not pick out its favourite bits and leave the rest. By introducing an element of choice the diet may become unbalanced and problems, such as rickets in juvenile animals, may arise from this.

### Age-related disorders

These are frequently linked to nutrition; dietary restriction (but without essential nutrient deficiencies) will increase survival and delay the onset of degenerative aging conditions. A persistently positive energy balance will lead to accumulations of adipose tissue with increasing body weight and obesity.

$$\text{Obesity index for rhesus} = \frac{\text{Weight (kg)}}{(\text{Crown-rump length (cm)})^2}$$

(Jen *et al.* 1985)

Social rank may be associated with obesity (Kemnitz 1984) since the dominant animal determines feeding time and the subordinates eat afterwards, depending on spatial distribution of food and the mix of food types. Chronic dietary restriction also protects against the development of diabetes in aging rhesus monkeys since, although it is not the sole causal agent, obesity is necessary for diabetes to develop.

### Euthanasia

The principles of euthanasia are set out in Chapter 17 and in Close *et al.* (1996, 1997) and American Veterinary Medical Association (AVMA) (2001); all of which refer to the animal welfare concerns with respect to carrying out of euthanasia. Having to kill a primate may be a more emotionally challenging experience for staff than having to kill some other species. Staff who carry out this procedure must not only be competent in the appropriate methods, but it is essential that they receive good training, adequate supervision and any necessary empathetic support.

Appropriate methods of euthanasia should be selected after discussion with veterinary staff and with due regard for the collection of scientific data. The most common methods for killing primates is an overdose of an anaesthetic, such as sodium pentobarbital (at 100 mg/kg) administered intravenously. For larger primates it will be necessary to sedate the individual before attempting an intravenous injection.

When primates are euthanased, every effort should be made to make full use of their tissues and blood, particularly if this will minimise the number of animals having to be used. This requires good mechanisms for communication to match supply and demand both within and between establishments. Establishing tissue banks and data exchange networks is one means of coordinating, optimising, reducing and refining primate use. In the USA Primate Info Net<sup>2</sup> achieves this objective and in Europe, EUPRIM-NET offers a tissue/gene bank<sup>3</sup>.

### Record keeping

A file or 'passport' giving full details on each individual primate should be maintained (JWGR 2009). It should keep

the details of their biography, enabling a full picture of previous experiences to be established. For example, it should include details of transport history, social grouping from birth through weaning to set up of experimental or breeding group, training records, husbandry system and type of environmental enrichment. This is in addition to reproductive history and full details of medical conditions (physical health and psychological health assessment details and screening records) and, of course, full details of any use in a research project.

The file should be sent with the animal if it is moved between institutions, together with general information on the establishment of origin, such as details of animal care and routine procedures, in order to assist in continuity of care and to ensure successful acclimatisation to the new facility.

### Future developments

It is very important to maintain current knowledge of technical developments that could benefit animal welfare. While a good deal is known about the needs of non-human primates in captivity, there are several aspects where more scientifically validated information would be welcome to supplement the experience on which the present recommendations are largely based.

Little is known of the effects of transportation on primates (Wolfensohn 1997). While it may seem ideal for primates to be bred in Europe, breeding in source countries may have some advantages for the animals in terms of climate. These advantages, however, need to be balanced against any stress the animals may be subjected to as a result of the additional transportation. The increases in cage sizes and use of enclosures and social housing that are now recommended produce more efficient use of space and cost savings over single housing of individuals, thus promoting the keeping of animals in groups. However, this leads to a necessity for more research to develop improved techniques for handling and training primates to facilitate their research use in this type of housing. This will encourage the development of humane techniques to facilitate the movement of primates from one cage to another or to a particular area of the home cage.

The use of sound through music or television as environmental enrichment is anecdotally reported to be beneficial, but this may be of more direct benefit to staff. While good well-being of staff may improve the well-being of the animals under their care, the provision of such aural enrichment requires evaluation, as does the use of water as enrichment in water features and provision of bathing. The provision of drinking water from bottles or automatic drinkers or from the water enrichment is another variable that requires assessment.

The validation of different methods of monitoring and quantifying stress and development of new parameters that are simple to measure would greatly benefit the debate on primate welfare and the impact of housing, husbandry and use in scientific procedures. Further work of this nature needs to be conducted on a routine basis as part of the continuing assessment of the welfare of primates held in captivity. It could also enable the identification of specific

<sup>2</sup><http://pin.primat.wisc.edu/>

<sup>3</sup><http://www.euprim-net.eu/>

behaviours, in which changes might provide an early indication of compromised animal welfare. Such tools would allow planning for the alleviation of any stress caused to the animal. For efficient, rigorous and objective studies of this nature it is important that a professional primatologist is involved in the planning. Perhaps with the increasing requirement that primate facilities include a primatologist on their staff, the objective study of the welfare of captive primates will become more commonplace and incorporated into research funding.

# 40 Chimpanzees

Steven J. Schapiro and Susan P. Lambeth

## Introduction

Entire volumes have been devoted to the care and management of captive chimpanzees (eg, Brent 2001a), so this chapter will not attempt to provide all the information necessary for the those involved in the care of chimpanzees. Instead, the aim of this chapter is to draw attention to those aspects of chimpanzee biology, care and management that have significantly changed since the last edition of the UFAW Handbook (Poole 1999).

## Biological overview

The previous edition of this Handbook contained an excellent treatment of chimpanzee biology (Fritz *et al.* 1999) as does the book by Brent (2001a) on management of captive chimpanzees. There has not been much change in knowledge of the basic biology of chimpanzees since the last edition of the UFAW Handbook. They are Great Apes and are among the most intelligent primates. Their similarities to humans make them, both an extremely attractive model for biomedical research (VandeBerg *et al.* 2005; Varki 2007) and, an extremely problematic model for many types of investigations (Knight 2007; Rowan 2007). Many readers will neither be able to fathom the need for using chimpanzees in research nor, the moral justification for doing so. On the other hand, many readers will understand that the value of the research can be more than adequate justification for the use of a species so similar to our own.

## Taxonomy

The taxonomy of the common chimpanzee (*Pan troglodytes*) is still being debated. Three subspecies are normally proposed (*P. t. troglodytes*, *P. t. verus* and *P. t. schweinfurthii*), and considerable academic discussion is currently devoted to the clarification of this issue (Gonder *et al.* 2006; Becquet *et al.* 2007). There does not appear to be much drive for maintaining distinct subspecies in the captive chimpanzee population in contrast to the situation for orangutans and certain other primate species (Groves 2005).

## Genetics

Chimpanzee genetics is an area in which substantial and important progress has been made since the last edition of this handbook. Specifically, both the human genome (Venter *et al.* 2001) and the chimpanzee genome (The Chimpanzee Sequencing and Analysis Consortium 2005) have been sequenced since 2001. As should be obvious, substantial similarities exist between the two genomes, providing opportunities to further exploit the genetic, physiological, behavioural and social similarities as well as the differences between the two species to learn more about both species (Varki & Nelson 2007). The high degree of genetic similarity between chimpanzees and humans highlights both the importance of chimpanzees as animal models in human-focused research as well as the problems associated with conducting research with such close relatives (VandeBerg *et al.* 2005; Rowan 2007; Varki 2007).

## Social organisation

Chimpanzees are usually described as living in fission–fusion societies consisting of up to 100 members per community (Wrangham *et al.* 1994). Fission–fusion societies are frequently characterized by fairly fluid social relationships within the community; with subgroup composition varying considerably on a day-to-day basis. Unlike many other species of non-human primates that live in multimale–multifemale groups, male–male bonds (rather than female–female bonds) are the most important social factor in chimpanzee groups (Goodall 1986). Although chimpanzee social relationships are fluid within the group, relationships between communities of chimpanzees can be extremely aggressive (Mitani & Watts 2005). Multiple reports have described fatal encounters between individuals of different chimpanzee communities (Watts *et al.* 2006; Boesch *et al.* 2007, 2008). Females exhibiting maximal oestrous swellings appear to be the age–sex class of individuals that is least likely to receive high levels of aggression in intergroup encounters (Deschner & Boesch 2007).

The fission–fusion societies of wild chimpanzees include regular and frequent social separations and

re-introductions. It is therefore somewhat surprising that it is so difficult to re-introduce captive chimpanzees back into their social groups, even after only a short absence, such as for an annual physical examination. Development and use of appropriate standard operating procedures (SOP) for group formations and re-introductions are critical for the successful management of captive chimpanzees (Bloomsmith & Baker 2001; Fritz & Howell 2001; Lambeth personal observation). Since natural chimpanzee sociality in the wild includes repeated separations and re-introductions that are under the animals' control, it has been suggested that re-introduction difficulties may arise from the fact that separations and re-introductions in captivity are under the control of human care staff, rather than the chimpanzees themselves. Certainly, gradual, systematic and sometimes individualised re-introductions are necessary to minimise damaging aggression (Fritz & Howell 2001).

## Reproduction

Chimpanzees are a slow-producing, slow-maturing species (traits characteristic of a K-selected species). Under natural conditions, the average length of gestation is difficult to accurately determine, but the mean is estimated at 228 days (Tutin 1994) and females do not give birth to their first infant until around 11 years of age (Fritz *et al.* 1999). Females nurse their offspring for several years, with interbirth intervals ranging from 36–84 months (Fritz *et al.* 1999). Infants and juveniles remain in the company of their mothers and maternal kin for years, often forming reasonably stable subgroups within the fission–fusion community. In addition, young chimpanzees typically learn many foraging skills from their mothers, especially those that involve the use of tools, such as termite fishing and nut cracking (Biro *et al.* 2006). Captivity can influence virtually all aspects of this pattern of reproduction and development, with captive females giving birth for the first time earlier and having shorter interbirth intervals on average (Roof *et al.* 2005).

The female reproductive cycle lasts approximately 34 days and is characterised by conspicuous swelling of the perineal area leading up to a maximum on the day of ovulation (Wrangham 1994). The patterns of social interactions of an adult female with other females and with adult males differ according to the state of her oestrous swelling (Wallis 1992). Males will attempt to mate with females throughout their oestrous cycles, but male interest increases as swelling size increases. Maximally swollen females are able to move between social groups in the wild, whereas most other age–sex classes are not (Deschner & Boesch 2007). This fact can be used to advantage in captivity when attempting to introduce a new animal (swollen female) to other animals.

## Physiological parameters

Since the publication of the 7th edition of the UFAW Handbook (Poole 1999), several papers have been published that contain normal values for a variety of physiological parameters for captive chimpanzees. Many of these primary publications present normal ranges differentiated by the age

and sex of the chimpanzee. The reader can find the original sources for complete sets of normal ranges in Herndon and Tigges (2001); Ihrig *et al.* (2001); Lee and Guhad (2001); Howell *et al.* (2003); Lamperez and Rowell (2005); Videan *et al.* (2008). Representative values for adult males, adult females, aged males and aged females, the most common age–sex classes of animals currently in research colonies, are included in Table 40.1 (adapted from Herndon and Tigges 2001; Ihrig *et al.* 2001; Lee and Guhad 2001; Howell *et al.* 2003; Lamperez and Rowell 2005; Videan *et al.* 2008). It is important to note that the values in the table represent normal ranges; it is not necessarily correct to assume that animals displaying values outside of the normal range are clinically ill and/or in need of treatment.

Most physiological data obtained from adult chimpanzee blood samples come from anaesthetised animals. It is well known that ketamine and telazol, two of the most frequently used anaesthetics for captive chimpanzees, influence many of these physiological parameters in non-human primates (Woodward & Weld 1997). Efforts are currently underway to establish unanaesthetised normal ranges from samples obtained from adult chimpanzees that will voluntarily present their arms for conscious venepuncture (Schapiro *et al.* 2006b). Whether these unanaesthetised normal ranges will differ significantly from anaesthetised normal ranges has yet to be determined. Additionally, data are accumulating to establish normal ranges for several immunological parameters (eg, lymphocyte subsets, cytokine production, natural killer cell activity) for both anaesthetised and unanaesthetised chimpanzees (Schapiro *et al.* 2006a).

## Conservation and ecology

### Threats

Clearly, there are many factors that are threatening the survival of chimpanzees in their natural settings. Destruction of habitat, logging, disease and hunting for bushmeat are probably the biggest threats (Kormos *et al.* 2003; Fa *et al.* 2005; Arnhem *et al.* 2008; Hanamura *et al.* 2008; Kondgen *et al.* 2008). These factors are all interrelated and can in general be attributed to increased human encroachment into chimpanzee habitat. It is extremely unlikely that any of these threats will diminish in the near (or distant) future, leaving the chimpanzee at considerable risk of extinction in the not-so-distant future. It is unlikely that the captive population of laboratory chimpanzees, for whom a breeding moratorium is in effect, will play any role (positive or negative) in the conservation of the species. Zoo chimpanzees may play a small positive role, given the limited amount of breeding (zero population growth) that is permitted in the zoo population.

### Recent findings

Despite fairly gloomy news concerning the ultimate survival of chimpanzees in the wild, recent field studies of populations of chimpanzees (Pruetz 2007; Boesch *et al.* 2008; Stanford 2008) have yielded some extremely interesting findings. While most findings from field studies have implications for the captive management of chimpanzees, the

**Table 40.1** Physiological parameters for adult chimpanzees (values taken from Herndon & Tigges 2001; Ihrig *et al.* 2001; Lee & Guhad 2001; Howell *et al.* 2003; Lamperez & Rowell 2005; Videan *et al.* 2008).

Analyte	Units	Adult males	Adult females	Aged males	Aged females

findings from savannah chimpanzees in Senegal are among the most interesting and the most relevant. Pruett and her colleagues (Pruett 2007; Pruett & Bertolani 2007; Stewart *et al.* 2007; Roach 2008) have demonstrated that wild chimpanzees will play in water, live in caves, make comfortable nests and hunt for bushbabies in holes in trees using tools (modified and sharpened sticks). The implications for the management of captive chimpanzees should be clear; small pools, nesting material, and food stuffed into holes in structures that can be speared with sticks should be useful, naturalistic forms of environmental enrichment.

## Uses in the laboratory

### Biomedical research

When chimpanzees are used in infectious disease research, they are usually involved in studies of hepatitis viruses. In the past, chimpanzees had been infected with human immunodeficiency virus (HIV), but only a single chimpanzee may have developed AIDS, making them a less than ideal model for this type of research (Stump & VandeWoude 2007). They are a far superior model for hepatitis research; in fact vaccines for hepatitis B were successfully developed in chimpanzees and potential vaccines for hepatitis C are currently being tested and evaluated using chimpanzees (Elmowalid *et al.* 2007). An analysis of primate use in biomedical research (Carlsson *et al.* 2004) revealed that members of the genus *Pan*

were used in 4.9% of studies involving primates published in 2001, and infectious disease was among the most common topics of investigation involving chimpanzees.

Chimpanzees are also used in assessments of the efficacy of a variety of novel therapeutic approaches, including analyses of monoclonal antibodies as treatments for cancer (VandeBerg *et al.* 2005). Although mice are useful models for many aspects of biomedical research, they are not valid models for all aspects. For some investigations, it may be that chimpanzees are the most valid model. Use of words like test article suggests that a regulatory process is involved, and in fact, the United States Food and Drug Administration (FDA) often requires that compounds be tested in appropriate non-human primate models, using good laboratory practices (GLP), prior to approving the compound for the next stages of evaluation and/or use in humans. However decisions to use chimpanzees should always include a full consideration of ethical and welfare issues. Performing GLP studies with chimpanzees presents a series of significant management challenges for those responsible for the care and well-being of the animals. While it is difficult to bring a non-GLP-compliant chimpanzee programme up to GLP standards, once GLP-compliant protocols and record keeping practices become part of normal operating procedures, multiple benefits accrue for the research and care staff and for the chimpanzees used in research. Most of these benefits are related to: (1) the establishment of SOPs which promote consistent care and treatment of the animals and (2) enhanced record keeping systems that

promote the systematic collection of health, behavioural and research data.

## Behavioural research

### Applied research

The primary goal of most applied laboratory chimpanzee behavioural research projects is to improve the welfare, while simultaneously enhancing the definition of chimpanzees as animal models for biomedical research (Bloomsmith & Else 2005; Videan & Fritz 2007; Coleman *et al.* 2008). Such efforts should result in improvements in the quality and utility of the chimpanzee as a research model. A typical focus in applied research programmes is to 'refine' (one of the Three Rs as discussed by Russell and Burch (1959), see also Chapter 2) management and handling techniques so as to minimise psychological/behavioural confounds that might adversely affect subjects, research protocols and/or results. More specifically, attempts are being made to minimise the stress experienced by chimpanzees in an effort to limit inter-individual variation in the measures typically assessed by investigators working with chimpanzees as subjects (Lambeth *et al.* 2006; Bloomsmith *et al.* 2006b; Schapiro *et al.* 2007). Reducing inter-animal variability should make it possible to reduce the number of subjects required for experimental comparisons without diminishing the power of experimental designs. This addresses 'reduction', another of Russell's and Burch's Three Rs (Russell & Burch 1959); one that is of great relevance when dealing with an animal model as complex as the chimpanzee.

There are considerably fewer applied research projects focusing on factors that influence the quality and utility of chimpanzees as models in the zoo setting. However, findings from applied investigations that delineate beneficial management strategies for chimpanzees used in research can, should be and, in most cases, are, adapted to zoo settings. Similarly, findings from investigations conducted on chimpanzees in zoos that identify beneficial management strategies are adapted to laboratory settings whenever possible.

Various welfare-enhancing techniques have been developed, and are in use, to manage the behaviour and the psychological environments of captive chimpanzees (Bloomsmith & Else 2005; Videan & Fritz, 2007; Coleman *et al.* 2008). These techniques are designed to functionally simulate important components of the animals' natural environment/habitat, thereby providing them with opportunities to express species-typical behaviours and some degree of choice and control over what they experience. Conventional wisdom suggests that 'normally' behaving laboratory animals are likely to make better models than animals that behave abnormally. Since wild chimpanzees are able to control many aspects of their existence in their natural environments, providing laboratory chimpanzees with opportunities to choose should promote normal behaviour in the non-natural laboratory setting. Studies of behavioural management strategies are designed to empirically address the question of whether such procedures influence behavioural and physiological variables of interest to those working with and studying captive chimpanzees.

### Basic research

Captive chimpanzees are ideal subjects for both simple and complex investigations of learning, hemispheric specialisation, cultural transmission, behavioural economics, language development, cognition, facial expressions and prosociality (Silk *et al.* 2005; Hopkins *et al.* 2005, 2007; Brosnan *et al.* 2007; Hopper *et al.* 2007; Parr *et al.* 2007; Whiten *et al.* 2007), just to name a few. Many of these investigations can be combined with non-invasive imaging techniques to gather even more data to test critical hypotheses (Cohen 2007a). In addition, many of the procedures used to generate the data are quite stimulating, challenging and enriching for the participating chimpanzees.

### Laboratory management and breeding (or non-breeding)

Intelligent, powerful animals like chimpanzees present a number of management challenges for those charged with providing them with optimal care in captivity. Nothing is simple when managing chimpanzees and the volume edited by Brent (2001a) addresses many aspects of their management. Techniques for managing the successful breeding of captive chimpanzees are not of great concern at the time of writing, as the National Institutes of Health of the United States is maintaining the moratorium on the breeding of research chimpanzees (Cohen 2007b). This moratorium has been in effect for over a decade and was recommended by the advisory committee of the National Research Council (National Research Council 1997). Obviously, the indefinite continuation of this breeding moratorium will result in the eventual extinction of the population of captive research chimpanzees. This strategy is in harmony with legislation designed to outlaw invasive research on Great Apes that is currently under consideration in the United States (the only country that still allows and conducts 'invasive' research with Great Apes). As mentioned several times previously, some readers will find this an appropriate and commendable outcome, while others will find it extremely short-sighted and objectionable.

The main thrust of the rest of this section will be the breeding moratorium that is in effect for captive research chimpanzees in the US (National Research Council 1997; Cohen 2007b). Most female chimpanzees of breeding age in both the zoo and laboratory populations in the US are given some form of contraception to prevent the unplanned birth of additional chimpanzees (Bettinger & DeMatteo 2001). Different facilities are using oral birth control pills, intrauterine devices (IUD), hormonal implants, sexual segregation and/or surgical interventions to prevent additional chimpanzee births. Regardless of the technique, the overall goal is to prevent the addition of any new chimpanzees to the population of research chimpanzees (Cohen 2007b) and to maintain zero population growth among the zoo chimpanzees (Ross, personal communication). Given the slow reproductive rate, long interbirth intervals and the long lifespan of chimpanzees, it would be extremely difficult to rapidly produce a new set of subjects for an emerging health-related crisis that required the use of chimpanzees (VandeBerg *et al.* 2005).

For a number of reasons, reversible contraceptive techniques that allow reasonably normal oestrous cycles are preferred for chimpanzees. First, the possibility exists (VandeBerg *et al.* 2005) that the breeding moratorium will be at least partially lifted at some point in the near future. Reversible forms of contraception, such as sexual segregation, oral contraceptives, intrauterine devices and hormonal implants, are thus favoured. While there are few empirical data that guarantee that IUD and hormonal implants are completely reversible forms of contraception, the occasional failures of these contraceptives (in chimpanzees and humans) and the reversibility in humans suggest that reproduction could be effectively re-started in chimpanzees, even after a fairly long period of contraception.

Secondly, IUD and certain hormonal implants in particular, seem to minimally disrupt the oestrous cycling of mature female chimpanzees; many animals appear to swell and detumescence in patterns that are similar to female chimpanzees that are not on contraceptives (Bettinger *et al.* 1997). Given the importance that reproductive cycles play in the social dynamics of chimpanzee groups, where females are treated differently by other members of the group depending on the stage of their cycles (Wallis 1992; Wrangham *et al.* 1994; Deschner & Boesch 2007), it is important to maintain reproductive swelling cycles in order to maintain cyclical patterns of social activity as well. This aspect of the interplay between contraception, reproductive cycles and social behaviour is important in both the zoo and the laboratory, regardless of whether births are allowed to take place and animals are replaced or not.

Preliminary observations of animals with some of the newer hormonal implant contraceptives suggest that these contraceptives do disrupt normal oestrous cycles (Lambeth, personal observation). While this is clearly undesirable in terms of maintaining normal patterns of social interaction, there may be at least one circumstance in which the smaller and shorter swellings observed in females on the implantable contraceptive is an advantage. Aggression and wounding among males in social groups that are housed in proximity to, but not in contact with, adult females, increases when female(s) are maximally swollen. Aggression among males in groups housed in proximity to females with the new implants has decreased, as has the amount of time that the females are swollen (Lambeth, personal observation). Currently, this relationship is only correlational and needs further investigation.

Finally, evidence is accumulating that males that have been vasectomised are still occasionally impregnating females (Noon, personal communication). Preliminary investigations suggest that the vasectomies are being performed properly, but for reasons yet to be determined, the long-term effectiveness of the procedures has been less than desired.

## Husbandry

### Cleaning and hygiene

As with any species of laboratory animal, it is imperative that chimpanzees are maintained in sanitary conditions that enhance their welfare and do not compromise their health

and safety. Aside from the chapters contained in the Brent (2001a) book on captive care, little new chimpanzee husbandry information has been published since the last edition of the UFAW Handbook (Poole 1999). The book by Brent (2001a), the chapter by Fritz and colleagues (1999) in the seventh edition of the UFAW Handbook (1999), and the husbandry manual edited by Fulk and Garland (1992) are likely to remain the most useful guides to chimpanzee husbandry until the imminent publication of the new AZA (Association of Zoos and Aquariums) chimpanzee care manual (Ross, in press). The second edition of the International Primatological Society captive care guidelines are also available (International Primatological Society Captive Care Committee 2007), but they primarily provide general guidance for caring for non-human primates, rather than information specific to the care of chimpanzees. A much abbreviated discussion of selected aspects of chimpanzee husbandry follows.

A variety of different husbandry schemes are used with chimpanzees, including both 'wet' and 'dry' systems. In a dry system, some type of bedding (ie, shredded paper, hay, straw, wood chips) is typically used, and cleaning involves the removal of soiled bedding on a regular basis without using water (bedding would be shovelled, scooped, or vacuumed out). As the name implies, cages/enclosures maintained by a wet system are cleaned on a regular basis using water hoses (often high-pressure) and chemicals (ie, bleach, disinfectants, degreasers). In wet systems, drains are critical factors in the 'performance' of the facility and are often a limiting factor in determining what types of enrichment are regularly used. Drain placement, drain function and drain covers are critical variables in the effective management of captive chimpanzees using wet systems.

In both wet and dry systems, maintenance of the animals in multiroom 'suites' significantly enhances the ability to clean and sanitise cages/enclosures properly. When chimpanzees have access to more than one room, the animals can be securely excluded from Room 1 when it is being cleaned and then moved back into Room 1 so that Rooms 2, 3, etc can be cleaned. This removes the need to 'clean around' animals or 'jump' animals into transport boxes as may occur for other non-human primate species. However, this process works best when some effort is devoted to training the animals to shift on command, preferably using positive reinforcement training techniques (Laule & Whittaker 2001), see also Chapter 16. Since chimpanzees are so strong and are potentially dangerous, appropriate shifting and cleaning SOPs must be in place and rigorously adhered to, to minimise the risk of accidents in both zoo and laboratory settings.

Environmental enrichment devices often complicate the cleaning and sanitation processes of both types of husbandry schemes (including clogging drains in wet systems). The ideal environmental enrichment device from a husbandry perspective, is one that does not have to be put up and taken down frequently, does not clog drains, and can be easily sanitised while in place.

### Veterinary management and geriatric care

Veterinary management (Lee & Guhad 2001) has always been a critical component of the proper maintenance of

chimpanzees in captivity, but as the captive population ages, it will take on even greater significance. Middle-aged and older chimpanzees require considerably more care than do young to prime-aged chimpanzees, especially in the area of preventive medicine (Lammey *et al.* 2008). As animals age, biannual physical examinations are likely to replace the current practice of annual examinations. Echocardiograms should be added to health maintenance SOPs for older or 'at-risk' animals (Doane *et al.* 2006), although there may be some diagnostic limitations of echocardiograms conducted on anaesthetised chimpanzees (Bernacky personal communication).

Assessments of physiological parameters, usually through bodily fluid samples (blood, urine, saliva, semen) are routinely made to not only aid in the diagnosis of acute conditions, but also to provide a comparative database for assessments of chronic health conditions (Videan *et al.* 2008). Normal ranges (differentiated by age class and sex) for a variety of physiological parameters in captive chimpanzees have been published (Ihrig *et al.* 2001; Lamperez & Rowell 2005) (Table 40.1). Occasionally, clinical pathologists, veterinarians and behavioural scientists encounter animals whose physiological measures are outside the published normal ranges. This can lead to lively discussions concerning the health and/or welfare of the animals (young or old) when the numbers on paper do not agree with the clinical signs and behavioural observations. Frequently, chimpanzees with 'poor' readouts on paper appear to be in much better overall health than the readouts would suggest.

In addition to enhancements to monitoring and other types of preventive medicine procedures as the population of captive chimpanzees ages, other modifications to their veterinary care and management may become necessary. If advancing age is accompanied by non-lethal sensory, motor, cognitive, or health-related impairments, then animals may have to be removed from their 'normal' groups or enclosures and placed in other groups or enclosures that minimise the potential for injury and other negative consequences due to their impairment(s). Even though an older female may be an important participant in the social interactions of

her group, if a bad hip or impaired vision limits her ability to escape from an aggressive member of her group, then she may need to be removed and placed in a safer situation. The question then arises as to when an animal is too impaired to safely or usefully remain within the colony. The next obvious question is what is to become of an animal that is to be removed. Retirement is one obvious option and a number of sanctuaries do exist to house chimpanzees no longer 'useful' for research or exhibition (Brent 2007). Euthanasia of chimpanzees to solve management problems is not permitted (National Research Council 1997), although euthanasia of an animal that is suffering is clearly acceptable. There is still an ongoing debate over the definition of the terms that are critical to this discussion, including impairment thresholds, usefulness and suffering.

### Housing

Chimpanzees should be housed in physical and social conditions that: (1) functionally simulate natural conditions; (2) stimulate naturalistic behaviour patterns; (3) are safe; (4) can be sanitised; and (5) are functional for humans (Brent 2001b). Housing conditions for captive chimpanzees range from small cages (3.25 m<sup>2</sup>, 35 ft<sup>2</sup>) for a single animal up to 5-acre (20324 m<sup>2</sup>) corrals (Brent 2007) for groups of as many as 34 animals, and can include almost anything in between (Figure 40.1). Given the social tendencies of chimpanzees in their natural environment and the behavioural data demonstrating the value of social partners to captive chimpanzees (Bloomsmith & Baker 2001), social housing must be the default option in captivity. Single housing should be an infrequent and short-term condition in all but the most well justified situations (ie, recovery from injury or experimental manipulation; some infectious disease research; social incompatibility). As mentioned above, older and/or mildly impaired animals may need to be transferred from their normal groups to modified groups or enclosures for safety reasons.

While captive housing regulations typically focus on delineating minimum floor areas (National Research Council

**Figure 40.1** Chimpanzee enclosure (corral) at The University of Texas M. D. Anderson Cancer Center, Bastrop, TX USA.

1996), three-dimensional volume is probably a more useful 'engineering' measure for the chimpanzee, a species that spends a considerable portion of its day (and all of its night) above the ground. Single cages may be 1.8 m (6 ft) tall, while outdoor enclosures may include towers that are as high as 15.2 m (50 ft) (Figure 40.2). As with most non-human primates maintained in captivity, performance standards are usually more useful than engineering standards.

No chimpanzee enclosure is escape-proof and escapes do occur (no fewer than six escapes from all types of facilities across the globe have been reported in the popular media in 2006, 2007, and the first half of 2008 according to a Google search of the term 'chimpanzee escape'), so SOPs that minimise the risk of escapes must be developed and stringently followed. In addition, safe capture SOPs in the event of an escape must be developed and practised, for the safety of both the animals and the people involved in the capture process. Although chimpanzees have occasionally escaped from their enclosures through unanticipated feats of athleticism, the majority of escapes occur through human error – the failure of care staff to properly lock or secure doors, gates or chutes (Schapiro & Lambeth personal observation).

### Behavioural management

Behavioural management is a critical component of the captive care of all laboratory animals, and is especially important for the care of non-human primates (National Research Council 1998), and even more so for the care of chimpanzees (Bloomsmith & Else 2005). Behavioural management is typically described as an approach that integrates behavioural strategies (environmental enrichment, socialisation and training) designed to functionally simulate natural conditions with more traditional husbandry and veterinary management programmes. The general goal of most chimpanzee behavioural management programmes is to maintain and enhance the welfare/psychological well-being

of captive chimpanzees by providing them with opportunities to express species-typical activity patterns (Bloomsmith & Else 2005; Schapiro *et al.* 2007). This is usually discussed in terms of providing the chimpanzees with opportunities to control or to choose what happens to them (Schapiro & Lambeth 2007) and may be formalised in a facility's 'environmental enhancement plan' (see Table 40.2 for a sample environmental enhancement plan). The provision of bedding material (hay, blankets, excelsior, shredded paper, etc) each evening to stimulate nest-building behaviour is a clear example of providing the animals with opportunities to choose to perform naturalistic behaviours (Stewart *et al.* 2007) in the captive setting.

Behavioural management programmes are in operation at most primate facilities (Baker *et al.* 2007), although the maturity of the programmes differs considerably across facilities. The ultimate goal of most behavioural management programmes is to include all animal care staff as participants in the specialised functions of the behavioural-management team. However, during the early stages of the development of a behavioural-management programme, it is often more effective to identify a specific subgroup of people that is responsible for the training, enrichment and handling procedures that comprise the specialised behavioural-management duties. As the programme matures, these duties and responsibilities can then be distributed among all animal care staff.

A considerable amount of empirical data has been published that addresses how enrichment, socialisation and training can influence the welfare of captive animals (see Chapters 10 and 16), with a reasonable number of these publications focusing on chimpanzees (eg, Bloomsmith & Baker 2001; Baker 2005; Bloomsmith & Else 2005; Schapiro & Lambeth 2007; Schapiro *et al.* 2007). Many of these reports focus on the behavioural effects of these types of manipulations, but assessments of physiological effects are available as well (Lambeth *et al.* 2006).

1. Young animals and some adult groups in the indoor/outdoor runs.
2. During warm weather only.
3. Animals with access to Primadomes®.
4. Forage mix can consist of popcorn, raisins, dry cereals, nuts and graham crackers.
5. Visual items include windmills, birdfeeders, balloons, painted murals, decorative shower curtain, etc.
6. Pipe feeders are filled with liquid and semi-liquid foods (apple sauce, syrup, jelly, or tomato sauce, etc)
7. All browse (leaves, stick, roots, vines, plants) must be approved by the veterinarian.
8. Human interactions or training with the chimps is conducted regularly through the wire mesh. All precautions are taken to ensure human safety.
9. Other toys include, but not limited to Kongs, Dental Devices, Havaballs, Gumabones, Dumbbells, etc.
10. Destructible items include magazines, boxes, etc.

### Environmental enrichment

Captive chimpanzees respond well to a variety of environmental enrichment strategies and procedures (Brent 2001b; Baker 2005). Social enrichment opportunities typically work the best; these options will be discussed in more detail in

the Socialisation section. This section will focus on inanimate enrichment strategies, including brief treatments of physical, sensory, foraging and occupational enhancement approaches (Figure 40.3).

Enclosures for captive chimpanzees should be physically complex enough to stimulate species-typical levels and

**Figure 40.3** Foraging enrichment for chimpanzees in a Primadome at The University of Texas M. D. Anderson Cancer Center, Bastrop, TX, USA.

**Figure 40.4** Indoor portion of enclosure with barred ceilings for brachiation at The University of Texas M. D. Anderson Cancer Center, Bastrop, TX, USA.

types of locomotor activity. While this can usually be achieved in situations where the enclosures include an outdoor component, it is somewhat more difficult when access to the outside is not possible. For animals maintained only indoors, it is especially important to provide opportunities for brachiation (typically using barred ceilings see Figure 40.4). Since young chimpanzees are considerably more physically active than older chimpanzees, physical enhancements that promote running, jumping, swinging etc may be more important for younger animals. However, since older captive chimpanzees may develop and exhibit health problems related to weight gain and a lack of physical activity, it may be important to provide an environment that also stimulates physical exercise in this age group (it would not be appropriate however, to house geriatric, mobility-impaired animals in environments that require high levels of exercise). As the number of young chimpanzees in research settings continues to decrease, enhancements that

promote physical activity in older, mobile chimpanzees may be the most practical and valuable to implement.

While open-topped enclosures may provide especially naturalistic and functional environments for larger groups of chimpanzees, they also provide an additional opportunity for chimpanzees to escape. Complex climbing structures are typically provided in all outdoor chimpanzee enclosures – it is especially important when designing the structures to make sure that it is ‘impossible’ for the chimpanzees to jump out. Factors that require significant scrutiny include the distance (horizontal and vertical) between the structure and the top of the external wall and the availability of smaller items that could be stacked and used as ladders, or as poles for vaulting. Additionally, sufficient space must be provided between the walls and any overhanging objects outside the enclosure.

Sensory enrichment is most important for captive chimpanzees maintained in settings where there are limited

opportunities for species-typical sensory stimulation. This would apply primarily to chimpanzees housed by themselves or in small groups in potentially static or sterile indoor environments. For animals living under these conditions, auditory (CDs), visual (videos or TV), olfactory and tactile (contact comfort items such as blankets) stimuli can serve as options for sensory enrichment (Bloomsmith & Lambeth 2000; Sak *et al.* 2005; Videan *et al.* 2007). The empirical data are not particularly convincing concerning the value of these types of enrichment for socially housed chimpanzees, and many of the studies on the topic have used sensory stimuli that are probably not 'species-typical' (music, cartoons, bubbles, etc). Overall though, sensory enrichment is reasonably inexpensive and easy to provide in many captive circumstances, so the inclusion of such stimuli, especially species-typical stimuli (sounds, videos or odours of conspecifics), in a comprehensive enrichment programme should be worthwhile. The value of sensory enrichment can be significantly enhanced by providing chimpanzees with the opportunity to control the sensory stimuli; to turn lights, TVs, radios, fans, etc on and off or to change the type of stimulus (eg, classical vs rock music; cartoons vs live action video) that they are experiencing (Bloomsmith *et al.* 2001; Schapiro & Lambeth 2007).

Since wild chimpanzees spend up to 60% of their waking day searching for, finding, processing and eating food items (Goodall 1986), it is imperative that the captive environment includes opportunities for the animals to work (forage) for their food. In the past, in many captive situations, highly nutritious, though frequently heavily processed food (chow, pellets or biscuits) was simply presented to the chimpanzees on a scheduled basis, at times that were convenient for those providing the food. Current feeding practices for captive chimpanzees are much better simulations (although still far from perfect) of natural chimpanzee feeding and foraging behaviour: (1) various types of food are distributed so that they must be searched for and located by the animals; (2) food items are presented in forms in which the animals have to work to get to the edible portions (whole fruits, food puzzles, foraging devices); and (3) multiple small meals are fed, rather than one or two large meals (Bloomsmith & Else 2005; Bloomsmith 2007). These types of foraging enrichment strategies can be implemented with both unprocessed foods (fruits, vegetables, seeds, etc) and processed foods (biscuits, chow or pellets) and can involve the construction and use of tools, an important component of natural chimpanzee foraging behaviour.

Chimpanzees have considerable cognitive abilities and occupational enrichment is typically designed and implemented to provide the animals with opportunities to use their cognitive skills (Bloomsmith & Else 2005). Computers with levers, joysticks or touch screens can be used for occupational enrichment, although any piece of apparatus (enrichment-related or research-related) used, must be made as 'chimp-proof' as possible (no device or apparatus is completely chimp-proof). Occupational enrichment will occasionally include the provision of food rewards, however occupational enrichment differs from foraging enrichment in that the occupational enrichment task is more important than the reward. It is not unreasonable to consider the tasks performed by chimpanzees maintained for cognitive experi-

ments, primarily apparatus-based operant conditioning procedures, as occupational enrichment. Additionally, many of the tasks that comprise studies of cultural transmission, social learning, problem solving, laterality and behavioural economics (Silk *et al.* 2005; Hopkins *et al.* 2005, 2007; Brosnan *et al.* 2007; Hopper *et al.* 2007; Whiten *et al.* 2007) are also likely to function as occupational enrichment. Many of these techniques could serve as ideal behavioural assays of the effects of aging on cognitive function in the captive chimpanzee population.

### Socialisation

Captive chimpanzees should be maintained in social groupings that promote naturalistic social behaviours, are stimulating, are safe and can be managed. The typical fission–fusion community of chimpanzees in the wild (Goodall 1986; Wrangham *et al.* 1994) is an extremely difficult type of social organisation to simulate in captivity. This is partially due to space limitations, but is also due, in part, to the potential for damaging aggressive episodes when chimpanzees are improperly introduced or re-introduced to one another (Fritz & Howell 2001). In the wild, the space available to animals and their 'flight' options are significantly greater than they are in the laboratory or zoo. Although in captivity (and on many research protocols) it is not possible to maintain chimpanzees in a fission–fusion community of 100 animals, it is possible functionally to simulate other aspects of their natural social organisation (Bloomsmith & Baker 2001). Specifically, captive managers of chimpanzees have had good success maintaining chimpanzees in multimale–multifemale groups of between eight and 20 animals, where male–male social behaviour can be expressed in a manner similar to that seen in the wild. One specific example of such interactions would be the post-aggression reconciliation, which is observed in both wild and captive groups of chimpanzees (Koski *et al.* 2007). Although multimale groups may result in infrequent outbreaks of aggression (as may unimale groups; Alford *et al.* 1995), the daily positive consequences of male–male affiliative and agonistic interactions are typically thought to outweigh the rare negative consequences of aggressive interactions.

The social development of juvenile and adolescent female chimpanzees is another potentially critical aspect of captive chimpanzee socialisation that merits discussion. The moratorium on breeding of research chimpanzees is likely to have long-term social consequences, beyond the reduction in size of the chimpanzee population. Currently, young female chimpanzees have few opportunities to allomother younger chimpanzees and these opportunities are progressively declining over time. While many of these females will have been raised by their own mothers, data from Bloomsmith and colleagues (2006) suggest that opportunities to 'aunt' infants should increase the probability that young females will be competent mothers when (and if) they give birth and a lack of such opportunities should decrease the probability. However, their data also suggest that about one third of females that are not raised by their mothers should still become competent mothers themselves (Bloomsmith *et al.* 2006). These findings could be important for understanding and assessing maternal competence, if the breeding moratorium is eventually lifted.

### Positive reinforcement training

Positive reinforcement training (PRT) can be profitably employed in a number of ways in the management of captive chimpanzees. Animals can be trained to voluntarily participate in husbandry, veterinary and research procedures (Laule & Whittaker 2001; Lambeth *et al.* 2006; Schapiro & Lambeth 2007; Coleman *et al.* 2008), dramatically increasing the amount of control and choice available to them. This volume contains an entire chapter on PRT (Chapter 16), so only a few chimpanzee-specific highlights will be addressed here.

Chimpanzees have been trained to voluntarily present for injections (Lambeth *et al.* 2006). There are many benefits to having this behaviour under stimulus control, not the least of which is being able to administer a dose of anaesthetic (or antibiotic) in a manner that is as minimally stressful as possible. Recent studies have shown that numerous haematological and chemistry parameters obtained when chimpanzees voluntarily presented for an anaesthetic injection prior to a blood sample differed significantly from parameters obtained from samples in which subjects were non-voluntarily anaesthetised (Lambeth *et al.* 2006). This was true for comparisons across different subjects, but more importantly, was also true for within-subjects comparisons, in which the same subjects were non-voluntarily anaesthetised on one occasion and voluntarily presented for an anaesthetic injection on another occasion.

Chimpanzees have also been trained to voluntarily present for an unanaesthetised venepuncture and blood sample (Coleman *et al.* 2008). Among the small number of chimpanzees that have been trained to reliably perform this complex and difficult behaviour, the pattern of physiological results obtained is similar to that reported for present for injection above; haematology and chemistry parameters differed significantly between blood samples obtained voluntarily without anaesthesia and blood samples obtained from the same animals 2–3 days later when anaesthetised (Schapiro *et al.* 2006b).

PRT has been used to decrease food stealing and animal chasing during feeding times in relatively large ( $n = 8$ – $16$ ) social groups of chimpanzees (Bloomsmith *et al.* 1994). Briefly, chimpanzees that usually chased other animals and stole their food were trained using PRT techniques to perform a behaviour that was incompatible with chasing and stealing; namely, sitting in one place. Many management benefits were gained once the animals had been trained to feed in this 'co-operative' fashion, including a more equal distribution of food items (especially highly desirable food items) across all members of the group and the necessity of using fewer food items in order to make certain that each animal received the minimum portion.

### Feeding

Wild chimpanzees spend much of their time searching for, working for, processing and eating food items, including constructing tools to obtain food. Captive chimpanzees should be fed in a manner that promotes foraging and tool use. Since wild chimpanzees tend to eat a wide variety of food items during foraging bouts throughout the day rather

than large, human-like 'meals' of only one or two food items, captive chimpanzees should be encouraged to forage/feed on many foods in a number of bouts across the day to achieve a balanced diet (the National Research Council (2003) has published nutrient requirements for captive non-human primates, however this volume contains surprisingly little information of direct value to managers of captive chimpanzees). This is obviously a more work-intensive and potentially more costly approach for animal care staff than is feeding a few large, discrete meals of a limited number of foods. But the benefits to the animals of a more naturalistic feeding regimen are quantifiable (Bloomsmith 2007) and address the achievement of the general goal of functionally simulating natural conditions. Many of the strategies used to feed captive chimpanzees are predicated on issues of convenience, cost effectiveness and manageability for the care staff. Clearly, certain accommodations for such issues have to be made, but integrative strategies that take into account both human-related and chimpanzee-related factors are in use and are constantly being updated. As one example, by using small meals as positive reinforcement for the performance of timely shifting behaviour, the initial commitment of additional effort to the feeding of a larger number of smaller meals can ultimately reduce the amount of time required to get animals to voluntarily move from place to place.

### Safety

The importance of maintaining a safe environment for chimpanzees and those working with them in captivity cannot be overemphasised. Chimpanzees can be dangerous to those who work with them (care staff, researchers, veterinarians) and to one another. Housing, handling and research protocols must take into account the animals' strength, health, social relationships and cognitive capabilities. Additionally, the potential for humans to make mistakes must be factored into all aspects of chimpanzee care and management. Effective and efficient SOPs must be developed and implemented to promote a safe environment for the animals and those responsible for them. While it is essential to have SOPs for working with chimpanzees, it is also critical that SOPs are followed with little or no deviation. If aspects of SOPs are unmanageable or inappropriate, then the SOPs need to be modified. Even seemingly harmless enrichment tools and devices need to be 'safety-assessed' as chimpanzees will often use them for unintended (but no doubt enriching) purposes, such as using foraging tubes as projectiles and foraging sticks as weapons.

### Retirement and sanctuaries

As the population of laboratory (and zoo) chimpanzees continues to age, it will be necessary to retire some of the animals (Figure 40.5). Primary candidates for retirement include those animals that are deemed no longer 'useful' for research (or exhibition in the zoo). 'Useful' can be defined in a number of different ways, some of which are quite contentious, especially if animals have to be removed from social groups at their research facility and placed in one of

**Figure 40.5** Former laboratory chimpanzees in the 5-acre natural enclosure at Chimp Haven, Keithsville, LA, USA. Reproduced with permission of Chimp Haven.

the small number of credible chimpanzee sanctuaries. Many of these sanctuaries do not permit even non-invasive manipulations of their retired residents, a reasonable policy in certain circumstances, but one that may also prevent the non-invasive collection of extremely valuable research data, especially data related to the aging process.

### Common welfare problems

Most of the chapters in this Handbook include a section on common welfare problems, including disease issues and behavioural factors, and how to deal with them. Virtually everything contained in the present chapter has been written to address common welfare issues that must be considered and managed when housing chimpanzees in captivity; essentially all aspects of the management of captive chimpanzees have been designed and are updated to provide continual enhancements to the welfare of the animals.

### Priorities and future directions

While captive chimpanzees have been reasonably well studied in the past and new publications are accruing at a steady rate, there are still areas of investigation where additional important data should be collected. Management-orientated research questions that should receive considerable attention in the near future include: long-term consequences of developmental, management and reproductive schemes; captive techniques that optimally simulate natural conditions; and physiological consequences of providing control and choice, just to name a few. Additionally, a number of non-invasive imaging techniques should be more widely adapted and routinely used to collect dependent measures in investigations focusing on chimpanzee behaviour, cognition and physiology. Where possible, animals should be trained to participate voluntarily in these procedures without anaesthesia.

The amount of space 'required' by captive chimpanzees is another question that needs to be empirically investigated. Space per animal is one variable that is regularly 'addressed' by rules, regulations and/or regulatory bodies (International Primatological Society Captive Care Committee 2007), and may turn out to be a critical aspect in the performance of GLP studies with chimpanzees. GLP studies have additional experimental and documentation requirements compared to non-GLP studies, and often result in subjects living in more restricted housing conditions. It would be quite useful to have some objective criteria by which to determine how much space a chimpanzee (or other non-human primate) 'needs' as a study subject or simply as a member of a resource colony. While it is quite clear that the quality of the space and who else is occupying it are more important than the quantity of space for most captive non-human primates (in laboratories or zoos), empirically determined space guidelines would benefit both animals and humans. These are difficult and expensive investigations to perform however, requiring evaluation of a wide array of housing options, not just cages/enclosures that are slightly smaller or slightly larger than those recommended in the current and relevant guidelines (Crockett *et al.* 2000).

### Concluding remarks

Chimpanzees are extremely valuable animals that present a number of very significant moral, ethical and practical challenges for those involved with their management and use in captivity. Their many similarities to humans make them of great interest to all people and important models for a variety of investigations. However, these similarities also create dilemmas related to their appropriate care and use. Those responsible for the welfare of captive chimpanzees must continuously strive to provide them with safe environments that stimulate the performance of a wide range of species-typical behaviours. Those responsible for studying captive chimpanzees must continuously strive to develop innovative research procedures that refine the ways that these animals are handled in captivity.

### Acknowledgements

## The domestic fowl

Ian J.H. Duncan

### Biological overview

#### Origins

The domestic fowl is derived from the junglefowl, probably mainly from the Burmese red junglefowl (*Gallus gallus spadiceus*, Bonnaterre), but possibly with contributions from the other three junglefowl species (Siegel *et al.* 1992). The junglefowl is a ground-dwelling, gallinaceous bird with territorial males looking after small harems of two to ten females with their offspring. Junglefowl are considered graminivorous, feeding on leafy material, seeds and grains, but, as with many gallinaceous species, the young chicks require a higher-quality diet than this and feed on insects and other invertebrates for the first few weeks of life. Junglefowl are extremely timid and secretive and therefore difficult to study in the wild. They can fly reasonably and roost in trees at night and occasionally through the day. Otherwise they spend most of their time on the ground and tend to run from frightening stimuli.

Domestic fowl have probably been domesticated for about 5000 years but early archaeological records are scant. Two features of their early history are of note. The first is that it seems likely the original relationship between human beings and the progenitors of chickens was a predator-prey one. The usual reaction of prey species to predators is a fearful one and the evidence suggests that domestication has not removed this completely (Duncan 1990). The second is that during much of their domestication, chickens were selected for fighting ability, not for their egg- or meat-producing capabilities (Wood-Gush 1959), and this probably accounts for the aggressiveness of some modern strains.

#### Lifespan

Domestic fowl have a life span of 5–8 years. Commercially, egg-laying hens are kept for only 1 or 2 laying years, because egg production declines rather rapidly after this. Breeding birds of egg-laying strains are also kept for 1 or 2 years. Breeding stock for broilers are kept for less than a full laying year because fertility declines so quickly that it is not worthwhile keeping them longer. Broilers themselves, of course, are killed at ages ranging from 32–70 days depending on what final product is required.

The unnaturally short lives of commercial chickens should not necessarily set the pattern for laboratories. Chickens can live healthy lives for at least 4–6 years, and this should be made use of if possible.

#### Social organisation

The basic social unit of jungle fowl consists of about 4–12 females accompanied by a dominant male and their sub-adult offspring. Dominant males establish and defend territories (Collias *et al.* 1966). From the scant information that is available, it appears that domestic fowl that have gone feral, have a very similar organisation (McBride *et al.* 1969). When in a group, domestic fowl form a social hierarchy. Males and females do not generally interact agonistically, although males tend to dominate females passively. Male and female hierarchies are separate. Once formed, the social hierarchy is fairly stable with little social friction. On the other hand, mixing strangers together leads to a lot of fighting.

Under commercial or laboratory conditions, domestic fowl are fairly adaptable. In order to control disease transmission, they are normally kept in single-age groups and this is not a problem for them. Newly hatched chicks are precocial and develop normally without contact with their dam. They are also able to adapt easily to being kept in single- or mixed-sex groups. As males approach sexual maturity, they may become very aggressive to each other. This is generally not a problem if they are in mixed-sex groups and the sex ratio is kept at 10 or more females per male. However, in all-male groups, the aggression may lead to injury, and it may be necessary to house males individually. In general, domestic fowl will adapt to the range of group sizes normally found in a laboratory, (ie, from three to four to several hundred).

#### Breeds, strains and genetics

Chickens kept for commercial purposes can generally be divided into three main types, two of which are kept for eggs and one for meat production. In Europe and North America, white-egg-laying strains are derived from the White Leghorn breed, whereas brown-egg-laying strains are derived from a variety of breeds but usually include some Light Sussex and Rhode Island Red or Rhode Island White

blood. Elsewhere in the world, there may be incorporation of local genetic material such as the Australorp breed in Australia. Meat-producing strains (usually referred to as 'broilers') are derived from many different breeds including Cornish and White Rock. Primary breeding companies keep selected inbred lines which produce grandparent, parent, and eventually three- or four-way cross hybrid chicks which are sold on the commercial market. This method exploits hybrid vigour and gives an extremely productive and uniform final product, the hybrid chicken. This structure in the poultry industry also separates breeding from commercial production which provides good biological security. It also, of course, provides great genetic security to the primary breeding companies, since the result of breeding commercial stock would be genetic segregation and recombination and a whole mixture of genotypes of little value.

### Reproduction

Reproductive function in domestic fowl is at least partly controlled by day length. Commercially, egg-laying strains and breeders are kept under short day conditions (often 8h light and 16h dark or 10h light and 14h dark) until they are about 16 weeks of age in the case of laying strains and 20–22 weeks of age in the case of broiler breeders. They are then photo-stimulated by increasing day length by about 1h per week to 20–22 weeks (in the case of laying strains) to 14L:10D or 15L:9D. Thereafter, day length usually remains constant. There are various modifications that can be made (see, for example, Lewis & Morris 2006), but this basic lighting programme works well. For ease of management, males and females of the same age are usually used, although it would be possible to successfully photo-stimulate males earlier.

When hens of laying strains are photo-stimulated in week 16, the first egg is usually laid in week 18, the birds reach 5% production in week 20 and peak production, which should be well over 90% (90 eggs per 100 birds per day), is reached in weeks 26–28. There is then a gradual decline in egg production until at week 72 or 74 the birds should be laying at about 70%. Commercially, day length is often gradually increased through the laying year but there is no good evidence that this actually stimulates more production. A long day of only 14 or 15h (in contrast to a very long day of 16 or 18h) may have more welfare advantages for the hens, in that it provides them with plenty of rest and they do not have an exceptionally long day to fill with activities. With broiler breeders, egg production is delayed by 2–3 weeks and is lower.

It should be remembered that birds differ from mammals in that the male is the homogametic sex carrying two similar sex chromosomes designated ZZ, with females being heterogametic and designated ZW. The fowl has some useful sex-linked traits such as silver (S) and gold (s) down colour, and slow (K) and fast (k) feathering. These traits enable chicks to be sexed easily at hatching.

### Behaviour

The behaviour of the domestic fowl has been well studied and reported (eg, Wood-Gush 1971; Duncan 1980; Appleby

*et al.* 2004). Chickens spend a considerable part of the day foraging for food. This is true even if food is provided in a very concentrated and highly nutritious form so that they can consume their requirements in a short time; they still spend many hours pecking, probing and flicking with their beaks and scratching with their feet. A good husbandry system should allow this foraging behaviour to occur unimpeded. Chickens can adapt their drinking behaviour to different sources of water such as troughs, cups or nipples. However, if they have learned to obtain water from one source, they may not recognise it if it is offered from another source.

Other maintenance behaviour includes preening and other activities associated with feather care. Domestic fowl do not bathe in water, but show dust-bathing behaviour which functions to rid the feathers of excess lipids. Sleeping and resting are normally done in a perching position but domestic fowl seem able to adapt to flat-footed resting and sleeping.

As mentioned previously, chickens are highly social animals. They also tend to synchronise their activities and do things together as a flock. It is therefore important that the facilities provided allow them to do this. The only activity in which chickens will take turns, is drinking at a limited water source. All these social activities, both agonistic and associative, are organised by a rich repertoire of visual and vocal signals.

Domestic chicks are precocial when they hatch. Although the mother hen would normally be responsible for showing chicks sources of food and water, they are quite able to learn to feed and drink on their own when food and water are obvious. The one function they cannot manage well is thermoregulation; young chicks, therefore, have to be kept in a warm environment for the first few weeks of life.

Mating behaviour is preceded by elaborate courtship with the male being the initiator and main actor. Once inseminated, the hen remains fertile for about 14 days although fertility drops quickly after 7 days. Nesting behaviour is complex and involves both nest site selection and nest building and may occupy 60–90 minutes every time an egg is laid. The evidence suggests that the performance of this behaviour is very important to the hen (Follensbee *et al.* 1992).

One other behaviour pattern requires special mention, and that is feather pecking and cannibalism which can be a problem in some strains of laying fowl. Outbreaks of feather pecking and cannibalism can occur at any time in a chicken's life but the common times are from 6–12 weeks and at point-of-lay. This behaviour has nothing to do with aggression and is probably some form of foraging behaviour directed at other birds' feathers rather than a potential food source (Blokhuis & Arkes 1984; Blokhuis 1986). It is likely that many factors contribute to an outbreak of feather pecking, including large group size, wire floor housing and bright lighting (Kjaer & Vestergaard 1999). Feather pecking behaviour varies substantially between strains of domestic fowl and it has been shown to be a heritable trait (Kjaer & Sørensen 1997) which can be selected against (Muir & Craig 1998).

The most effective way to reduce the effects of feather pecking is to debeak (beak trim) the birds. However, there is strong evidence that this causes both acute and chronic

pain and therefore reduces the welfare of the birds (Duncan *et al.* 1989; Gentle *et al.* 1990). Therefore, where possible, strains with low tendencies to feather peck should be chosen; if the chosen strain has a bad reputation for feather pecking, then the chicks should be precision debeaked at the hatchery – a procedure which is less traumatic than later debeaking (Gentle *et al.* 1997).

### Standard biological data

Body weights for various strains of domestic fowl are shown in Table 41.1. Growth rate depends on the strain of chicken being used. The primary breeding companies produce 'Management Guides' with growth curves for each of their hybrids. As an example, females of a light hybrid strain should weigh around 450, 900 and 1350 g at 6, 12 and 18 weeks of age. If reproductive fitness is important for the research being undertaken, then it is essential that chickens reach the correct weight for age as they are growing. There is usually no problem with light hybrids which can be fed *ad libitum*. Medium hybrids have a slight tendency to gain weight too rapidly, so growth rate must be checked regularly during the rearing period. Moderate food rationing can easily correct any tendency for the birds to gain too much weight. Broiler breeders, on the other hand, have enormous appetites and have to be very severely food restricted in order to be reproductively fit later in life. This is a big animal welfare problem in the poultry industry. There is no easy solution; the short-term welfare of broiler breeding fowl must be reduced by keeping them on severe food restriction so that they suffer from extreme hunger every day, or they suffer later in life from diseases of excessive weight gain, including abnormalities of limb bone development (leg weakness) and obesity. For this reason, laboratories should avoid using broiler breeding fowl if at all possible. Of course this may not be possible if the birds are being used as a model in obesity or pathological bone growth studies.

Chickens have a core temperature of about 41.5°C (Whittow 1986). Like many avian species, they have good

control over blood flow to the lower, unfeathered part of the leg and the feet and can use this to conserve or dissipate heat. The resting heart rate of adult fowl is about 230 beats/min and this increases to about 280–320 beats/min in active but undisturbed birds. When frightened, the heart rate can rise to 460 beats/min (range 380–460) (Duncan 1981).

### Uses in the Laboratory

The domestic fowl (*Gallus gallus domesticus*) continues to be a popular laboratory animal. It is small and comparatively cheap and easy to maintain. It also has several biological features that make it the species of choice for several avenues of research. For example, there is still great interest in immune function in chickens. B lymphocytes were first described in chickens, the 'B' referring to the bursa of Fabricius. The chicken is also often preferred for classical studies in developmental biology. It lost ground to the mouse some years ago when mouse genetics surged ahead, but the convenience of having the embryo on hand outside the mother has meant that many laboratories have continued to work with chick embryos. The chicken is also favoured for certain oncological studies probably because the avian leucosis viruses are amongst the better characterised tumour-forming viruses. The chick embryo is also used fairly widely in general virus research and toxicology studies. Of course, in addition to being used as models for other species and for some general biological principles, chickens are also used in agricultural laboratories specialising in chickens.

### Sources of supply

Laboratories using domestic fowl can buy day-old chicks from commercial hatcheries each time more birds are required. A commercial type can be selected to suit the requirements of the particular lines of research. Moreover, the sex of bird required can be specified. This strategy will result in a dependable source of uniform birds. Over the short term, it will also result in birds with a very similar genetic make-up. However, the primary breeding companies are constantly striving for improvement, and, every few years, introduce new hybrids and discontinue old ones. If genetic similarity is important for the research over an extended period, then a different strategy should be adopted. Many countries have specialised non-commercial lines of poultry available. These may be research lines maintained by other laboratories, or pure breeds maintained by local fanciers. Information on these sources can usually be obtained from government agricultural departments/ministries, university animal science departments, or poultry research institutes/centres. Pure breeds may be of interest because they carry particular genes such as the gene for polydactyly carried by the Silkie breed. Another solution is to maintain breeding stock, but this tends to be expensive. The minimum number of breeding birds required to avoid inbreeding problems is about 20 males and 20 females in each generation. This assumes that all 40 birds will contribute to the next generation, which implies the use of artificial

**Table 41.1** Average body weights of various types of domestic fowl.

Type of bird	Average weight (kg)
Light <sup>a</sup> hybrid adult females	1.3–1.8
Light <sup>a</sup> hybrid adult males	2.0–2.6
Medium <sup>a</sup> hybrid adult females	1.5–2.2
Medium <sup>a</sup> hybrid adult males	3.0–3.6
Female broilers at 42 days	1.9
Male broilers at 42 days	2.2
Broiler breeder adult females <sup>b</sup>	3.0
Broiler breeder adult males <sup>b</sup>	4.0

<sup>a</sup>'Light' and 'medium' refer to light and medium body weight birds, the two common types of fowl kept for table egg production.

<sup>b</sup>These weights refer to birds which are food-restricted according to the management guidelines.

insemination. It should be remembered that if the research to be carried out involves chick embryos, then the source of the eggs is very important. For example, certain research projects might require background information on the disease status and vaccination programme of the parent flock; such information may or may not be available for fertile eggs purchased from a commercial hatchery.

## Laboratory management and breeding

### Housing

Any well designed laboratory animal house can be used for chickens. There is advantage in having rooms of sufficient size such that commercial poultry equipment can be used. This would include a ceiling height of 2.5 m. Large rooms also allow for flexibility in the configuration of penning or caging. The surfaces of rooms should be of some impervious material that can be thoroughly cleaned and disinfected. There are various plastic laminates available which, although expensive, serve this purpose extremely well and these should cover the walls and ceiling. The floors of rooms should slope to drains and be of sealed concrete. If possible, all electrical fittings should be sealed so that each room can be pressure-washed. The lights in each room should be fitted with a timer and dimmer so that the length and level of illumination can be controlled automatically. Incandescent or fluorescent lights can be used but fluorescent lights, although more efficient, are difficult to dim at the present time (although this is likely to change in the near future).

A system for the removal of manure should be incorporated. As a rough guide, 100 light hybrid laying hens produce about 12 kg manure per day. Also, local authority rules and regulations governing the disposal of waste water should be carefully observed. It may be necessary to provide a large settling tank within the building to remove the bulk of the solids. Ideally, advice from an architect and sewage engineer, who are familiar with local by-laws, should be sought during the design phase of the building. These people should also be consulted if an existing building is being converted to hold chickens.

### Environmental provisions

General advice on environmental requirements can be found in the report on birds by the Joint Working Group on Refinement (JWGR 2001). The ventilation system should have sufficient capacity to cope with the local climatic conditions and the maximum numbers of birds held in each room. The main purpose of a ventilating system is to remove excess heat and water vapour from the building. It is unlikely that bird density in a laboratory setting will ever be so high as to constitute an over-heating problem, but it should be noted that a light hybrid, medium hybrid and broiler breeding hen produce about 42, 48 and 59 kJ of heat per hour. With regard to water production, 100 light hybrid laying hens at normal room temperature produce 11.4 kg respiratory water per day and 8.8 kg faecal water per day, giving a total of

20.2 kg water per day. The ventilation system has to remove much of this water and the efficiency of the system will depend on the relative humidity of the air at the time. The usual formula for calculating fan capacity is to allow 0.17 m<sup>3</sup> air per bird per minute. If the laboratory is located in an area where summer temperatures of over 30 °C are common, then an air-conditioning system should be installed.

It is essential that the whole building is fitted with an alarm system which will give warning if there is a power failure to any room. The building should have an emergency generator which switches in automatically in the event of a power failure and, in addition, an alarm system which will notify a responsible person that there is an emergency. Systems are available whereby the alarm will ring a series of telephone numbers until one is answered.

### Pens or cages?

Probably the first important decision to be made is whether birds can be kept on the floor or if they must be housed in some form of cage. The nature of the research will probably determine which route must be followed. In general, it is possible to provide the birds with a better, more appropriate environment if they are kept on the floor. However, the fact that a cage environment separates the bird from its faeces, means that cages are more hygienic although more restrictive. There may also be many good scientific reasons for deciding on cages, such as projects requiring faecal collection or if the nature of the research precludes medication with a coccidiostat. It should also be remembered that conventional battery cages will be banned for commercial use in the European Union (EU) from January 2012. Moreover, the EU has recently adopted recommendations for animals used in research that provide advice on housing and husbandry, including enrichment (European Commission 2007). These recommendations (portions of which may become compulsory within the EU) also provide minimum enclosure dimensions and space allowances that are substantially greater than previous recommendations (eg, a minimum enclosure size of 2 m<sup>2</sup> for birds above 600 g). It may also be possible to brood the chicks and rear the young stock on the floor, while keeping the adult stock in cages. It may even be possible to keep all stock on the floor and move birds into cages for the duration of an experiment. Of course, there are not the same financial constraints on the keeping of birds in a laboratory. So, for example, it may be perfectly feasible to keep laboratory hens in a small floor pen on litter and maintain hygiene by cleaning the pen out each week which would be totally unacceptable financially in commercial practice.

### Equipment

The equipment selected will depend very much on the nature of the research being carried out. For many research projects, commercial equipment may be used. In other cases, for example in nutritional studies into trace elements, specialised equipment made of stainless steel or special plastics, may be needed.

## Brooding phase

Chicks may be brooded on the floor or in tier brooders. They are not able to regulate their body temperature very well for the first few weeks of life and require warmth. It is usually best to raise the temperature of the room in which chicks are being brooded to say, 24–26°C, and to provide some supplemental heat.

If chicks are brooded on the floor, the extra heat is most easily provided by a suspended electrical heater. More powerful commercial brooders operated by natural gas and other fuels are available if large numbers of chicks are being brooded. For a laboratory, electrical brooders are probably more convenient. It is recommended that dull emitter heaters are used rather than heating lamps since this means that the lighting and heating programmes can be controlled independently. The heater should be suspended above the floor of the pen with some means of adjusting the height, since this is how temperature is controlled. The heater should be switched on 24h before the chicks are due. A thermometer can be used to check the temperature before the chicks arrive. It should be about 32°C 15cm outside the brooder canopy or reflector and 5cm above the floor. However, the main guide to brooder temperature should be the chicks themselves. When they are placed, they should arrange themselves in a ring below where the brooder is radiating heat. If they huddle directly below the brooder, then they are cold and the brooder should be lowered. If they are spread out as far from the brooder as possible, then they are hot and the brooder should be raised. Dull emitter heaters are capable of brooding a few hundred chicks. Supplemental heat is gradually reduced through the brooding period by raising the height of the brooder.

For the first few days, chicks are usually not allowed access to the whole pen, but are confined to a smaller area, about 1.5m in diameter, under the brooder using a brooder guard. This is simply a temporary construction made out of a roll of corrugated cardboard, perhaps 30–40cm high with the ends clipped together to make a circle. It is scrapped after a few days.

Some form of litter with good insulating and absorbing properties should be placed on the floor to a depth of about 3–5cm. Wood shavings are common but many other materials can be used. If wood shavings are used, they should be from untreated wood.

Water can be provided in various ways. Chick founts, with a large glass or plastic jar inverted in a plastic or metal dish, are common (Figure 41.1). Automatic drinking nipples, cups and bells also work well. A bell drinker is a plastic bell-shaped container suspended from the ceiling and supplied with water via a flexible water line from above. Water flows over the outside of the bell and is held in an upturned rim. When a set amount of water is in the rim, the weight of the water operates a stop valve in the supply line. As the birds drink the water, the weight decreases and the valve opens allowing water to flow again (Figure 41.2). There is some advantage to using nipples since they often have a drop of water hanging from the nipple and this attracts chicks which have a natural tendency to peck at bright shiny objects. Allow 1.5cm/chick of water trough access, 1.3cm/chick if pans or bells are used, four automatic cups/100 chicks, or eight automatic nipples/100 chicks. There should be a daily inspection of all drinkers to ensure there is an unimpeded supply of water.

There is also a variety of feeders available in metal and plastic. Allow 5cm/chick of trough access or 4cm/chick if round pans are used. In addition, some extra food should be provided on 'scratch trays' for the first few days. Cardboard trays used for egg storage are ideal for this purpose.

Tier brooders are cages for groups of chicks. Each cage is commonly divided into an enclosed section which is heated electrically with the heat being controlled by a thermostat, and a more open section which allows for inspection. Food and water are supplied from troughs running round the outside of the cage (Figure 41.3). Tier brooders save space and are often on wheels so they can easily be moved between rooms. The thermostat should be adjusted to provide a temperature of about 32°C in the enclosed section of the brooder.

**Figure 41.1** A chick fount suitable for supplying chicks with water for the first few weeks of life.

**Figure 41.2** A drinking bell suitable for supplying water to all growing and adult birds on the floor.

**Figure 41.3** A tier brooder.

As with all neonates, rest and sleep are extremely important for chicks (Malleau *et al.* 2007). Therefore, chicks should be given at least 8 h of darkness every 24 h. When the lights are on, the level of illumination should be fairly high (40 lux) for the first 3–5 days. After this, birds should go on to a lifetime lighting programme. For laying hens and all breeding birds, this will generally mean that, from about 5 days until they are photo-stimulated, they will be kept on a short day, perhaps 8L:16D. Commercially, chickens are kept under very dim light. However, since they are very visual animals, it is suggested that, in a laboratory setting, the level of illumination should be as bright as possible, at least 20 lux.

### Rearing phase

After about 4 weeks, young birds generally do not require supplemental heat. The phase that follows brooding until they reach sexual maturity at 19–24 weeks is considered the rearing phase. The optimum room temperature is about 20°C, but growing birds can easily cope with a range of

18–26°C. Birds can be reared on the floor or in cages. Once again, the nature of the research will determine which husbandry method is selected. If they are destined to become breeding stock, breeding naturally, then they should be reared on the floor.

Birds should be given plenty of space. If they are being reared in cages, each bird will require a minimum of about 600 cm<sup>2</sup> as they approach sexual maturity, so this capacity should be available. They can be kept at a higher density when they are young, and then be split into smaller groups at a lower density as they grow. If they are reared on the floor on litter, the space required as they approach maturity is about 5 birds/m<sup>2</sup>. Once again they can be kept more densely than this when young and the groups sub-divided as they grow.

There are many different kinds of commercial feeders available for floor rearing. Allow 9 cm/bird of trough access or 4 cm/bird if large-diameter (120 cm) tube feeders are used. Of course, if any type of food restriction is going to be practised, then these allowances must be greatly increased to 15 cm/bird for troughs and 8 cm/bird for tube feeders, to ensure that all the birds can very easily feed at once. For cage-reared birds, towards the end of the rearing period, allow 9–10 cm/bird of trough space.

Water can be provided by means of troughs, bells, automatic cups or nipples, with cups and nipples being more hygienic. Allow 2.5 cm/bird of water trough access, 2.0 cm/bird of bell access, nine automatic cups/100 birds, or 12 automatic nipples/100 birds. Birds should be monitored closely if the type of drinker is changed between phases. For example, chicks that have been brooded with nipple drinkers may not recognise water when it is presented in a trough or bell drinker. There should be a daily inspection of all drinkers to ensure there is an unimpeded supply of water. Drinking troughs require frequent cleaning. Bells and cups also require cleaning but less frequently than troughs.

Since domestic fowl learn to perch at an early age, and since, if given the opportunity, they rest in a perching posture and are strongly motivated to do so (Olsson & Keeling 2002), it is recommended that perches be provided. These should be round, or round with a flattened top, of

about 25mm in diameter for younger birds, and made of reasonably hard wood. As the birds approach adulthood, the perches should be exchanged for ones with a diameter of about 36mm (Tauson & Abrahamsson 1994). It is recommended that perches be provided at different heights, one at 5–10cm above the floor, and at least one other at about 30cm above the floor. Allow about 30cm perch length per bird at each level so that the birds can perch communally.

### Adult phase

Birds should be moved to their adult quarters at about 16 weeks of age so that they can settle down before the first egg is produced. The optimum temperature for adult chickens is 20–21 °C but the range 16–26 °C is satisfactory. Below 16 °C birds will eat considerably more food to keep warm, and above 27 °C hens may not eat enough to maintain a high level of egg production. At 28–29 °C they begin to encounter heat stress problems.

It is the housing of adult chickens that raises the most animal welfare concerns. The traditional battery cage, although being a hygienic and profitable husbandry system commercially, is much less than ideal from a welfare point of view. It should also be remembered that conventional cages will be banned in the EU from January 2012. Standards of care in a laboratory should be higher than those in commercial conditions. Laboratories should, therefore, make every attempt to find an alternative, more welfare-friendly husbandry system for keeping adult chickens.

If some type of conventional cage is essential for the research, then it must be of the best possible design. Tauson (1980, 1985) describes how design features of conventional cages may be modified to improve welfare. For some years Sweden has insisted on this improved cage design, therefore a cage manufacturer supplying the Swedish commercial market should be sought. If some form of conventional cage in a special material such as stainless steel or plastic is necessary, then the cages may have to be built to order. Once again, the modifications suggested by Tauson (1980, 1985) should be incorporated into the design, including an absence of V-shaped spaces where birds can be trapped, a floor slope of no more than 8°, and an appropriate distance that the bird has to stretch to the bottom of the food trough. Cage height should be at least 40cm throughout the cage. If possible, birds should be kept in small groups of three or four with 800cm<sup>2</sup> floor space per bird or at least 600cm<sup>2</sup> if the birds are small. If birds must be kept in single-bird cages these should allow about 1200cm<sup>2</sup> floor space per bird. If birds are kept in pairs, each cage should have at least 1800cm<sup>2</sup> floor space. The minimum feeding space should be 12cm per bird. In multi-bird cages, birds retain better plumage condition if there are solid rather than wire mesh divisions between cages.

Conventional cages, even those with all the improvements described above, are not suitable for males. It will not generally be possible to keep more than one male to a cage because of the risk of fighting and injury. Cages for males should be 60cm in height and a space allowance of about 2500cm<sup>2</sup> is recommended. Since there are no eggs to roll away, the floor should be level.

The simplest and most hygienic method of supplying water to cages is by means of nipples or cups. One nipple or cup per cage of three to four birds is sufficient. However, since chickens do not compete over water, a better configuration is to locate nipples or cups at cage junctions so that two or four cages can share the facility. This means that birds in each cage will have access to more than one water outlet. There should be a daily inspection of all drinkers to ensure there is an unimpeded supply of water. Drinking cups also require periodic cleaning.

If the type of research being conducted by the laboratory allows alternatives to cages, then there are many systems to choose from. The past 20 years has seen a burgeoning of alternative commercial systems (eg, Appleby *et al.* 2004) and a laboratory could easily adopt one of these, either in its commercial form or as a modified scaled-down version. There are two main types of system, one based on floor-housing and the other on modified cages. A good housing system should include the following essential features:

1. The birds should be in reasonably small groups. There is no hard evidence on what the upper threshold might be, above which welfare is reduced, but it is likely that a group size of 15–20 is ideal and that problems may arise with groups over 40. Maintaining birds in appropriately sized groups should not be a problem for most laboratories. Within the group, each bird should have 800cm<sup>2</sup> of space. Since, in many of these systems, more use is made of vertical space, and birds may 'share' floor space by being at different levels, it is sometimes difficult to make this calculation. As a general rule, laboratories should be generous with space allowances.
2. The birds should be able to feed at the same time; this means that at least 10cm feed trough space per bird is required, slightly less than this if food is provided from a round pan.
3. Birds should have access to water at all times. Any of the previously described drinkers is suitable. Allow about one cup for 12 hens or one nipple for eight hens.
4. Hens should have access to a suitable nesting place. Single- or pair-housed birds should each have access to a nest box, with a ratio of at least one nest box per two birds provided in larger groups (European Commission 2007). The nest should be secluded but not necessarily dark. It should allow the hen to express the various nest-building motor patterns. Loose nesting material is not essential but a round cup-shaped nest is preferred (Duncan & Kite 1989). It is possible to collect eggs automatically from a nest of this type. If individual nest boxes are used, then allow one nest box for five hens.
5. Perches should be available for roosting at night and for resting through the day. The best perch designed so far (a perfect perch has not yet been designed) is of reasonably hard wood, circular in profile, 36mm in diameter and flattened on the top and bottom giving a vertical cross-section of 31mm (Tauson & Abrahamsson 1994). If perches are provided at different levels, there should be sufficient length of perch to allow all the birds in a group to perch at the same level. This will require about 15cm of perch per bird. It should be pointed out that,

although on balance, the provision of perches increases welfare, they do have some costs. Perches increase the incidence of bumble foot (an inflammatory infection of the foot pad) and keel bone deformations, compared with birds kept without perches. On the other hand, perches decrease the incidence of toe pad hyperkeratosis when they are added to conventional battery cages (Tauson & Abrahamsson 1994).

The best alternative systems, whether based on floor-housing or cage-housing, incorporate all these features. The following features are not equally available in the two types of system:

1. It is much easier to provide opportunities for foraging in floor-based housing systems. Since foraging normally occupies a great deal of time, it is probably very important to the chicken. It is not impossible to allow hens in cage-based environments to forage, but it takes some ingenuity and stamina on the part of the animal care staff. For example, some type of fresh green material, such as a cabbage or piece of cabbage or net filled with clover could be hung in the cage. The hygiene associated with a mesh floor would thus be maintained. However, the labour involved in such a scheme would be considerable and if fresh greens are not provided after the chickens have become used to the routine, there would then be a grave risk of the chickens starting to featherpeck. Therefore, if foraging behaviour is considered essential, a floor-based system should be selected.
2. Dustbathing behaviour can be encouraged in cage-based systems by the provision of sand boxes. However, there have been problems associated with these, notably hens laying in the sand boxes, probably because the design was not ideal. On the other hand, dusty locations quickly develop in the litter of floor-based systems and these are used for dustbathing.

Fowl are highly motivated to perform 'comfort behaviour' such as wing flapping, feather ruffling and leg stretching, which help to maintain strong leg bones. Birds should therefore be housed in enclosures large enough to permit all of these behaviours whenever possible (European Commission 2007). There are so many housing systems available that it is impossible to describe each. One that is showing considerable promise is a type of modified cage called the 'Edinburgh modified cage' (Appleby & Hughes 1995) or the 'modified and enriched cage' (Abrahamsson *et al.* 1996). This is essentially a cage for four to six hens with a perch, nest box and sand box for dustbathing. These cages can be tiered to save space, and feeding, drinking and egg collection can be automated. They also provide a fairly high standard of hygiene.

## Hygiene

It is essential that newly hatched chicks go into a clean environment. In a laboratory the best way to achieve this is to copy commercial husbandry and operate an 'all-in, all-out' system. Of course, in a laboratory, all-in, all-out will apply to individual rooms and not to the whole establishment. When each room becomes empty of birds, the room and all the equipment in it, should be thoroughly cleaned and dis-

infected. If individual rooms can be hermetically sealed, then they should also be fumigated at this time. There may be some advantage in rotating disinfectants and in allowing rooms to stand empty for some days after disinfection. All the equipment in the room should be cleaned and disinfected at the same time as the room is being treated.

It is also good practice to have disinfectant foot baths outside each room so that diseases are not spread inadvertently by the animal care staff. Of course, if the laboratory is dealing with diseases, then much more stringent precautions will have to be taken such as specialist protective clothing and apparatus, and showering in to and out of each room or unit.

## Identification and sexing

Small, numbered, metal or plastic wing-tags can be used to give day-old chicks a unique, lifetime identification. A special tool is used to clip the tags through the wing-web on the front edge of the wing taking care not to pierce any muscle tissue. These wing-tags seem to have minimal adverse effects.

Commercial breeding companies often arrange their day-old chicks to be auto-sexed. Use is made of certain genes carried on the sex chromosomes, such as silver down colour, barring, or fast feathering. In the case of silver down colour for example, cocks (the homogametic sex) which are homozygous recessive for the trait (and gold) are mated with females which are hemizygous dominant (and silver). This results in male progeny in which the males are all heterozygous (and silver) and the females are all hemizygous (and gold). If breeding companies cannot arrange for auto-sexing then they use vent-sexing in which highly trained personnel are able to sex the chicks using differences in genital papillae.

It is thus simple for a laboratory to buy day-old chicks of the required sex but not so easy to arrange auto-sexing or vent-sexing within the laboratory. If birds of a certain sex are required, the solution may be to rear all the chicks until feather differences become obvious. These differences can usually be identified at a few weeks of age.

## Natural breeding

Domestic fowl will breed easily if kept in floor pens. If the experimental procedures dictate that the breeding birds should be kept in cages, then it is advisable to use artificial insemination, since cage breeding is never very successful. Birds are usually photo-stimulated to bring them into breeding condition at around 17–21 weeks of age (a few weeks later for meat-type birds). Rapid growth and reddening of the comb is characteristic of birds coming into breeding condition. In hens, the vent becomes moist and red a few days before the first egg is due and the pubic bones separate from about 1 finger-width to about three finger-widths.

A sex ratio of about one male to ten females usually works well. Eggs laid 2 days after the sexes are mixed should be fertile. If the laboratory is practising some form of pedigreed mating system, then it should be remembered that hens

remain fertile for 7–10 days after one successful copulation. Fertility then drops quite quickly and few fertile eggs should be produced 15 days after the sexes are separated.

Fertile eggs should be collected often in order to get them into ideal storage conditions as quickly as possible. They should be stored, blunt end up, in egg trays, in an egg storage room designed for the purpose, with a temperature of about 16–18°C and a relative humidity of 75%. Fertile eggs may be stored for 1 week but hatchability will decrease after longer storage times.

It is best to warm hatching eggs at room temperature (20–22°C) for 4–6 h before setting them in the incubator. The incubation period for domestic fowl is 21 days. Optimal incubation conditions are a temperature of 37.5–37.7°C and a relative humidity of 60% for the first 19 days and a temperature 36.1–37.2°C and a relative humidity of 75% for the final 2 days. This is normally achieved by moving the trays from the setter to the hatcher on day 19 of incubation; if the chicks are to be pedigreed, the hatcher must have individual boxes for each egg/chick. The eggs must be turned regularly (commercially they are turned every hour) during the first 19 days. If incubation is going to be carried out regularly in a laboratory, then papers which cover the topic such as Hulet (2007), Fassenko (2007) and Decuypere and Bruggeman (2007) should be consulted.

### Artificial insemination

Artificial insemination may be necessary because, for example, of a scientific requirement for individually housed hens, or when natural mating results in low fertility, or if specific pedigreed matings are required. The technique is straightforward. For best results, males should be housed individually, otherwise homosexual mating may deplete semen yields. Males can be photo-stimulated to produce semen at a fairly young age but it is normal to do this at about 18 weeks for laying-type males and 20 weeks for meat-type males. They will then start to produce semen at about 20 weeks and 22 weeks respectively, and collection of semen should start at that time. The procedure for semen collection is well described by Etches (1996) but requires a highly skilled technician for best results. The male is held with his feet at right angles to his body, and his belly and back stroked towards the tail with quick firm strokes. This stimulates erection of the phallic folds. When stimulated, the hand massaging the back is then transferred to the cloacal area with the thumb and index finger located on the lateral aspects of the cloaca and slightly anterior to the vent. Gentle pressure can then be used to expel semen from the ductus deferens. The flow of semen can then be collected by aspiration into a collecting ampoule. Care should be taken to collect semen only and avoid urates and faeces. Males should be handled gently and consistently. They become accustomed to being milked by the same operator and changes of personnel should be avoided if possible. A collecting schedule of three times per week (Mondays, Wednesdays and Fridays) will yield good volumes (0.15–0.35 ml) of semen. Etches (1996) recommends collecting the semen into semen diluent at 15°C, evaluating the semen for sperm density and quality, then arranging the rate of dilu-

tion such that each hen gets a standard insemination volume of 0.05 ml containing 100 million sperm cells.

Females can be inseminated as soon as they are in lay and it is better to inseminate later in the day when there is not a hard-shelled egg in the shell gland. The hen is held in the palm of the left hand facing left with the thighs held by the thumb and index finger. Gentle pressure is then exerted in a posterior direction with the left hand as the tail is pressed in an anterior direction with the right hand. This everts the hen's cloaca. A second person then inserts the inseminating pipette into the oviduct to a depth of about 3 cm. The first person releases the pressure on the body cavity allowing the cloaca to return to its natural position and the second person inseminates and withdraws the pipette. Inseminating hens every 5 days will usually maintain a high fertility rate.

### Inspection of birds

All birds in a laboratory should be inspected at least twice a day, first thing in the morning and again later in the day. The inspection should be carried out by personnel who are familiar with the healthy appearance and normal behaviour of various classes of domestic fowl. It is good laboratory practice to have check sheets in every bird room on which any departure from normal appearance or behaviour can be recorded. Of course, if birds are subjected to any experimental treatment that might jeopardise their welfare, then inspections should be more frequent than this. During routine inspections of the birds, equipment such as feeders and drinkers should be checked. This is also a good opportunity to monitor and record environmental variables such as temperature and ventilation.

### Feeding

Commercial poultry rations are formulated to very high standards and laboratories can have confidence in buying these. Complete balanced rations are usually fed, either as a dry mash, pellets or crumbles, which are partially ground-up pellets. The steam and pressure used in pelleting increase the digestibility of a ration so that weight-for-weight, pellets and crumbles are slightly more nutritious than the same ration in mash form. It is advantageous to feed chicks crumbles; the particle size of crumbles is very attractive to chicks and ensures that they ingest plenty of food in the first few days. In the rearing and adult stages, it is usual to choose a mash ration if over-consumption is a problem or if it is necessary to occupy the birds with feeding through a large part of the day and essential if feather pecking is likely to be a problem. (Birds take longer to eat the same quantity of mash compared with pellets or crumbles.) If high consumption and quick growth are necessary, or if under-consumption is a problem, then pellets or crumbles should be fed.

The energy in poultry diets normally comes from a cereal, often maize, wheat or barley or a mixture of these, sometimes boosted with tallow. The protein comes from a source of vegetable protein such as soybean meal supplemented with animal protein or individual synthetic amino acids. To this is added a pre-mix containing minerals, vitamins and

possibly some additives such as an anti-oxidant, a coccidiostat, xanthophylls to give yolk colour, etc.

Different ages and types of bird have different nutritional requirements which means that, in a laboratory housing chickens with a range of ages and types, several rations have to be fed. The specifications for the most commonly fed chicken rations are shown in Tables 41.2–41.8.

It should be noted that if hens are producing fertile eggs for hatching, then it is usual to increase the nutrient density of the diet slightly. In addition, special attention is paid to minerals, vitamins and essential amino acids in breeder diets. It is normal for the males in a breeder flock to receive the same ration as the hens. However they should receive less calcium (<1.0%). If artificial insemination is being practised and the males are separate from the females, this can be arranged. It can also occur in broiler breeder flocks in which the sexes are fed separately.

It is usual to include a coccidiostat in the rations of young birds being kept on the floor. Rations containing tallow should also have an anti-oxidant, such as ethoxyquin, to prevent the fat going rancid.

More information on poultry nutrition can be obtained from Leeson & Summers (1997).

If commercial poultry rations are not available, then there are other possibilities which, although not ideal, will provide the essential nutrients. However if standardised commercial

**Table 41.2** Chick starter diet specifications for egg-type strains (from day-old to week 5). The quality of the protein must be high and this can be verified by checking the levels of certain amino acids which should be present at least at the level shown.

<i>Diet specification</i>	<i>Value</i>
Metabolisable energy (ME) (MJ/kg)	12.13
Protein (%)	18–20

Phosphorus (%)	0.45
Plus a good vitamin and mineral supplement at the recommended level	

rations are not available, then consider whether it is worthwhile performing research that may not be replicable.

1. Any other commercial laboratory animal ration may be fed (eg, rat chow or dog chow). If the birds are hens in laying condition, this type of diet should be supplemented with a source of calcium such as oyster shell or ground limestone sprinkled over the food.
2. Birds are very good at balancing their own diet if provided with a variety of ingredients (Dove 1935). Therefore, they could be given a selection of locally available seeds and grains. The local ingredients should be checked against tables of nutrient composition (in any good nutrition textbook) to ensure that they are likely to provide sufficient energy and protein. Leeson and Summers (1997, pp. 61–62) provide tables of ingredient constraints showing the maximum amount of various ingredients that should be included in diets for different classes of domestic fowl. If soluble vitamins and minerals are available, they could be supplied in the water to supplement local rations. Again, if the birds are laying hens, then some form of supplemental calcium will be required. Also, if whole grains are being fed, then the birds should have access to some form of insoluble grit which is needed to grind the grains in the gizzard.

## Laboratory procedures

### Handling

As pointed out previously, many strains of domestic fowl have retained their ancestral fear of human beings. They should therefore be handled gently but firmly in order that fear responses are not exacerbated. There is little problem with very young chicks, since fear responses to human beings only develop over the first few days after hatching. There may be some advantage for laboratory managers to habituate birds to human beings and to handling early in life. There is evidence that early handling reduces fearful responses to human beings later (Hughes & Black 1976; Jones & Faure 1981) although some particularly flighty strains may not show much improvement (Murphy & Duncan 1978). Birds should be caught using both hands to pin the bird's wings against its sides. When held firmly like this, birds usually settle down very quickly, and they can be transported over short distances, say between a pen and an examination table within a room. For transporting between rooms, a carrying crate is recommended. Disposable cardboard carrying crates are ideal for this purpose. If birds are difficult to catch because they show excessive avoidance behaviour, dimming the lights usually helps.

### Restraint and blood sampling

Birds may be restrained on their backs, say for examination, with one hand gripping both legs firmly, leaving the other hand free for manipulation. Blood samples are usually drawn from the brachial vein close to where it passes over the ulna and radius just distal to the joint with the humerus.

The easiest method is for one person to restrain the bird on its side using one hand to hold both legs with the other hand over the breast pinning the lower wing to the bird's side. The person taking the sample can then use one hand to extend the other wing. The axillary feathers should be removed from the site and the skin swabbed with spirit. Whether the needle is inserted into the vein towards or away from the heart is a matter of personal preference. The following sizes of needles are recommended for blood sampling; 0.7 mm × 15 mm long needle (22G) for 0–2-week-old chicks, 0.7 mm × 19 mm (21G) for 2–6-week-old chicks, 0.8 mm × 38 mm (20G) for 6–18-week-old birds, and 0.9 mm × 38 mm for adults.

### Monitoring physiological variables

The fact that restraint is an extremely stressful procedure for domestic fowl means that obtaining undisturbed physiological data can be a challenge. Birds are also very intolerant of leads or catheters running from the skin surface. With a great deal of patience birds can sometimes be habituated to the presence of leads or catheters, but one would then need to question how normal their behaviour was. Birds have extremely flexible necks and can reach almost every part of their bodies with their beaks, which are usually very efficient at removing attachments. The upper neck and head, which cannot be reached by the beak, can be very effectively scratched by the bird's feet. A solution to this problem could be bio-telemetry, by which physiological variables are sent from a radio transmitter on (Duncan *et al.* 1975) or in the bird (Filshie *et al.* 1980; Duncan and Filshie 1980) to a receiver some distance away. A bird will habituate to a small device strapped to its back whereas it is very intolerant of attached leads. Once a bird with an implanted device has recovered from anaesthesia, it is free to move about unencumbered. Biotelemetry techniques have improved in the past 30 years and now multichannel devices are available which can transmit up to nine variables simultaneously and even have a two-way capability by which the implanted device can accept commands to perform various tasks within the animal (Axelsson *et al.* 2007).

### Injections and dosing

Intravenous injections are usually given in the brachial vein (see Restraint and blood sampling). Intramuscular injections are usually given in the muscles of the upper leg. Subcutaneous injections can be given in the web of the wing or, with the bird restrained on its back, into a patch of loose bare skin at the junction of the breast and leg which makes a very convenient site.

Birds can be dosed orally very easily. With the bird restrained in an upright position and the beak held open, pills can be gently pushed to the back of the mouth with a finger. When the head is released the pill will be swallowed. Liquids can be injected into the crop by way of the oesophagus (taking care to avoid the trachea) by means of a syringe and a flexible plastic tube and with the bird restrained as described above. For best practice, after insertion the correct

position of the tube should be confirmed by ensuring it can be felt within the oesophagus.

### Anaesthesia and analgesia

Birds are not the easiest class of animals to anaesthetise and those administering anaesthetics to chickens should be properly trained. Specialist texts that should be consulted include Sinn (1994), Schaeffer (1994) and Lawton (2008).

Chickens should be fasted sufficiently to empty the crop before proceeding with anaesthesia. This will vary from an hour or two with young chicks to overnight for adult birds. It should also be remembered that birds can quickly become hypothermic. Therefore, a warming pad should be used during anaesthesia and some provision should be made to provide heat during recovery, such as a heating lamp over the recovery cage.

With regard to pre-anaesthetics, atropine is generally not used in birds; diazepam (0.5–1.5 mg/kg im or iv) is the pre-anaesthetic of choice.

Isoflurane is the best anaesthetic agent for chickens. They can be induced in a chamber or by means of a mask with 3–5% isoflurane. They may then be intubated with a non-cuffed endotracheal tube and maintained on 1.0–1.5% isoflurane. Halothane and methoxyflurane may also be used as anaesthetics but are more likely to produce undesirable side effects.

For short-term procedures, an injectable mixture of ketamine and xylazine may be used to anaesthetise chickens. The required dosage is about 20 mg/kg ketamine and 2 mg/kg xylazine both given im. This anaesthesia may be partially reversed by yohimbine injected iv at a rate of 0.1 mg/kg.

There is very little information available on analgesics for chickens (see Howlett (2008) for brief review of local anaesthesia and analgesia in birds). It is thought that butorphanol at a dosage rate of 0.2–2.0 mg/kg im and buprenorphine at a rate of 0.01–0.05 mg/kg im have good analgesic effects. Lame broilers will self-medicate with the anti-inflammatory drug carprofen sufficiently to reduce their lameness, which suggests that this drug is an effective analgesic for joint pain (Danbury *et al.* 2000).

### Euthanasia

When chickens are to be killed, the method must be humane; that is, it must be painless and must minimise fear and anxiety (see Chapter 17). It must also be reliable, reproducible, irreversible, simple, safe and rapid (Canadian Council on Animal Care 1993; Close *et al.* 1996; 1997; Humane Slaughter Association, 2001). The recommended method for humanely killing chickens is by overdose of an injectable anaesthetic, such as a barbiturate, given intravenously. Laboratory managers should ensure that a suitably qualified person is readily available to carry out this procedure in emergencies as well as in planned procedures. In an emergency, if barbiturates are available but the carer is inexperienced in intravenous injection, then it can be administered by intraperitoneal injection at about 1.0–1.5 ml/kg of 20% pentobarbital sodium solution. This causes very little dis-

stress, and death occurs quietly after a slightly longer period. In every case after euthanasia by injection, the body should be kept until *rigor mortis* has occurred before disposal of the body.

In cases of emergency when someone with authority to use barbiturates is not available, it is preferable to kill a chicken by cervical dislocation rather than let it suffer for long, even though this may not be an approved method of killing in some countries. Cervical dislocation can be carried out manually, but requires a little training on cadavers. In young chicks, the neck may be dislocated by using the thumb to press the neck against the sharp edge of a table or bench. An older bird is held by the legs with the head downwards. The other hand is then placed with the head between the index and second fingers so that the other fingers are under the jaw. By applying pressure downwards with the knuckle of the index finger while simultaneously pulling the jaw upwards, the neck can be dislocated. In the case of large birds, the neck can be dislocated using mechanical dislocators or Burdizzo forceps. If cervical dislocation is used, the dislocation should be at as high a level as possible, preferably at the atlas (C1) and axis (C2) joint.

## Common welfare problems

### Disease

Chickens suffer from a variety of infectious diseases caused by viruses, bacteria, mycoplasma and larger parasitic organisms as well as several metabolic diseases. Birds in a laboratory should be monitored regularly for signs of sickness. Symptoms are usually fairly obvious and would include lethargy, poor appetite, loss of condition, hens going out of lay, production of malformed eggs, coughing, wheezing, blood in faeces, etc.

It is beyond the scope of this chapter to describe each disease in detail and for more information a standard text should be consulted such as Saif *et al.* (2003), Jordan (1990) or Sainsbury (1992). Neither is this text meant as a diagnostic tool; birds which die or are sick should always be sent to a pathology laboratory for proper diagnosis. What follows is simply a rough guide to the more important diseases. The mode of transmission is given; 'vertical transmission' means that the organism is passed from generation to generation via the egg; 'horizontal transmission' means that the organism is passed from bird to bird by a variety of routes.

### Bacterial diseases

There are several *Salmonella* diseases of poultry.

*Pullorum disease* (*Salmonella pullorum*)

**Symptoms** This is a disease of all poultry and some wild birds with acute white diarrhoea and deaths (up to 50%) in young chicks. If chicks have become infected through the hatching egg, then symptoms, including huddling, can start very early (2nd day). Survivors can be chronically infected with few symptoms. In older birds, there are few symptoms except green–brown diarrhoea.

**Transmission** Vertical through the hatching egg (this is the most important).

Horizontal:

- in the hatcher, debris and dust from infected eggs;
- through the droppings (into feed and water);
- cannibalism, birds eating infected blood and tissues;
- birds eating infected eggs;
- from infected equipment eg, debeakers;

**Diagnosis** Bacteria are isolated and can be cultured in the laboratory.

**Treatment** None is practised. The idea is to eradicate the disease and this is done by blood-testing breeders for antibodies.

**Prevention** Breeders should be blood-tested for the presence of pullorum antibodies and reactors eliminated.

*Fowl typhoid* (*S. gallinarum*)

**Symptoms** This is a slow-spreading disease of all poultry of all ages. Birds show loss of appetite, green diarrhoea, with pale combs and wattles in adults. Mortality can eventually reach 50%.

**Diagnosis** Bacteria are isolated and can be cultured in the laboratory.

**Transmission** Exactly the same as for pullorum disease.

**Treatment** None is practised and, as for pullorum, eradication is the answer.

**Prevention** Breeders should be blood-tested using an agglutination test.

*Paratyphoid* (eg, *S. typhimurium*, *S. montevideo*, *S. derby*)

These are important infections because of the risk of food poisoning to humans.

**Symptoms** There are often no symptoms in the birds, sometimes diarrhoea.

**Diagnosis** Bacteria are isolated and cultured in laboratory.

**Transmission** Spread is mainly horizontal through droppings, equipment and people.

**Treatment** This is not a major disease of poultry and treatment is not usually required. However, sulfadimethoxine, furazolidone and tetracycline are all quite effective.

**Prevention** Cleaning and disinfection between batches of birds, plus the use of footbaths for personnel, help to reduce the incidence.

*A disease as yet unnamed* (*S. enteritidis*)

This is very important, not because it causes big losses in poultry, but because the organism infects the ovary and hens lay infected eggs which can cause food poisoning in humans. This disease is now fairly well controlled in most countries through testing and elimination of reactors. There are also vaccines available.

**Symptoms** No clear symptoms.

**Transmission** Vertical through hatching egg.

Horizontal through egg-eating and possibly through droppings.

**Treatment** Recommended not to treat but to eradicate.

**Prevention** Breeders should be blood-tested using an agglutination test.

*Arizona disease* (*S. arizonae* also known as *Arizona hinshawi*)

**Symptoms** Important in turkeys and to a less extent chickens. In young birds there is diarrhoea, listlessness, sometimes nervousness. In older birds there can be paralysis of legs. Mortality can reach 25%.

**Transmission** Horizontal:

- in the hatcher (from outside of shell);
- through the droppings (into feed and water);
- from infected equipment.

**Treatment** Furazolidone is commonly used but eradication is the real answer.

**Prevention** The organism is very resistant to disinfectants and fumigants (which is why it can be present on the outside of hatching eggs after fumigation). Fumigate at double strength.

*Fowl cholera* (*Pasteurella multocida*)

**Symptoms** In the acute form there are rapid deaths (up to 50%), with 12–18 weeks of age being a very susceptible stage. In the chronic form there is swelling of wattles and internal organs can be affected.

**Transmission** Horizontal, entry by respiratory tract or digestive tract.

**Diagnosis** Bacteria are isolated and can be cultured in the laboratory.

**Treatment** Sulfa drugs in drinking water are fairly effective.

**Prevention** A live vaccine is available and can be given by wing web but aim for eradication (a blood test is available).

*Infectious coryza* (*Hemophilus paragallinarum*)

**Symptoms** This is a persistent but non-fatal disease of the upper respiratory tract with sneezing, discharge from nostrils and swelling of the face. Organism can only live 5–6h outside bird.

**Transmission** Horizontal through air and drinking water.

**Diagnosis** Symptoms plus laboratory tests.

**Treatment** Sulfa drugs are fairly effective.

**Prevention** Isolation from other poultry, and use all-in, all-out management.

*Vibronic hepatitis* (*Campylobacter fetus*)

**Symptoms** Birds have pale, withered, scaly combs, show a drop in egg production, and watery green diarrhoea. A swollen liver and thickened bile duct are evident at *post-mortem* examination.

**Transmission** Horizontal through the droppings and so in the feed and on equipment and from room to room on people's feet.

**Diagnosis** Sick birds should be sent to the pathology laboratory, where diagnosis is by isolation of organism from bile.

**Treatment** Furazolidone in feed gives quite good results. Injection of streptomycin is also effective.

**Prevention** Stressed birds seem more susceptible – so avoid stress. Normal sanitary precautions will stop spread.

*Coliform infections* (Escherichia coli)

#### Coli enteritis

**Symptoms** The organism multiplies and causes lesions in the upper digestive tract. There can be blood in droppings similar to coccidiosis plus listlessness.

#### Coli septicaemia

**Symptoms** This is often the next stage of coliform infection. The organisms enter the blood stream and infect internal organs.

#### Air-sac infection

**Symptoms** Eventually *E. coli* reach the air sacs and cause an infection there. The birds cough and wheeze and production falls.

**Transmission** Mainly horizontal:

- in the hatcher, infected shells etc;
- through the droppings (into feed and water);
- from infected dust (into lungs);
- from infected feed.

**Diagnosis** Bacteria are isolated and cultured in the laboratory.

**Treatment** Furazolidone and tetracycline can be useful if disease is caught at early stage. Once air-sacs are infected, treatment is not effective.

**Prevention** *E. coli* infections are a sign of dirty surroundings, so treatment should be accompanied by a clean-up campaign. The usual cleaning, disinfecting and fumigating plus all-in, all-out management will do much to prevent coliform infections.

*Omphalitis or navel infection* (*E. coli*, *Staphylococcus*, *Pseudomonas*, and others)

**Symptoms** This is a disease of hatching chicks, which seem weak, huddle together, have watery diarrhoea, and an infected open navel. It may be accompanied by 10% mortality.

**Transmission** Horizontal transmission in hatcher. This disease is **very** infectious.

**Diagnosis** Send suspect chicks to pathology laboratory for diagnosis. They will identify which organism is responsible.

**Treatment** No effective treatment. There is little spread of infection once chicks are out of the hatcher.

**Prevention** The seat of this infection is always the hatcher. If an outbreak occurs, the hatcher must be thoroughly cleaned and fumigated with a fumigant at three times normal strength. Hatching eggs should be fumigated at twice normal strength until infection is eradicated.

*Malignant oedema or gangrenous dermatitis* (*Clostridium septicum*)

**Symptoms** Disease of broilers particularly towards end of the growing period. There is gangrene of muscle and skin so that birds 'fall apart' whilst still alive. Massive mortality (up to 50%) is common.

**Transmission** Horizontal.

**Diagnosis** Fairly obvious but send suspect birds to laboratory for diagnosis. Although *Clostridium septicum* is the usual organism, *Staphylococcus aureus* can also cause the disease and treatments differ depending on the bacterium that is involved.

**Treatment** Penicillin works quite well if the main organism is *Clostridium*. The synthetic penicillin ampicillin is better if *Staphylococcus* is the main organism.

**Prevention** This disease can be associated with dirty conditions (but not always). Using litter more than once can increase problem. The disease sometimes appears as a secondary infection after the birds have been weakened by, say, an outbreak of gumboro disease.

*Necrotic enteritis* (*Clostridium welchii*)

**Symptoms** This disease is more usually found in broilers. Birds fail to thrive. Mortality commonly reaches 5–10%.

**Transmission** Horizontal.

**Diagnosis** Small intestine grossly inflamed and distended. Send suspect birds to laboratory for confirmation of diagnosis.

**Treatment** Penicillin works quite well.

**Prevention** This disease can be associated with dirty conditions (but not always). Thorough disinfection between batches of birds can reduce the incidence.

#### Mycoplasma diseases

*MG* (*Mycoplasma gallisepticum*) or  
*PPLO* (*pleuro-pneumonia-like-organism*) or  
*CRD* (*chronic respiratory disease*)

**Symptoms** This is a respiratory disease affecting the whole respiratory tract particularly the air sacs. Young chicks show sniffing, sneezing and rattling. It is not a killer itself, however, it is often followed by secondary infections particularly with coliforms which make symptoms worse and can lead to 30% mortality. Adult birds have a few symptoms – inactivity, drop in production – but low mortality.

**Transmission** Vertical through the hatching egg – this is important.

Horizontal:

- through air within a room;
- on feet, clothing, feed and equipment between rooms.

**Diagnosis** Suspect birds can be diagnosed in a pathology laboratory. There is an agglutination test available.

**Treatment** Should only be regarded as a temporary solution. Tylosin is an antibiotic with specific activity against MG.

**Prevention** Control can be by vaccination (usually layers) or eradication (usually broilers). Eradication is centred on identifying broiler breeder hens reacting to a blood test, and eliminating them. However, eradication is difficult because MG is **very** infectious.

*MS* (*Mycoplasma synoviae*)

**Symptoms** Although this is a respiratory disease, the respiratory symptoms are slight and easily missed. What causes the problem is that the organism tends to move to the synovial fluid and the hock and foot pad joints are often affected and become swollen and inflamed. This is mainly a disease of growing birds, particularly 6–14 weeks of age, which become lame and lose their appetites. In older birds there is a drop in egg production and lameness.

**Transmission** Vertical through the hatching egg.

Horizontal:

- through air within a room;
- on feet, clothing, feed and equipment between rooms.

**Diagnosis** Suspect birds can be diagnosed in a pathology laboratory. There is an agglutination test available.

**Treatment** Oxytetracycline in feed can be useful, but aim for eradication.

**Prevention** Eradication by identifying breeder hens reacting to a blood test and eliminating them. Also, hatching eggs can be heat treated to 46°C before incubation. This kills the organism and only lowers hatchability slightly.

### Viral diseases

#### *Infectious bronchitis (IB)*

**Symptoms** This is a disease of domestic fowl only. In chicks there is wheezing and sneezing and perhaps a nasal discharge. Birds gasp for breath. Typically it starts very suddenly and spreads very quickly with up to 50% mortality. In a flock it is likely that all birds will be affected and those that recover will have poor performance in adult life. It is often followed by secondary infections particularly by the coliforms. In adult birds, there are few respiratory symptoms. There is however a huge drop in egg production and a dramatic decrease in egg quality. Soft-shelled, misshapen and wrinkled eggs are very characteristic and albumen quality is poor. Many birds become internal layers.

**Transmission** Horizontal:

- through air within a room;
- on feet, clothing, feed and equipment between rooms.

**Diagnosis** Diagnosis is difficult and is often done by eliminating other possibilities. Agglutination tests for antibodies are available.

**Treatment** No treatment.

**Prevention** There are several vaccines, mostly attenuated, available:

- Broilers – at day-old, spray vaccine into mouth or eye (ocular).
- Layers – at 2 and 6 weeks give a water-borne or ocular vaccine.
- Breeders – at 1, 10 and 30 weeks then every 10–20 weeks during the laying cycle, give a water-borne or ocular vaccine.

#### *Newcastle disease (ND)*

**Symptoms** A very infectious disease affecting all poultry and some wild birds. There are different forms depending on where in the body the virus strikes. The main symptoms are one of the following:

1. respiratory difficulty;
2. nervous disorders ('twisted necks' and 'tumbler');;
3. reduced egg production and quality.

**Transmission** Horizontal:

- through air within a room;
- on feet, clothing, feed and equipment between rooms.

**Diagnosis** The nervous symptoms give an accurate diagnosis, otherwise it is difficult. Pathology laboratory diagnosis is possible.

**Treatment** No treatment.

**Prevention** The usual method is to try to keep completely

free from this disease. However, if it gets into the area, then it is wise to vaccinate, since transfer from other sites is very easy. The vaccination program is complicated – so take advice.

#### *Fowl pox*

**Symptoms** There are two forms of the disease:

1. Dry pox (scabs) on comb, wattles, eyes and ear-lobes.
2. Wet pox in mouth, trachea and respiratory tract which eventually cause suffocation. This often follows dry pox.

**Transmission** Horizontal. The skin must be broken for the virus to enter. This can happen in two ways:

1. Birds pecking each other during fighting.
2. Mosquitos can transmit the disease.

Transmission is therefore usually slow.

**Diagnosis** The lesions are very symptomatic. If in doubt, a pathology laboratory will take some material from an infected bird and inject it into the face of another bird. If the typical pox develop, then the disease is fowl pox.

**Treatment** No treatment.

**Prevention** If fowl pox is a problem, then there are vaccines available. However, vaccines are not used routinely.

#### *Infectious laryngotracheitis (ILT or LT)*

**Symptoms** A very severe respiratory disease usually in chickens over 6 weeks old. The infected birds gasp for breath. There is often haemorrhaging in the respiratory tract and blood can be coughed up. Mortality varies but can reach 30%.

**Transmission** Horizontal:

- through air within a room;
- on feet, clothing, feed and equipment between rooms.

**Diagnosis** Can only be diagnosed in a lab.

**Treatment** No treatment.

**Prevention** There is now a very good attenuated vaccine which gives good immunity. Vaccinate at 6 and 16 weeks using ocular route.

#### *Gumboro disease or infectious bursal disease (IBD)*

**Symptoms** Affects chicks aged 20–60 days. Birds are listless, nervous, sleepy, with a whitish diarrhoea which causes them to peck at their vents. Mortality is variable. The problem is that the virus damages the cells in the Bursa responsible for proper working of the immune system. Organism can live several months outside bird – so important to clean and disinfect between batches.

**Transmission** Horizontal through droppings.

**Diagnosis** Can only be diagnosed in laboratory.

**Treatment** No treatment.

**Prevention** If IBD is a problem in an area, then the usual method is to vaccinate breeders which pass on antibodies in their eggs and this gives protection to the chicks at least for the first part of the vulnerable period.

#### *Avian encephalomyelitis (epidemic tremors)*

**Symptoms** Mainly a disease of chicks between 6 and 21 days. They show nervous symptoms including quivering, which is very obvious if the chick is held in the palm of the hand, and paralysis. Many chicks lie on their sides.

Mortality is high because chicks cannot get to food or water. Adult birds which become infected show few symptoms but lay infected eggs.

**Transmission** Vertical in the hatching egg.  
Horizontal through the droppings.

**Treatment** No treatment.

**Prevention** Vaccination of breeders is the answer. Their immunity should be checked regularly as they pass on antibodies to their chicks and this gives good protection.

#### *Marek's disease*

**Symptoms** A tumour-causing virus which is present in most chickens worldwide, but does not always cause tumours. Sometimes tumours enlarge and cause death. The virus can infect the bursa of Fabricius and reduce birds' immunity to other diseases.

**Transmission** Horizontal. This virus has a unique method of transfer – it lodges in the feather follicles and then gets into the air on skin debris and feather particles. It floats around and is inhaled by other birds. The infected dust and debris can be carried around on feet, clothes, etc.

**Diagnosis** Tumours are very symptomatic.

**Treatment** No treatment.

**Prevention** Several vaccines are available, all derived from herpes virus turkey (HVT).

#### *Avian influenza (bird flu)*

**Symptoms** A contagious infection caused by the influenza virus type A, which can affect most bird species, including all poultry species and occasionally some mammalian species. Avian influenza can be classified into two categories, low pathogenic (LPAI) and high pathogenic (HPAI) forms, based on the severity of the illness caused in birds. Avian influenza is a reportable disease. The LPAI form commonly causes only mild symptoms (ruffled feathers, a drop in egg production) and may easily go undetected. The HPAI form spreads very rapidly through poultry flocks, causes disease affecting multiple internal organs, and has a mortality that can approach 100%, often within 48h. The great concern is that the H5N1 strain of this virus has been known to infect human beings with a very severe form of influenza with a high mortality rate.

**Transmission** Horizontal. The main route of transmission is probably as an aerosol but other routes may be possible.

**Diagnosis** Laboratory diagnosis is required.

**Treatment** No treatment.

**Prevention** No vaccines are available yet for avian influenza.

#### Parasitic diseases

Other important infectious diseases of chickens are caused by coccidia. These are protozoa that live in the intestinal tract and can cause great damage there. There are several species of coccidia that infect chickens and all belong to the group *Eimeria*. The 3 most important ones are *E. tenella*, *E. necatrix* and *E. acervulina*. The diseases are generally called 'coccidiosis' no matter which organism is responsible.

Coccidia have a complex life history spent partly in the chicken and partly outside it. Coccidiosis is spread by

single-celled bodies known as oocysts. These are passed in the droppings, but are not infectious. They must first go through a process called sporulation, which requires correct conditions of temperature, moisture and air and takes 2–4 days. If the sporulated oocyst is eaten by a chicken it ends up in the intestines where it multiplies in the gut wall and causes damage. Eventually after 4–7 days, more oocysts are produced and expelled in the droppings and the whole cycle starts again.

The amount of damage is closely related to the number of oocysts present and if only a few are present then little damage is caused. However, if the bird goes on ingesting more and they keep multiplying, very soon there can be millions present – and then the bird has a big problem. If the numbers build up slowly, then the bird can develop immunity. However, this seldom happens under the artificial conditions found in a laboratory and numbers usually build up very quickly.

#### *Coccidiosis (Eimeria species)*

**Symptoms** Bloody droppings, ruffled feathers, paleness (anaemia due to blood loss) loss of appetite, poor growth, poor production, diarrhoea. The different species of coccidia produce different lesions in different parts of the intestine.

**Transmission** Through droppings – but of course infected material can be carried on feet, equipment etc, and so be spread from room to room.

**Diagnosis** Bloody droppings and characteristic lesions in gut are usually enough for diagnosis. A pathology laboratory can identify the species involved.

**Treatment and prevention** There are lots of good coccidiostats available, which can be added to the feed. However, some of them are very specific to some species of coccidia, so it is advisable to get a laboratory identification. Also, coccidia can develop resistance to a particular coccidiostat, so it sometimes helps to rotate coccidiostats from time to time. Birds on the floor will be at biggest risk (ie, most young birds, all broilers, some layer replacements and all breeders). A coccidiostat is usually fed to broilers at a rate to completely suppress coccidia since there is no time for broilers to develop immunity. With replacement birds (layers and breeders) another strategy is employed. A coccidiostat is fed at full strength for the first 5–6 weeks. It is then gradually withdrawn so that the birds get a very mild coccidiosis. They then slowly develop an immunity and in time the coccidiostat can be withdrawn completely. Another approach is to use a so-called 'vaccine'. This is a material which contains a limited number of oocysts and is fed to chicks at about 10–12 days of age. The idea is that the numbers of oocysts are small and immunity will build up. Obviously a coccidiostat should not be used with this approach. **Warning** – Some coccidiostats are **very** toxic to other classes of livestock. For example, monensin at normal poultry dosages causes acute heart failure in horses and dogs.

There are some other parasitic diseases of poultry caused by various round and flat worms, but these are unlikely to be a problem in the laboratory. There are also various species of lice that parasitise the skin of domestic fowl, but these are unlikely to be a problem in the laboratory. However, mites

can be a serious problem, particularly the common red mite, *Dermanyssus gallinae*. Every effort should be made to keep laboratory facilities free of red mite since an infestation can cause birds extreme distress and major blood loss, and the mite is very difficult to eradicate because of resistance to all permitted arachnidicides. Precautions would include an all-in, all-out policy and allowing only hatching eggs or day-old chicks into the facility.

### Metabolic disorders

The implementation of good biological security and the use of vaccines have resulted in control of most of the infectious diseases of chickens. Non-infectious diseases are now of more importance to the poultry industry, and these diseases, usually referred to as metabolic disorders, will no doubt be evident in the laboratory, particularly if modern, high-producing strains of chicken are used. The most important ones are sudden death syndrome, ascites, fatty liver and kidney syndrome, and various skeletal disorders in broiler chickens, and liver haemorrhagic syndrome and osteoporosis in laying hens. Most of these disorders have a multifactorial aetiology and are therefore complex. They are mentioned here, simply to warn laboratory managers of their existence. If morbidity due to metabolic disorders is suspected, then more detailed texts such as Saif *et al.* (2003) and Leeson *et al.* (1995) should be consulted.

### Abnormal behaviour

The occurrence of abnormal behaviour is often a sign that birds are suffering. As mentioned previously, the laboratory manager should be able to recognise behavioural signs of disease. In addition to this, some other behavioural symptoms of suffering are fairly easy to recognise. Severe frustration is often characterised by stereotyped back-and-forward pacing and increased aggression (Duncan & Wood-Gush 1971, 1972). Lack of a suitable nesting place is the most likely cause of severe frustration. Severe food restriction often leads to stereotyped pecking at the feeder or some other aspect of the environment (Savory 1989).

Occasionally some strains of chickens in some circumstances will show panic or hysteria. These may be defined as excessive and inappropriate flight–fright reactions, panic having some external trigger and hysteria without an apparent cause (Mills & Faure 1990). Both panic and hysteria seem to have complex aetiologies. However, since they are often associated with large group size, they are unlikely to occur in the laboratory.

### Further reading

The primary breeding companies produce ‘Management Guides’ for each of their hybrids. These set out the management conditions that will optimise the productivity of that particular strain. Laboratories using these hybrids should always ensure that they have the relevant guide. In addition, there are several excellent text books on poultry manage-

ment and husbandry such as Sainsbury (1992) and Bell and Weaver (2002) which should be used to expand this text. The welfare implications of different commercial husbandry systems are dealt with in some detail by Appleby *et al.* (2004) and this should also be studied.

## The Japanese quail

Kimberly M. Cheng, Darin C. Bennett, and Andrew D. Mills<sup>1</sup>

### Biological overview

The Japanese quail (*Coturnix japonica*) is a small, chubby, brown-coloured terrestrial migratory bird (Wetherbee 1961). The species is indigenous to East Asia (Latitude 17°N to 55°N) and is sympatric with the common quail (*Coturnix coturnix*) in their breeding range in Mongolia (Wakasugi 1984). Their habitat is in grasslands, croplands, riversides, alpine meadows and grass steppes (Long 1981).

The Japanese quail belongs to the order Galliformes, family Phasianidae, genus *Coturnix*, and was previously considered to be a sub-species of the common quail (see Crawford 1990). It was given full species status in 1983 (American Ornithologists' Union 1983; Howard & Moore 1984) because no interbreeding has been observed between the common quail and the Japanese quail in areas where the two species are sympatric. Barilani *et al.* (2005), however, have suggested that natural hybridisation is a possibility on the basis of mtDNA and nuclear DNA analyses of a small sample of five birds. In captivity, hybridisation is possible but difficult (Derégnaucourt *et al.* 2002), and only after some failed attempts (Lepori 1964; Pala & Lissia-Frau 1966; Moreau & Wayne 1968). The Japanese quail (Old World quail) should not be confused with Bobwhite quail (*Colinus virginianus*), a species in the family Odontophoridae (New World quail). Both species have been domesticated and used as food and as research animals.

Japanese quail were originally introduced to North America by the US Fish and Wildlife Service as game birds in 1870, and releases continued into the late 1950s (Standford 1957). Most of the birds released were domestic birds imported from Japan. All stocks released in North America failed to establish and perished within 1 year. However, release attempts in the 1940s on the Hawaiian Islands were successful. Populations survived on Kauai, Molokai, Lanai, Maui and Hawaii (Peterson 1961) and have been regularly hunted (Munro 1960). Although the populations originated from released domestic birds, they are now considered wild.

### Domestication and origin of domestic and laboratory lines

The first records of domestic Japanese quail were from twelfth century Japan and it appears that the species was

domesticated there during the eleventh century, or imported from China in an already domesticated form (Chang *et al.* 2005), at about that time (Howes 1964, Crawford 1990). Japanese quail were originally kept for their song (Howes 1964) and it has been inferred that lines of quail with particular call types were bred for use in song contests (Taka-Tsukasa 1935; Wakasugi 1984).

Between 1910 and 1941, the Japanese selected quail for increased egg production and by 1940, a thriving industry existed (Howes 1964; Wakasugi 1984). However, all lines of song-type quail and the majority of egg production lines were lost during World War II. Following the war, the quail industry was rebuilt from the few remaining domesticated birds available, possibly with the addition of domesticated lines from Korea, China and Taiwan and quail captured in the wild (Howes 1964; Wakasugi 1984). All present day laboratory and commercial lines of Japanese quail appear to have been derived from this post-war population (Crawford 1990).

### General biology

#### Morphology

The wild-type natal plumage of Japanese quail is the same in both sexes (Cheng & Kimura 1990). Chicks have tawny coloured heads with small black patches above the beak. A buff stripe bordered by black stripes runs along the top of the head and there are four dark brown stripes on the back. The back and wings are pale brown (Cheng & Kimura 1990). Juvenile plumage is present at 3–4 weeks of age and full adult plumage is present at about 6 weeks of age. The species is sexually dimorphic in adult plumage (Figure 42.1). In both sexes, body plumage is predominantly brown (Wetherbee 1961; Kawahara 1967, 1973) but it is highly variable in terms of shades of brown and some of the markings on the breast and the throat (Cheng & Kimura 1990). Females have pale-coloured breast feathers which are speckled with dark-coloured spots whereas males have uniform dark rufous breast and cheek feathers. Furthermore, males may develop a white collar while females have cream coloured feathers on the cheeks and do not develop white collars (Urbanski 1984). With domestication came the development of many strains with various plumage colour and pattern (Cheng & Kimura 1990).

Domestic quail reach sexual maturity at 4–5 weeks of age, depending on the lighting schedule. Females enter into full

lay at about 6 weeks of age (see also Gerken & Mills 1993). Quail eggs are variably mottled. The background colour of shells varies from white through to pale brown or blue. The shell colour pigments are porphyrin and biliverdin (Poole 1965). Shell colour, mottling pattern, size and shape vary considerably between females but are consistent for and unique to a given female (Jones *et al.* 1964). Eggs weight varies between 8 and 13 g depending on the strain of the bird (see below).

#### Size range and lifespan

Adult wild males and females weigh about 90 and 100 g, respectively (Kawahara 1967), and unselected domestic males and females weigh about 100 and 120 g, respectively. There is considerable variability in body weight between different genetic strains of quail (Gerken & Mills 1993). Some domestic strains that have been selectively bred for meat production weigh as much as 300 g at 6 weeks of age (Cheng & Nichols 1992).

The domestic Japanese quail is notable for its rapid growth rate (Figure 42.2). Chicks weigh between 8 and 12 g at hatching. They double this weight by 5 days of age and triple it by 8 days of age (Lucotte 1974). By 5–6 weeks of age, birds may weigh 160–250 g depending on sex and strain (Gerken & Mills 1993).

There appear to be no reports concerning the lifespan of wild quail. Under artificial husbandry conditions,

**Figure 42.2** Growth curve for male (dashed line) and female (solid line) domestic Japanese quail from hatching to 8 weeks of age (data from Aggrey (2003)).

reported lifespan varied depending on breeds, rearing conditions (e.g. continuous lighting) and nutrition factors. In most cases, life was terminated artificially and the reported lifespan may mean productive lifespan (eg, see Table 42.1 and Gerken & Mills 1993). Woodard & Abplanalp (1971) reported that males live longer (more than 5 years) than females (less than 4 years). In the authors' laboratory, a male that was kept as a mascot lived for 8 years before being euthanased because of the development of skin tumours.

#### Social organisation

Studies of social organisation in wild Japanese quail appear to be limited to those by Taka-Tsukasa (1935), and opportunistic observations of wild quail have produced conflicting reports (Kawahara 1967; Dement'ev *et al.* 1967). It has been reported that the birds live in pairs during the breeding season but gather in large flocks during migration and in the winter (Crawford 1990). Observations of feral Japanese quail in Hawaii indicate that males are territorial, and mating and nesting take place within these territories (Schwartz & Schwartz 1949). Members of a pair remain in close proximity before and during the egg-laying period (which implies mate guarding and thus the possibility of extra-pair copulations (McKinney *et al.* 1983)). Dement'ev *et al.* (1967) reported that the species is polygamous. Kawahara (1967) noted that males and females live in pairs during the breeding season. On the basis of such evidence and studies of other *Coturnix* species, Kovach (1975) concluded that the mating system of wild Japanese quail is in a transitional state between polygamy and monogamy. However, one of the few studies with captive quail (Orcutt & Orcutt 1976) indicated that males and females formed strong pair bonds, and that males were monogamous and courted only their own female. There is also evidence that Japanese quail are able to recognise the calls of a pair-bonded mate (Guyomarc'h 1974). Crowing rate increases in males visually separated from females, and crowing intensity increases with rises in ambient noise levels (Potash 1972, 1975). Crowing patterns of pair-bonded males differ from those of unmated males (Potash 1975). Potash (1975) argued that crowing by males

and cricket calls by females serve the function of contact calls when a bonded pair is out of sight of each other. Nichols *et al.* (1992) studied captive Japanese quail in outdoor flight pens and confirmed that males were paired with one female for the whole breeding season. Females also paired with only one male during the breeding season. Nichols (1991) concluded that wild Japanese quail are monogamous with some opportunistic forced extra-pair copulations by the male.

Under simulated natural conditions in outdoor flight pens, domestic quail males are serially monogamous with significantly higher frequencies of extra-pair copulations compared to wild males (Nichols 1991). With higher density rearing in floor-pens or cages, they become promiscuous. Cheng *et al.* (1989a) observed that the cloacal foam gland in domestic males is much more prominent than that of wild males. Adkins-Regan (1995) suggested that the enlarged foam gland of the domestic males '*hints at a genetically non-monogamous mating system*'.

The common courtship displays performed by wild males include zig-zag dancing, leading, tidbitting, strutting and squatting (Eynon 1968; Nichols 1991). The male initiates sexual behaviour by strutting towards the female. During strutting, the male stretches himself such that his beak, body, head and neck are parallel to the ground, erects his body feathers and walks on his claws and digits with a characteristic stiff-legged gait. Under simulated natural conditions, domestic males also perform these displays but with significantly less frequency and with less specific contexts (Nichols 1991). An indication of female acceptance of the male could be solicitation of copulation by the female. A female would walk in front of her suitor and crouch, inviting the male to mount her (Nichols 1991). A mated pair also keeps in close vocal contact with each other, giving very quiet calls as they move around together. Under husbandry conditions, the role of the female in courtship and mating appears to be minimal (Kovach 1975). Sefton and Siegel (1973) reported that male courtship displays were rare. The male approaches the female, grabs her head or neck feathers and attempts to mount her without any additional courtship or display behaviour (Farris 1964, 1967; Wilson & Bermant 1972). Cheng (unpublished data) observed mating behaviour of domestic quail using two-male, six-female mating groups in 2.5 × 3.1 m indoor floor-pens. Under this situation, a male could dominate the other male and attempt to keep the subordinate male from mating with the females. Often the subordinate male would dash into a group of females and perform zig-zag dancing, and the females responded by scattering in different directions, crouching and hopping up in the air. The subordinate male, and sometimes both males, would start to grab and mount females. During mounting, the male 'grabs' the head or neck feathers of the female, positions himself on the back of the female, spreads his wings and begins treading. The copulatory response sequence results in ejaculation in about half of these cases. On those occasions, the male brings his cloaca down and underneath the female, establishes cloacal contact and ejaculates. The male releases his grip on the female and dismounts immediately after ejaculation. Following dismounting, both the male and the female may show ruffling and shaking of the feathers. While males mount females

regardless of the females' receptivity (Lucotte 1974), the type of female's reaction significantly influenced the latency of the male's grab, mount and cloacal contact responses and also determined the efficiency of the male's copulatory behaviour (Domjan & Nash 1988).

Under husbandry conditions Japanese quail form dominance hierarchies. Although the nature of these hierarchies has not been extensively studied, they appear to be of the peck order type and confer priority of access to resources (Otis 1972; Nol *et al.* 1996). In group-housed birds, subordinate birds show ambivalent behaviour (Edens *et al.* 1983). This ambivalent behaviour comprises aspects of both aggressive and submissive behaviour and is an attempt to displace dominant birds from feeders or drinkers. Furthermore, under conditions of deprivation, levels of aggression increase as distance from the food source decreases, and dominance relationships change from a peck order system to a peck dominance system.

Domestic males do not respond well to disruption of established hierarchies. If birds are introduced into established groups, they are likely to be attacked. Attacks are more likely if a stranger is introduced into the home cage of other birds. As a consequence, it is unwise to mix groups of birds or to introduce replacement birds into groups where hierarchies have been established.

## Reproduction

Reproduction in Japanese quail is strongly dependent on the lighting regimen. Wild birds breed in spring and summer. However, in the laboratory, birds can be maintained in breeding condition all year if they are kept on day lengths of 12h or more. If birds are kept on short day lengths (6h or less) sexual development is delayed or inhibited. Social factors as well as photoperiod influence the onset of sexual maturity. The sound of male vocalisations can speed female sexual development (Guyomarc'h & Guyomarc'h 1984) and males housed with females show faster sexual development than males housed alone (Delville *et al.* 1984). If birds are transferred from long to short day lengths the gonads regress and reproduction ceases (Sachs 1967). However, some females will lay eggs under short photoperiods or even under continuous darkness (Noble 1972; Stein & Bacon 1976).

If the photoperiod is sufficiently long, sperm production commences at around 4 weeks of age (Mather & Wilson 1964; Ottinger & Brinkley 1978; Ottinger & Brinkley 1979a) and sperm are present in large numbers in the vas deferens and testes by 35 days of age (Ottinger 1978). Males begin crowing at about 2 weeks of age, show cloacal gland development (Cheng *et al.* 1989b) at about 4 weeks of age and begin mating attempts. Completed copulations may occur only a few days later (Ottinger & Brinkley 1979b).

Male fertility starts to decline as early as 15 weeks of age (Ottinger 1991). Old males have lower fertility than younger males (Ottinger *et al.* 1983; Woodard & Abplanalp 1967) and males kept on a chronic long day length photoperiod develop more age-related abnormalities in testes and sperm than males kept on shorter day length photoperiods (Eroschenko *et al.* 1977). Advanced age adversely affects sexual behaviour in male quail (see reviews by Ottinger 1983; 1991).

**Figure 42.3** Hen-day egg laying rate as a function of age in domestic Japanese quail (data from Minvielle *et al.* (2000)).

Egg production declines with age (Figure 42.3) and eggs from older females (post 20 weeks) have low hatchability and fertility even though older females are more sexually receptive than younger females (Woodard & Abplanalp 1967). Wild females in their first breeding season display little sexual activity until late in the season and are usually not successful in laying a clutch until their second breeding season (Nichols 1991). Keeping females on chronic long photoperiods shortens their reproductive life presumably because of the physiological demands associated with high egg production.

### Breeds, strains and genetics

A wide variety of plumage colour mutants exist (Cheng & Kimura 1990; Butkauskas 2001) and various strains have been selected for physiological and behavioural traits. Details of existing known mutations, gene nomenclature, mutations, physical linkage maps and specific genetic lines can be found in Cheng and Kimura (1990), Cheng and Nichols (1992) and Somes (1984).

The karyotype of the Japanese quail consists of seven pairs of macrochromosomes (including the sex chromosomes) and 32 pairs of microchromosomes. The integrated linkage map has been published by Kayang *et al.* (2006).

### Standard biological data

There is a paucity of recent information concerning common physiological parameters in present-day strains of Japanese quail. Tables 42.1 and 42.2 show physiological and baseline haematological and clinical chemistry data, respectively. However, these tables should be considered only a guideline since present-day laboratory and domestic strains may be physiologically different because of selection for other traits, such as body weight or increased egg production.

### Quail as food animals

Japanese quail have been farmed in many parts of the world. Due to their small body size, fast growth, high rate of egg

**Table 42.1** Standard biological data for the Japanese quail. Modified from Cooper (1987) and Mills *et al.* (1999).

Parameter	Value
Body weight (g)	
1 day	6–8
Adult male	100–130
Adult female	120–160
Organ weight (% body weight)

<sup>1</sup> mean ± se

production and ease of management, they are a practical solution to the problem of animal protein shortage in developing countries and an alternative to chicken in developed countries (Shanaway 1994). Under commercial production systems, quail can be marketed at about 5 weeks of age with an average weight of about 215 g. A feed conversion ratio (feed/gain) ratio of 3.5 is not as efficient as that of broiler chickens (Hoffmann 1990). However, the strength of the Japanese quail is in egg production. Domestic quail hens start egg-laying at about 5 weeks of age, eggs are about 10 g each, and a hen can produce 280–300 eggs in a year (Minvielle 1998). The feed conversion (feed/egg) ratio of 3.3 makes the Japanese quail the champion species in converting feed into eggs (Shanaway 1994).

In the past four decades, commercial quail farming has developed in many parts of the world, particularly in Japan, China, Korea, India, Italy, France (Bessei 1977; Minvielle 1998), Spain, Hungary, Poland, Estonia, Russia, Czech Republic, Slovakia (Baumgartner 1993), Saudi Arabia, South-eastern United States, Brazil (Murakami & Ariki 1998) and Chile.

### Quail as laboratory animals

The Japanese quail's small size, inexpensive rearing requirements, rapid maturation and adaptability to a wide range of husbandry conditions have made it popular as a laboratory

**Table 42.2** Haematological and clinical chemistry values for adult domestic Japanese quail (mean  $\pm$  se). Data from Nirmalan and Robinson (1971) and Faqi *et al.* (1997).

animal for studies of behaviour, development, genetics, growth, endocrinology, nutrition, physiology, pharmacology and toxicology (Landsdown *et al.* 1970; Padgett & Ivey 1959; Wilson *et al.* 1959; Reese & Reese 1962). Since quail have been used as a model organism in many research studies, there is an abundance of background information available. Additionally, numerous mutations are known (Cheng & Kimura 1990) and several strains have been developed for use in research (Marks 1978; Shih *et al.* 1983; Hazard *et al.* 2005; Minvielle *et al.* 2007).

Japanese quail have been used extensively as a research model in neuroendocrinology. Since they have prominent and clearly defined sex differences in their behaviour (Ottinger 1989), they have been particularly useful in studies on the endocrine and neural mechanisms that control sexual differentiation and reproductive behaviour (Balthazart & Ball 1998; Balthazart *et al.* 2003; Ball & Balthazart 2004). Gonadotropin-inhibitory hormone, which directly acts on the pituitary to inhibit gonadotropin release, was first discovered in quail (Tsutsui *et al.* 2000). Since much is known about their hormonal regulation of sexual development and behaviour, Japanese quail are often used as model species for avian toxicology tests (Ottinger *et al.* 2002; Scanes & McNabb 2003). They are a key model for examining the effects of endocrine-disrupting chemicals (Halldin *et al.* 1999; Ottinger *et al.* 2001, 2002). Because of their early maturation and short generation time, quail are best suited for testing trans-generational effects of chemicals (Ottinger *et al.* 2002; Kamata *et al.* 2006). For similar reasons the quail has been a popular model for studying avian genetics (eg, Yang *et al.* 1999; Aggrey 2003; Minvielle *et al.* 1999; Piao *et al.* 2003; Suda & Okamoto 2003; Kim *et al.* 2007).

The species has been of particular value in studies of photoperiodism and the hormonal control of sexual behaviour (Mills *et al.* 1997). Quail are strongly photoperiodic and been used to examine how circadian rhythms are entrained in birds and the role of melatonin in various physiological processes (Underwood 1994; Cheng *et al.* 1994; Underwood & Edmonds 1995; Ohta *et al.* 1989; Moore & Siopes 2000, 2003; Fu *et al.* 2002; Houdelier *et al.* 2002; Nakahara *et al.* 2003).

Furthermore, Japanese quail have many characteristics and behaviour patterns in common with the domestic chicken (*Gallus gallus domesticus*). They have been used to test the nutritive value of various feedstuffs for chickens (eg, Kaya *et al.* 2003; Elangovan *et al.* 2003), and are increasingly being used as model of that species for studies of applied animal ethology related to animal welfare (Gerken & Petersen 1987; Gerken & Mills 1993; Mills & Faure 1990; Odeh *et al.* 2003).

Although Japanese quail have been, and continue to be, a useful laboratory species, Minvielle (2004) reported that their popularity as a research model, as measured by the number of published papers, had declined between 1992 and 2002. His analysis showed that only 115–120 papers per year were published on Japanese quail in 2001–2002. The authors searched BIOSIS Previews for research papers published between 2003 and 2006 on Japanese quail, and found that the number had increased to an average of 154 papers per year. Like Minvielle (2004), they found that the number of papers published on Japanese quail is small in comparison to those published on other laboratory species like rats and mice. However, given the significance of many of the studies outlined above, solely counting the number of published studies on quail may not be a good reflection of their importance as a research model.

Although the amount of research involving Japanese quail has been considerable, the species has largely been used as a model or for comparative purposes, and little attention has been paid to the bird itself (Cheng & Kimura 1990).

### Sources of supply (conservation status)

In those countries where quail are farmed for meat or eggs, it may be possible to obtain birds from commercial suppliers. However, one has to be aware that the quality and genetic background of birds from commercial suppliers may vary. This may compromise comparison of results from different experiments or the potential to obtain consistent results from long-term studies. Other sources of supply are laboratories or research stations that maintain breeding populations. In North America, birds of known genetic history and lines selected for particular traits such as atherosclerosis resistance or susceptibility used to be maintained by the Quail Genetic Resource Centre at the University of British Columbia. Because of budgetary problems, the Centre was closed in 2003 and the quail populations have been transferred to and are maintained by the Agassiz Poultry Research Centre (Agriculture and Agri-Food Canada, 6947 #7 Highway, P.O. Box 1000, Agassiz, British Columbia V0M 1A0, Canada). In Europe, The French National Institute for Agricultural Research (INRA) (Department of Animal Genetics, 78352 Jouy-en-Josas, France), and in Asia, The Japan National Institute for Environmental Sciences (NIES) (16-2 Onogawa, Tsukuba Ibaraki, 305-8506, Japan), are both involved in quail research and maintain conservation populations and specialised lines.

### Laboratory management and breeding

#### General husbandry

Different strains of domestic quail differ greatly in their husbandry requirement. The information provided in this section is generic in nature. Researchers working with particular strains of quail may need to modify their husbandry practice accordingly. Management information can usually be obtained from the organisation from which the birds were obtained. Other sources of information include Ottinger and Rattner (1999) and Randall and Bolla (2007).

#### Housing

Quail can be housed in facilities as diverse as battery cages or outdoor aviaries. The type of housing used will be determined by the nature of the research, statutory requirements, welfare considerations and other factors. Although battery cages have frequently been used, the Joint Working Group on Refinement (JWGR) recommended that, when it is not possible to keep the birds in outdoor aviaries, indoor pens were more suitable than cages, and that if cages have to be used these should be modified to improve the quality of the space they provide (JWGR 2001b). In that report, information on cage sizes used in common practice is also presented together with recommendation for best practice. The European Commission has provided updated housing guidelines (European Commission 2007) which provide advice on rearing, enrichment and housing. These guidelines also recommend pens rather than cages and that housing systems should allow for the provision of substrate for scratching, pecking and dustbathing, nest boxes and

**Table 42.3** Space allowances for domestic Japanese quail (modified from JWGR (2001b), European Commission (2007)).

Parameter	Body mass (g)	
	Up to 150	Over 150
Minimum enclosure size (m <sup>2</sup> )	1.0	1.0
Area per bird: pair housed (m <sup>2</sup> )	0.5	0.6
Area per bird: group housed (m <sup>2</sup> )	0.10	0.15
Minimum height (cm)	20	30
Minimum length of feeding trough (cm)	4	4

cover whenever possible. In European agricultural research where the housing condition has to be similar to that of commercial farms, the standards laid down by the European Union Directive 98/58/EC and Council Directive 1999/74/EC should be followed (see also Table 42.3). General recommendations adopted under the Council of Europe Convention for The Protection of Farm Animals (ETS No 87)<sup>2</sup> and general and species-specific recommendations under The Protection of Vertebrate Animals used for Experimental and other Scientific Purposes (ETS No 123) should also be consulted. In the UK, in circumstances in which Japanese quail are not defined as domestic poultry under the legislative framework, the housing condition guidelines encompassed within the Wildlife and Countryside Act may have to be followed. In the following sections the authors provide a description of some commercially available caging systems. These are not intended to be descriptions of the ideal as there has been little research in this area, and further research into optimal quail housing is required.

#### Breeding facilities

Because domestic quail hens do not take to nest boxes readily and eggs laid on the floor are easily soiled and broken, difficult to collect and impossible to pedigree, cages are by far the most practical system for the housing of breeder or layer stock. Even though Buchwalder and Wechsler (1997) have found that quail may use solid-sided nest boxes with a small entrance, no further research has been carried out to facilitate housing breeding quail in floor pens as an alternative to conventional battery cages. New non-cage housing requirements for farmed poultry will come into effect in Europe in 2012.

A lighting regimen of 16–18h of light and 6–8h of dark is usually sufficient to maintain a bird in good breeding condition.

#### Brooding facilities

Deep litter floor pens can be used to house birds from hatching to the end of their lives. Deep litter systems can range in size from entire rooms to small boxes mounted on wheels.

<sup>2</sup>[http://www.coe.int/t/e/legal\\_affairs/legal\\_co-operation/biological\\_safety%2C\\_use\\_of\\_animals/farming/A\\_texts\\_documents.asp#TopOfPage](http://www.coe.int/t/e/legal_affairs/legal_co-operation/biological_safety%2C_use_of_animals/farming/A_texts_documents.asp#TopOfPage)

Heat is provided by lamps, gas burners or radiant heaters suspended above the floor. Wood shavings are the most frequently used floor covering.

Chicks can be kept in wooden boxes until they are 2–3 weeks of age. Typical boxes measure 40 cm × 65 cm × 30 cm (w × d × h). When there is no place to hide, quail will jump upwards with tremendous force in a flight response when startled. If cage height exceeds 30 cm, it will allow the quail to pick up momentum in the flight response and which may result in severe head injuries (Gerken & Mills 1993). For this reason, ceilings can be of soft material. However, the soft material should be: (1) non-porous and washable; (2) non-flammable; and (3) not obstruct ventilation. Brooding boxes with soft ceilings are not commercially available. Heat and light can be provided by an infra-red lamp suspended over one end of the box. Temperature directly under the heat source should be 37°C, allowing the chicks to find their comfort zone as they move towards the other end of the box. The floor of the boxes should be covered with wood shavings or some other form of litter. After 2 weeks, the heat source is no longer needed if the room temperature is maintained within the 18–26°C range. At this age, the juveniles can also be moved to deep litter floor pens.

Chicks and juvenile birds have also been kept in commercial battery brooder cages (Figure 42.4). As their name suggests, battery brooder cages are arranged in batteries mounted on metal frames. Heat is provided from radiant heaters which are usually built into the roof of the cage. Light and additional heat can be provided by lamps mounted on the ceiling of the cage. In most commercial brooder cages, the heat source can be controlled by a thermostat. At hatching quail chicks require an ambient temperature of 37°C. After 3 days the temperature can be reduced to 35°C. Thereafter, the temperature can be progressively reduced by 5°C per week until 25°C.

Battery brooder cages can be of different sizes but usually measure at least 100 cm × 75 cm × 16–20 cm (w × d × h). Cage roofs are made of solid metal sheeting. Cage sides are made of 1 cm<sup>2</sup> (or smaller) wire mesh or solid metal sheeting. The cage fronts usually serve as hinged doors and are usually made out of vertical wire grill. If trough feeders are attached to the front of the cage, then the space between the bars should be large enough to allow the birds to reach the feeder

**Figure 42.4** Box brooder for Japanese quail chicks. Reproduced with permission of GQF Manufacturing Company.

easily but not so large as to allow chicks to escape. Similar provisions should be made for access to drinkers if these are located outside of the cage. The vertical distance between tiers of cages should be sufficient to allow easy collection and removal of droppings. Obviously, there must be an impervious separation between each tier of cages so as to prevent faeces falling from one level to another. Droppings can be collected on sheets of paper, pull out trays or moving belts.

Cage floors of 1 cm<sup>2</sup> mesh have been used, which allow for the passage of the droppings from the cage. However, this mesh size is too large to support the feet of chicks under 1 week of age. Therefore, for chicks of less than 1 week of age, the cage floor should be lined with sheets of paper or fine mesh plastic mesh (0.2 cm<sup>2</sup>). Some droppings will pass through plastic mesh of this size and with reasonable stocking densities, a single sheet of plastic mesh can be left in place from hatching to about 10 days of age when it is no longer required. Paper sheets, pull out trays or moving belts should be cleaned before there is excessive accumulation of droppings. In this context, it is important to remember that droppings will not be evenly distributed over the cage floor but will be concentrated in the areas around feeders and drinkers.

Feeders for young chicks must not have high (<2 cm) sides or the birds may not be able to reach the food. Petri dishes make excellent feeders for chicks from hatching to 4 or 5 days of age when food spillage becomes an important problem. From hatching onwards it is usual to present food in both petri dishes and some other form of feeder so that the chicks are familiar with these other feeders when the petri dishes are removed. In brooder and battery cages food is usually presented in feeders attached to the front of the cage. These feeders can be simple troughs or more complicated 'back-well feeders'.

The appropriate type of drinker varies with the husbandry system. In small cages and boxes, cage-bird drinkers can be used (one per five birds). When birds are housed in deep-litter pens, or boxes, plastic 0.5l gravity-fed bell drinkers are probably the most appropriate for chicks and sub-adult birds. However, for small chicks it may be advisable to fit drinkers with a grill or rubber ring to reduce the available watering area or some chicks may drown. An alternative solution is to partially fill the drinker with pebbles. Bell drinkers should be placed on wooden sheets to prevent them becoming clogged with litter. However, this is only a partial solution to clogging and drinkers should be inspected daily and cleaned out when necessary.

Irrespective of the type of housing system used, chicks less than 2 weeks old should be kept under continuous illumination at a minimum of 20 lux light intensity. This is of particular importance when birds are kept in large deep litter pens with a single heat source such as a gas burner. Under such conditions, if a period of darkness occurs, chicks will disperse from beneath the heat source and may die. There is no evidence that quail suffer from being kept under UV-deficient lighting (Smith *et al.* 2005).

### Rearing and holding facilities

Juvenile and adult birds can best be housed in deep litter floor pens. They can also be kept in colony or pedigree

battery cages that do not have internal sources of heating or lighting (Figure 42.5). Commercial colony cages for adults can often be sub-divided into smaller cages for one to three birds.

Floor pens have to be custom built. They can be of various dimensions depending on the number of birds to be housed and other research requirements. Readers should consult JWGR (2001b) and also see Chapter 41 on domestic fowl.

Like brooder cages, adult cages can be of different sizes. However, commercially available colony cages normally measure 100 cm × 50 cm × 16–20 cm (w × d × h) and pedigree cages suitable for up to three or four birds measure 25 cm × 50 cm × 20 cm (w × d × h).

Pedigree and colony cages usually have roofs made of solid metal sheeting. If the cage roof is not solid metal sheeting but of wire mesh, it is advisable to hang soft, wide plastic strips vertically from the cage roof half way down the cage for birds to hide behind. This will minimise their flight response and head injuries. The material used for making these strips should be able to withstand high pressure or steam cleaning without turning brittle. Cages with soft mesh netting roofs are not commercially available, but can be custom installed. However, soft mesh netting roofs have the disadvantages that they are flammable, not easily cleaned and disinfected, there is a risk of birds tangling or strangling themselves in a flight response, and they may not easily used with rack cage systems. Cage sides are made of 1 cm<sup>2</sup> or smaller wire mesh or solid metal sheeting. Cage floors are made of 1–2 × 1 cm mesh to allow the passage of droppings. The cage floors should be sloping so as to allow eggs to roll out. As for brooder cages, the cage fronts are usually hinged and serve as the cage doors. The cage fronts and backs should be made from wire grill with 2.5 cm spaces between the bars to allow birds to reach food and water easily. Adult cages are mounted on metal frames and arranged in

**Figure 42.5** Battery breeding cages for adult Japanese quail. Reproduced with permission of GQF Manufacturing Company.

batteries with an impervious separation between tiers. The vertical distance between tiers should be sufficient to allow easy collection and removal of droppings. Again, as for brooder cages, droppings can be collected on sheets of paper, pull out trays or moving belts.

Domestic quail grow rapidly and reach adult size in 4 weeks. Therefore, stocking densities should be predetermined at hatching or should decrease with the age of the birds, until they reach adult size. Strain, breed and line differences in body weight may confound this problem. Lucotte (1974) suggested that stocking densities should be 250 birds/m<sup>2</sup> during the first week after hatching and 175 birds/m<sup>2</sup> during the and third weeks after hatching. However, sex ratio and body weight may require that these estimates be modified. Current recommendations suggest that adult birds should not be kept at stocking densities greater than 40–45 birds/m<sup>2</sup>, thus providing each birds with 225–250 cm<sup>2</sup> of space (National Research Council (NRC) 1996; National Advisory Committee for Laboratory Animal Research 2004; see also Table 42.3).

In deep litter systems, food can be provided in hoppers which require less maintenance than other feeder types. Quail have high nutritional requirements throughout their lives, particularly during the growing period, so it is important that the feeding space provided is adequate (see Table 42.3). In large deep litter systems, continuous-flow bell drinkers can be used for juvenile and adult birds. These drinkers can be suspended at a height within easy access by the birds but sufficiently high to minimise clogging with litter. Alternatively, cup or nipple drinkers can be installed. Colony cages and pedigree cages are usually equipped with cup or nipple drinkers (one per five birds).

Although juvenile birds readily adapt to changes in drinker type, this is not the case in adult birds. Birds which have been raised with bell drinkers may not recognise nipple or cup drinkers and *vice versa*. Therefore, when birds are transferred from one type of husbandry system to another, it is important to ensure that the animals find the drinkers.

From 3–6 weeks of age birds should be kept under a lighting regimen of 8 h light to 16 h darkness. If this is not the case females may enter into lay too early, giving rise to reproductive problems (see later in this chapter). Adult birds can be kept on photoperiods of 12–18 h.

#### Environmental provisions

Quail do not readily use conventional nest boxes (see Buchwalder & Wechsler (1997) for a discussion of the improvement of nest box design and usage) but do use litter for dust-bathing. Enriching the environment of chicks by providing coloured objects and other 'toys' reduces fear and aggressive responses in later life (Jones *et al.* 1991; JWGR 2001b). Providing soft background music and human conversations from radio stations may lessen fear responses elicited by human entering the room.

#### Social grouping

Male quail react vigorously to the presence of unfamiliar males (Selinger & Bermant 1967) and rearing males in pairs

and then interchanging pair members leads to an increase in the frequency of aggressive interactions relative to that observed in the original pairs (Edens *et al.* 1983; Edens 1987). Further, birds that have been left in their 'home' cages are more aggressive than birds that have been transferred to an unfamiliar cage (Edens *et al.* 1983). Therefore, once groups have been established it is inadvisable to attempt to mix groups or introduce new animals into established groups.

In groups where the male:female ratio is high, misdirected head grabs by males (particularly if the female is not receptive) may result in head wounds and eye damage or loss. Under such circumstances, frequent attempts at mounting may result in wounds and, in extreme cases, the death of the females.

Where possible, housing of females in single-sex groups is desirable on welfare grounds. However, this is not the case for males. In all male groups, or in groups where the male:female ratio is high, homosexual copulation attempts are frequent (Wilson & Bermant 1972). This leads to subordinate males suffering feather loss and injuries similar to those sustained by females in mixed-sex groups. In breeding flocks, the ratio of males to females is usually kept at 1:4 to avoid repeated mounting by males leading to injury of the females.

### Sexing

Day-old chicks can be vent sexed (examination of the cloaca) (Homma *et al.* 1966) but accuracy is difficult to achieve in practice, except perhaps in Japan where hatcheries hire professional sexers to sex the chicks. However, by the time the chicks are 3–4 weeks old they can be sexed on the basis of plumage colour (Figure 42.1). Researchers working with strains that have plumage colour other than the wild type can identify males at 4 weeks of age by the protruding foam gland above the cloaca (Cheng *et al.* 1989b).

### Identification

Individual birds can be identified by means of leg bands or wing tags. The use and application of split rings and wing tags is described in JWGR (2001b). Wing bands and tags are readily available from commercial suppliers. Both bands and tags can be placed on birds of any age. However, the banding and tagging of chicks present certain difficulties. Leg bands, which are suitable for small chicks, do not have a diameter sufficient to accommodate the leg of juvenile or adult birds and must be replaced with larger ones when the birds are 1–2 weeks of age. Wing tags can be left in place throughout the life of the birds but only if they are correctly placed in the propatagium (the membrane or fold of skin in front of the humeral and radio-ulnar parts of the wing). However, in chicks the propatagium is very small and there is a risk that some tags will be placed in the muscles of the wing. If this is the case, then the tag will progressively become imbedded in the musculature of the wing as the bird grows. Therefore, birds should be inspected at 1–2 weeks of age and any incorrectly placed tags replaced. #5 Fingerling tags are suitable for quail chicks and aluminium chick wing bands are suitable for adult quail. Ear tags for mice may also be suitable for the wing tagging of chicks and adults.

Transponder microchips could be used as an alternative to leg bands or wing tags. However, these are relatively expensive and do not appear to have been widely used.

In pedigree breeding systems, where two or more hens are kept with a male, egg colour, size and shape can be used to identify which of the hens laid them. These parameters vary greatly between individuals but are extremely consistent within individuals over a 3 week period (Lucotte, 1974; Cheng, personal observations).

### Hygiene

Good hygiene is essential at all stages of husbandry. Incubators and hatchers should be cleaned and disinfected after each use. Rooms, cages, feeders and drinkers must be kept clean and disinfected after each cycle of use. When birds are kept in cages, dropping collectors should be changed or cleaned on a weekly basis. As far as possible, cages floors should be kept free from droppings. In deep litter floor pens, litter should be topped up weekly, with a total clean out and replacement every 2 months. If breeding birds are kept in deep litter floor pens, a cleaning schedule has to be carefully planned because the cleaning procedure will disrupt egg laying.

Where possible, the buildings used to house quail should be emptied periodically and cleaned and disinfected before being used again.

### Health monitoring, quarantine and barrier systems

Birds should be carefully inspected at least once daily and any birds showing signs of sickness or injury should be examined and treated appropriately and any dead birds removed. From hatching to 6 weeks of age, the mortality rate should be less than 5%. During breeding, the mortality rate should be less than 2%. Disease may be indicated by reduced egg output, morbidity and emaciation (see also section on disease). If animals are introduced to existing stock from an external source (this should be avoided if at all possible), it is very important that the source flock is disease free. It is better to bring in fumigated eggs or chicks than adult birds. If chicks or adult birds are brought in from external sources, they should be kept in quarantine for a period of 5–6 weeks. Contact between quail and other birds (particularly game birds) should be avoided. Access to housing facilities should be restricted to persons who have not been in contact with other birds for 72 h. It is prudent to provide disinfectant footbaths and protective clothing for workers and, for biosecurity reasons, visitors should not be allowed into the husbandry unit. Rodents and insects should be prevented from access to buildings housing quail.

### Transport

It is advisable not to ship quail less than 2 weeks old, but if unavoidable, chicks are best transported in commercially available cardboard chick boxes (46 cm × 31 cm × 15 cm) with a floor lining of wood shavings. The boxes should have air

**Figure 42.6** Specially designed shipping crate for adult Japanese quail. The crate has openings on the top and the side to facilitate the introduction and removal of birds. Reproduced with permission of KUHJ Corporation.

holes of a size sufficient to allow adequate ventilation but small enough to prevent the chicks from escaping. When transporting chicks, it is important to ensure that the ambient temperature is suitable (35–30°C, depending on the age of the chicks) and the time in transit be kept to less than 4h. Adults should be transported in crates with solid floors and mesh or grill walls and roofs (65 cm × 52 cm × 19 cm for 20 birds). Specially designed crates can be purchased (Figure 42.6). For shipping adults over long distances, it is recommended that a cut open apple be attached to the inside of the crate for birds to peck at to obtain moisture. Time in transit should be limited to less than 8h unless drinking water can be applied every 4h. Information on the transport of laboratory animals is given by Laboratory Animal Science Association (LASA 2005) and IATA<sup>3</sup> (see also Chapter 13).

## Breeding

### Condition of adults

The reproductive status of both male and female quail can be determined from behavioural, hormonal, neuro-anatomical and morphological parameters (for details and references see Mills *et al.* 1997). However, in practical terms, behavioural and morphological measures are the most easy to apply. Age of sexual maturity can be manipulated by photoperiod. Birds kept under short photoperiod will not become sexually mature. Birds kept under long photoperiod will become sexually mature at 4–5 weeks of age. At sexual maturity, the cloacal diameter of females and the protodeal (foam) gland of males increases. These anatomical changes and the beginning of sexual behaviour are reliable indicators of sexual maturity.

### Breeding systems

The main criteria for the selection of breeding stock are that the birds are in good physical condition and meet the requirements of any selection criteria. However, it should be remembered that quail are extremely susceptible to inbreeding depression. According to Lucotte (1974) the hatchability of eggs falls to near zero after three generations of brother × sister mating. No full-sib mating inbred line has

been maintained for more than eight generations (Kim *et al.* 2007). Therefore it is important to avoid consanguineous matings. To achieve this in small populations, it is important to maintain pedigree records for breeding stock.

At least three methods exist for the management of breeding birds. Each of these has particular advantages and disadvantages but there is a clear order of preference on both welfare and husbandry grounds.

1. Birds can be housed in small cages containing one male and two or three females. Under such conditions, males do not usually damage the females, the method is not labour intensive and it is possible to pedigree offspring or identify birds which are not reproducing well.
2. Males and females may be kept in individual cages and the males introduced into the cages of the females at intervals of 2–3 days since females are fertile for 3–9 days after a single insemination (Reddish *et al.* 1996). Males are introduced into the female cages in the morning for a period of 15–30 minutes. This is a sufficiently long period for copulation to take place but short enough to prevent the males from injuring the females. However, this method is extremely labour intensive although it permits one male to be mated to a relatively large number of females.
3. Males and females may be kept together in colony cages containing 5–10 males and 20–40 females. This is not labour intensive but the males may fight or attempt to copulate with one another, the mating of individual females is irregular and the parents of chicks cannot be identified. This method is probably the least satisfactory method for the management of breeding birds.

In the authors' laboratory, they keep two males with four females as a unit in a breeding cage and keep 24 cages (total of 48 males and 96 females) for propagating their random-bred population. They have found this arrangement much more satisfactory than the colony cages.

Techniques for the artificial insemination (AI) of Japanese quail have been developed (Marks & Lepore 1965), but fertility by AI is highly variable. AI is seldom used in practice because it is difficult to obtain semen that is not contaminated with foam or cloacal products (Buxton & Orcutt 1975). In addition, the volume of semen collected per male is between 3.9 and 6.9 μl (Marks & Lepore 1965) whereas an inseminating dose of 2.5–15 μl is required to achieve acceptable fertility levels. Furthermore, quail lay at the end of the photoperiod (late afternoon). Inseminating the female when there is a hard-shell egg in her oviduct will result in very poor fertility. The best time to inseminate after the egg is laid would be in the dark. For these reasons, reproduction of Japanese quail is usually by natural mating rather than by artificial insemination.

### Incubation of the eggs

The nest of the Japanese quail, like those of most gallinaeous species, is little more than a simple scrape on the ground with a rim of dry grass or similar material (Kawahara 1967; Nichols 1991). In the wild or in aviaries, quail hens choose to nest in secluded sites within areas containing rough grasses and scattered shrubs (Taka-Tsukasa 1935;

<sup>3</sup><http://www.iata.org>

Kawahara 1967; Nichols 1991; Schmid & Wechsler 1997). However, little is known about the nesting behaviour of wild birds although it appears that nest-building and incubation are carried out exclusively by the female (Schwartz & Schwartz 1949; Orcutt & Orcutt 1976; Nichols 1991).

In deep litter floor pens, natural incubation of eggs is not practical because quail hens do not readily become broody. Even with nest boxes provided, her nest-building and incubation behaviour is disrupted or not expressed because of close proximity and disturbance from other birds in the pen (Nichols 1991). Eggs can be incubated by bantam hens or pigeons but by far the most practical method is artificial incubation.

Eggs which are intended for incubation should be collected daily. Collection is usually carried out in the morning since most eggs will have been laid at the end of the previous day. Quail eggs have thin and fragile shells and they therefore should be handled carefully during collection and subsequent manipulations. After collection, the eggs should be stored on cardboard or specially designed polystyrene or foam-rubber trays for quail eggs. Eggs should be stored at 10–15°C in a well ventilated room (with a relative humidity of about 40%). Turning stored eggs at regular intervals may help to maintain hatchability. Storage time from collection to setting should be less than 7 days for maximum fertility and should not exceed 14 days since extended storage increases the incidence of embryonic abnormalities (Sittman *et al.* 1971). Further, there is a fall in hatchability from 10 days onwards (Kraszewska-Domanska & Pawluczuk 1977). Before setting, eggs should be inspected and any that are dirty, cracked, under- or over-sized, or with shell abnormalities (soft or under or over pigmented) eliminated.

Artificial incubators are of two types – horizontal or vertical. The major difference between these two types of incubators is that horizontal incubators have a single fixed shelf for eggs whereas vertical incubators have several tiers of shelves which can be inclined up to an angle of 45%. Most horizontal incubators are simple in design and can be purchased cheaply. However, they may have low capacity and relatively poor stability of incubation temperature and humidity. More sophisticated horizontal incubators for research use are also available. Vertical incubators have higher capacity and better controlled temperature and humidity than the simple horizontal incubators. Popular models for incubating quail eggs can be obtained from commercial incubator companies.

Incubation conditions for quail eggs are similar to those for chicken eggs, but because quail eggs are much smaller than chicken eggs they are more sensitive to temperature and humidity fluctuations during incubation. In vertical incubators temperature should be between 37.5°C and 38°C. In simple horizontal incubators, where heat loss to the environment tends to be greater than in vertical incubators, the temperature should be set at 39°C. This higher temperature is used to compensate for the greater temperature fluctuations inherent in these incubators. In both types of incubator, humidity should be 40–50%.

Incubation lasts 16–18 days. Under normal incubation conditions, there are peaks in embryonic mortality during the first 3 days of incubation and during the last 2 days of incubation (Figure 42.7).

Figure 42.7 Daily embryonic mortality during incubation of Japanese quail eggs (modified from Mills *et al.* (1999)).

### Hatching of young

On day 14 of incubation, eggs should be prepared for hatching by transferring them to a hatcher apparatus or arranging them in hatcher trays in the incubator. Eggs should be placed on their sides and should not be turned thereafter. The temperature should be increased to 40°C and the humidity increased to 70–80%. Eggs hatch between days 16 and 18 of incubation with most chicks hatching on day 17 (Lucotte 1974). However, these values may vary slightly depending on incubation conditions. For example, Wilson *et al.* (1961) found that the time from setting of eggs to external pipping was about just under 16 days, the time from pipping to hatching about 10h and the time from hatching to complete drying of the down about 5h.

Within batches the time of hatching of quail chicks is synchronised to some degree. This synchronisation of hatching is partially the result of communication between embryos by means of a vocalisation known as clicking which accompanies each air intake (Kovach 1975). Clicking by advanced embryos accelerates hatching in retarded embryos and vice versa (Vince 1966, 1968; Vince & Cheng 1970). Hatchability is therefore better when eggs are put close together in the hatching tray.

### The young

Quail chicks are nidifugous (precocial) and do not necessarily require parental care post hatching. Provided that the rearing environment is adequate (see earlier) they have no other specific requirements. In 1974 Lucotte suggested that a mortality rate of 10–15% during the first weeks after hatching should not be considered excessive but with modern management systems it should be considerably less. In the authors' laboratory, quail mortality rate has been below 5% for the last 25 years. The greatest mortality occurs due to 'starve out' on the third and fourth days after hatching when the nutrients from the yolk sack (vitellus) have been depleted and some chicks may fail to adapt to external sources for water and nourishment. It is important to monitor closely at this time.

**Table 42.4** Nutrient requirements of Japanese quail (NRC, 1994). Dietary requirements are on a per kg diet basis, assuming 90% dry matter.

Nutrient	Unit	Diets	
		Starting and growing	Breeding

## Feeding and water

### Dietary requirements

Quail chicks have very high requirements for dietary protein and amino acids early in life but these requirements diminish as the birds age. Recommended nutrient levels for

**Table 42.5** Food consumption of sample lines of Japanese quail at different ages.

Age (wk)	Food consumption (g/day)	
	Random-bred line <sup>1</sup>	Commercial meat lines <sup>2</sup>
1		6.8
2	10.2	13.7
3	13.0	15.7
4	17.5	19.8
5		23.5

<sup>1</sup>Data from Farrell *et al.* (1982).

<sup>2</sup>Data from Güler *et al.* (2005) and Hyánkova *et al.* (1997).

growing and breeding birds are shown in Table 42.4. In the case of laying hens, although food intake is low (20–30 g/day), the ratio of egg weight to body is high (approximately 5%) and it is particularly important to ensure a high intake of protein and sulphur amino acids.

### Natural and laboratory diets

Wild quail are omnivorous and have a diet composed of small seeds, insects and spiders (Kawahara 1967). Table 42.5 shows the food consumption of birds up to 5 weeks of age. The metabolisable energy value of diets should be in the range of 2600–3200 kcal/kg (Shim & Vohra 1984). In commercial operations where maximising production is a premium, it is usual to provide the birds with 'starter' diets until they are 21 days of age, with 'grower diets' from 3–6 weeks of age and 'breeder or layer' diets thereafter. In laboratory operations, the authors found that using a commercial turkey starter diet (26% protein) fortified with extra calcium (2.5%) is satisfactory for feeding quail of all ages. The diet comes in 'crumble' form (crumbled pellets) and has to be ground to a dry mash for feeding newly hatched chicks to 2 weeks old. Thereafter, the diet can be fed as crumbles. Specially prepared diets for quail may be available from some feed companies. Some commercial game bird diets can also be used for quail. Diet with high wheat content should be avoided, as the feed will become glutinous when moistened and will stick to the toes of the birds and ball up. Advice on quail nutrition in the tropics is available online<sup>4</sup>.

For nutritional physiology studies, commercial diets may not provide the background consistency of the feed ingredients and the precise level of various nutrients needed. In this situation, a synthetic diet (Table 42.6) may be used.

### Water

Clean drinking water must be provided at all times. Water consumption (Table 42.7) increases with age (Farrell *et al.* 1982; Visser *et al.* 2000), and is greater in lines selected for increased body mass (Visser *et al.* 2000). Drinking rates of adults increase as salinity of their drinking water increases, but quail do not tolerate salinities greater than isotonic (150 mM NaCl; Roberts & Hughes 1983).

<sup>4</sup><http://www.thatquailplace.com/quail/coturn1.htm>

**Table 42.6** Formula for a synthetic basal diet for laboratory Japanese quail. This diet is used at the UBC Quail Genetic Resource Centre for nutrition research projects.

Ingredient	Amount (g/kg diet)
Soya protein flour (50% protein)	340
Corn starch	400
Limestone	50
Mineral premix	5
Monofos	30

<sup>4</sup>Rapid growth line (body mass at 7 wk of age = 294 g).

## Laboratory procedures

### Handling and capture

Quail chicks are very small and must be handled very gently. They should be picked up using only the thumb and forefinger and held in the palm of the hand. When frightened or presented with unfamiliar stimuli, quail frequently injure themselves during the expression of escape behaviour. Therefore, care should be taken to minimise disturbances and staff and visitors should wear clothing with colours familiar to the birds. When birds are caught, they should be held so that their wings are pinned against the body and their legs hang freely. If birds are held by the legs or in such a manner that they can flap their wings, there is a high risk of bone breakage.

### Physiological monitoring

#### Recording of body temperature

Methods for the measurement of body temperature of Japanese quail are similar to those used for domestic chickens. Yousef *et al.* (1966) studied the temperature of the

hypothalamus, rectum and skin under different environmental conditions. The temperatures observed had the following ranges: hypothalamus 42.7–42.8°C, rectum 42.0–42.2°C and skin 39.0–39.8°C. McNabb and McNabb (1977) describe the measurement of heat transfer across the skin and feather pelts in young birds. Woodard and Mather (1964) have described circadian rhythms in body temperature and Woodard and Wilson (1972) have measured body temperature in relation to oviposition. For further information concerning body temperature in Japanese quail see Wilson (1972).

#### Collection of blood samples

Blood samples can be taken from the jugular or brachial veins. The blood volume of quail is approximately 7 ml/100 g body weight (Nirmalan & Robinson 1971) and 0.5 ml blood/100 g body weight can be safely withdrawn. Arora (1979) suggested 0.5 mm diameter (25G) needles for obtaining blood from the jugular vein and 0.46 mm diameter (26G) needles for obtaining blood from the brachial vein (see also JWGR 1993). Arora (1979) suggested that for ease of collection, safety and for repeated sampling, the jugular vein was the most suitable site. However, repeated bleeding is not advisable.

### Administration of medicines

#### Dosing and injection procedures

The jugular vein is the most suitable site for intravenous injections. Intramuscular injection should be made in the pectoral muscles. Subcutaneous injections should be placed under the skin of the neck. Intra-coelomic injections are sometimes used to administer anaesthetics, but care should be taken not to place the injection into the air sacs.

Liquids can be administered orally by direct intubation of the crop using a standard 12–16G gavage needle (bulbous tipped 100 mm long) (Ichilcik & Austin 1978). If doses do not need to be precise, it is possible to incorporate compounds into the diet or drinking water.

Although quail are not specifically dealt with, detailed information on the procedures involved in the administration of substances to animals can be found in JWGR (2001a).

### Anaesthesia

There has been limited research into appropriate anaesthetics for use in quail but knowledge of the principles of avian anaesthesia have developed considerably in recent years. The report of the Joint Working Group on Refinement (JWGR 2001b) provides a useful introduction and source of information on anaesthesia and analgesia. Currently, inhalational anaesthesia is the preferred method for anaesthetising birds in many cases. The gas anaesthetic of choice is isoflurane (Carpenter 2000) due to its rapid induction, rapid recovery and minimal myocardial depressant effects. Concentrations have not been set for quail, but the recommended minimum concentration for isoflurane use in birds

is 0.5–3%. Although now not often recommended, injectable anesthetics can be used when inhalation anesthesia is unavailable (Paul-Murphy and Fialkowshi 2001). However, as many injectable anesthetics are no longer recommended, a veterinarian should be consulted before they are considered. Paul-Murphy and Fialkowshi (2001) summarise the various injectable drugs and dosages that have been used in birds. Further valuable information on avian anaesthesia is provided in Chapter 44 on pigeons and doves.

## Euthanasia

Methods of euthanasia for birds are reviewed in the Report of the Joint Working Group on Refinement (JWGR 2001b). Quail are usually killed by cervical dislocation or lethal injection. For a small bird like the quail, cervical dislocation is often the preferred method. However, it should be noted that unless the brainstem is destroyed in the process, brain function may persist for some seconds. A suitable agent for lethal injection is sodium pentobarbital. The dose rate for intra-coelomic injection is 6 ml/kg body weight of a 6% solution (Mills *et al.* 1999). See Chapter 44 for further information on euthanasia of birds.

## Common welfare problems

### Causes of mortality

The highest rates of mortality are usually seen during the first week post-hatching (Lölinger & Schubert 1966; Zucker *et al.* 1967; Lucotte 1974). Careful management (control of temperature, pre-heating of husbandry units and avoidance of draughts) and correct nutrition are important in reducing early mortality. Under proper management, mortality should be less than 5%.

In adult male birds, traumatic injury is the most frequently cited cause of death. Infections of the reproductive organs following prolapse of the uterus, or shell gland, are a common cause of death in adult females (Ernst & Coleman 1966; Lölinger & Schubert 1966; Nagarajan *et al.* 1991; Woodard *et al.* 1973). Woodard & Abplanalp (1971) estimated that approximately 1% of female birds died from injury or prolapse of the shell gland during each week of their study. However, such mortality can be reduced or prevented by delaying the onset of sexual maturity through manipulation of the photoperiod. The authors found that the frequency of prolapse varied among different strains. If the female can be taken out of egg production (put under a short lighting scheme) when prolapse is first observed, and housed individually to avoid pecking by other birds, the prolapse can generally recover. Prolapses that occur for more than 24 h are difficult to revert.

Other reported causes of mortality in quail include head injuries and emaciation and careful measures should be taken to avoid these. Emaciation appears to occur for a variety of reasons including social competition (Lölinger & Schubert 1966; Zucker *et al.* 1967; Benoff & Rice 1980; Edens *et al.* 1983) and mechanical difficulties in reaching drinkers and feeders.

## Disease

### Prophylaxis

Good hygiene and barrier systems which prevent infection from outside sources are the most important aspects of prophylaxis in Japanese quail. Good ventilation and husbandry (see earlier in this chapter) are important for the prevention of aspergillosis. Fumigation of eggs before incubation may help prevent the transmission of diseases from one generation to the next. Vaccination is not widely practised. With the exception of quail pox vaccine, no vaccines have been developed for quail. However, adult (5 week old) birds can be vaccinated against Newcastle disease using chicken vaccines (Lima *et al.* 2004). Chicken vaccine against avian encephalomyelitis (AE) is also effective in adult quail. Many commercially produced feeds contain antibiotics and anticoccidials to prevent diseases and coccidiosis. It is generally advised not to vaccinate quail unless there is a disease outbreak in the area.

### Signs of disease

The quail is an extremely disease-resistant species. Although it is susceptible to the majority of diseases found in gallinaceous birds, quail appear to have a much greater resistance to these pathogens than do domestic fowl (Farrow *et al.* 1975). Where disease and excessive mortality do occur they are frequently a consequence of management failures in high-density production flocks. Many of the symptoms of disease in quail (reduced egg output, morbidity, mortality and emaciation) are common to a wide range of infections. Furthermore, infected birds do not always present obvious clinical symptoms and it is important that specialist help for diagnosis, treatment and control be sought if outbreaks of disease are suspected.

### Common diseases

Japanese quail are susceptible to the majority of diseases found in gallinaceous birds. A list of some of these diseases is given in Table 42.8.

### Abnormal behaviour

Feather pecking, cannibalism and head-banging (caused by the birds jumping and striking their heads on the cage roof) are the most frequently cited behavioural causes of injury in Japanese quail (see Gerken & Mills 1993). Ways to minimise these behaviour patterns have been mentioned in previous sections of this chapter. Females kept in battery cages show pre-laying restlessness similar to that observed in some strains of domestic chickens (Gerken & Mills 1993) and birds of both sexes show vacuum dust-bathing behaviour (Gerken 1983). In deep litter floor pens, at higher than recommended stocking densities, and when eggs are not collected daily, egg eating has been observed in some flocks of birds. Stereotyped behaviour can be induced experimentally (Kostal *et al.* 1992) but its incidence under other conditions is unknown.

**Table 42.8** Natural and experimentally induced diseases of the Japanese quail. Modified from Mills *et al.* (1999).

Disease	Reference

Inclusion body hepatitis (adenovirus)	Mills <i>et al.</i> (1999)

## Reproductive problems

The main reproductive problem observed in quail is prolapse of the shell gland (Woodard & Abplanalp 1971). The condition is most frequently seen in young birds at the start of lay. Its incidence is greatly increased if birds are brought in lay early by keeping them on long photoperiods (eg, 16L:8D) as juveniles.

## Acknowledgements

This chapter is written based on a manuscript submitted by Andrew Mills for the previous edition of this book. The authors would like to dedicate this chapter to Andrew. They also thank Cathleen Nichols (UBC Quail Genetic Resource Centre) for valuable inputs and Dr Chris Harvey-Clarke (UBC Animal Care Centre) for reviewing an earlier draft of this manuscript.

## The zebra finch

Ruedi G. Nager and Graham Law

### Biological overview

#### Natural history

The zebra finch is a small passerine from the family *Estrildidae* (weaver finches), a group that is found in the Old World tropics and Australasia. All estrildids are similar in structure and habits, but vary widely in plumage colour and patterns. Within the estrildid finches, the zebra finch has occasionally been placed in the genus *Poephila*, but morphological, behavioural and genetic characteristics set it clearly apart from *Poephila* (Christidis 1987) into its own genus *Taeniopygia*, the name of which is based on the zebra finch's earliest name.

The zebra finch is abundant and widespread in the wild and there are two subspecies. The first of these, the Australian zebra finch *Taeniopygia guttata castanotis* (Gould 1837), has a range that covers most of the continental arid and semi-arid zones of Australia only avoiding the cool moist south and the tropical far north. The second subspecies, the Lesser Sundas zebra finch *T. g. guttata* (Vieillot 1817), lives on the Lesser Sundas and neighbouring islands north of Australia. *T. g. guttata* is smaller, the male having a smaller chest-band and less barring on the throat and upper breast compared with *T. g. castanotis*. Zebra finches are sexually dimorphic, the males having a more ornate plumage and a redder bill than females (Figure 43.1).

Zebra finches inhabit arid open steppes that provide grass seeds for food, accessible surface water for drinking and scattered bushes and trees for nesting and roosting. They are adapted for feeding on a large variety of grass-seeds and rely much more on these for food than the other estrildines. Zebra finches usually take ripened seeds from the ground, but also take half-ripe seeds from the heads of standing grasses; and this is what they feed their young on almost exclusively in the wild. Despite their tropical and subtropical distribution, zebra finches tolerate low temperatures, as in the wild they can be exposed to low overnight temperatures.

#### Size range and lifespan

There are clear morphological differences among different breeding stocks of zebra finches. Among a sample of 18 captive populations, zebra finches in European laboratories were found to be the largest (mean body mass: 16.1 g, range

13.7–18.6 g,  $n = 10$ ), presumably due to selection for large body size by the European aviculturists and Australian captive birds were the smallest (mean: 12.1 g, range 11.9–12.4 g,  $n = 2$ ) and similar in size to wild birds. North American birds were intermediate in size (mean: 14.4 g; range 13.7–15.2 g,  $n = 6$ ; information on body mass from Forstmeier *et al.* (2007)). Domesticated females are also skeletally larger, but take longer to reach adult skeletal size compared to wild birds; no such differences were found for domesticated males compared to wild birds (Zann 1996).

In the wild, there is an initial steep decline in numbers between fledging (day 15–20) and nutritional independence (day 35) when 68.5% of fledglings are lost (Zann 1996). Zann reported high offspring mortality at his field sites with only 9% of eggs leading to young surviving to breeding age. Mature free-living birds have an annual mortality of between 72 and 96%, but can occasionally live for up to 5 years; and there is no difference in the survival rates between males and females (Zann 1996). In captivity, domesticated males typically live about 3 years and females about 2 years, although under optimal conditions, the potential lifespan of domesticated zebra finches is 5–7 years (Burley 1985; own unpublished data); the oldest recorded bird in captivity reached 17 years. Among captive, domesticated birds annual mortality in females is higher than in males throughout their lives (Burley 1985).

#### Social organisation

The zebra finch is a gregarious species forming feeding flocks of a few hundred individuals when not breeding. During breeding, they nest in colonies ranging from just a few pairs up to 40–50 pairs and territoriality is confined to the nest itself (Zann 1996). Zebra finches can form pair bonds any time during the year when conditions are favourable for breeding and, once paired, develop a strong pair bond (Butterfield 1970). The pair bond is maintained through a series of calls that allow them to recognise and locate their mate (Zann 1996). Mates are selected on the basis of colour and song, and patterns of choice are similar in artificial choice chambers and free-choice aviary situations (Collins & ten Cate 1996; Zann 1996). Due to high mortality rates in the wild there is frequent formation of new pairs, but even when the pair mate has survived birds have never been observed to re-pair with their previous mate. No bird has

**Figure 43.1** Male and female wild-type zebra finches. Females have a grey back, whitish undersides and a white cheek patch bordered by a black stripe. Males are more ornate with reddish brown cheek patches, chestnut brown flanks with white spots and a black and white barred chest. Legs are orange in both sexes, but males have a deeper red bill while females' bills are more orange. (Photo: G. Law.)

been observed with more than one mate at any one time and only the two parents attend the nest (Zann 1996). In the wild, intraspecific brood parasitism is common with 10.9% of offspring and 36% of broods usually containing one or more parasitic eggs, whereas extra-pair paternity is less common with 2.4% of offspring and 8% of broods affected (Birkhead *et al.* 1990) and hence the attending parents may not always be the genetic parents of all of young they rear. Thus zebra finches are socially, but not genetically monogamous.

### Biological data

Nestlings of domesticated zebra finches weigh 0.6–0.9 g at hatching. Over the first 10 days they gain 0.4–0.7 g/day in body mass and about 1 mm/day in tarsus length (Skagen 1988; Martins 2004), but this varies with sex, size of the adult stock birds and food levels (Boag 1987). Typical rectal temperature of healthy birds during the day is 41.8°C (Conover & Messmer 1996). Haematological values for wild and captive zebra finches are given in Ewenson *et al.* (2001), with healthy captive zebra finches typically having a heterophil:lymphocyte ratio of 0.17. Birkhead *et al.* (2006) give a mean haematocrit of 51.2 (standard deviation = 3.58) for male captive zebra finches.

### Reproduction

Zebra finches are opportunistic breeders that breed whenever favourable conditions occur, regardless of time since the last breeding event and photoperiodicity (Zann 1996). This allows them to respond to the unpredictable arrival of favourable conditions and to breed rapidly at any time of year. The hatching of eggs coincides with the appearance of ripening grass seeds (Zann *et al.* 1995). Wild zebra finches in unpredictable habitat maintained a high level of repro-

ductive readiness (large gonad size and high level of circulating gonadotrophins) and more males showed readiness to breed than females (Perfito *et al.* 2007). Wild zebra finches in a predictable habitat, where breeding occurs during approximately the same months each year, changed reproductive readiness consistently between the breeding and non-breeding state. When non-breeding birds from the predictable environment were taken into the laboratory they were able to activate their reproductive axis quickly (Perfito *et al.* 2007). This suggests that there is constant activation of gonads without a refractory period and that they can rapidly respond to the presence of favourable breeding conditions. Along with this high reproductive readiness or 'hypersexuality' goes an early reproductive maturity in young birds; birds as young as 62–67 days old (median age of birds breeding in the same breeding season in which they hatched: 95 and 92 days for males and females, respectively) have been seen to breed in the wild (Zann 1996). 'Hypersexuality' distinguishes zebra finches from other small passerines and is presumably an adaptation to the unpredictable arid conditions in Australia. However, some aspects of this trait have declined in domesticated zebra finches, which show slower sexual development than wild females; domesticated females lay eggs only as early as 90 days old (Sossinka 1972a).

Zebra finches typically lay a clutch of five white eggs (range two to seven eggs) that measure about 1.5 × 1 cm, laying one egg each day in the wild and captivity. Each egg takes about 4 days of rapid follicle growth before it is laid (Houston *et al.* 1995). In the wild, parents usually start to incubate on the last or penultimate egg so that hatching occurs over 24–48 h. In captivity, parents start incubation much earlier during laying and clutches hatch far more asynchronously than in the wild. Both sexes incubate, although only the female has a brood patch (Zann 1996). Incubation takes between 11 and 14 days from the day the last egg has been laid. Zebra finches are altricial, the chicks depending on their parents for food and warmth. Young are fed by both sexes, with parents transferring seeds from their crop to the chick's crop. Chicks that have not been fed can easily be spotted as the crop of fed chicks bulges and seeds can be seen through the skin of the crop. Parents may brood their young for the first few days, and can feed their chicks several times during one nest attention bout; therefore, the number of nest visits is a poor measure of parental feeding effort.

### Normal behaviour

Males sing a complex courtship song but females do not sing. Zann (1996) estimates a foraging time of 2–4 h and that about 4 g of seeds per day is needed for wild zebra finches to meet their daily requirements. In search of food, individual zebra finches can range over an area up to at least 1 km around the nest during breeding and are highly mobile, deserting an area when conditions become unfavourable (Zann 1996). The lack of genetic differentiation of populations up to 2000 km apart (Forstmeier *et al.* 2007) supports the view that populations can range over such large distances. Non-breeding zebra finches often roost in old breed-

ing nests or purpose-built nests (Zann 1996). As another adaptation to their arid and semi-arid habitat, zebra finches have an unusually slow moult for passerines and females moult more slowly than males. Arid conditions in the wild and intense breeding activity in captivity slow the moult.

### Sources and supplies

Zebra finches used in research laboratories are derived from *Taeniopygia guttata castanotis* and have been domesticated for more than a century. In Europe, zebra finches were frequently bred in captivity by the late 1800s, but large numbers of zebra finches were still being imported from Australia until World War I, and in the 1950s further small numbers of birds that had been domesticated in Australia were imported (Sossinka 1970). In 1960, the Australian government implemented export bans on all native wildlife. Currently, zebra finches in research laboratories worldwide have presumably been domesticated for more than a century without any significant input of wild zebra finches and are genetically clearly distinct from the wild stock (Forstmeier *et al.* 2007). Domestication has altered a number of behavioural and other traits resulting in larger body size and delayed female sexual maturity in domesticated zebra finches (see earlier in this chapter) as well as in changes to the structure of distance calls and duration of song phrases (eg, Sossinka 1970; Slater & Clayton 1991; Zann 1996).

Many research laboratories maintain their own breeding stocks derived from larger stocks of aviculturists. Compared to wild birds, all captive populations have lost genetic variability, but all populations still show substantial genetic variability at 12 highly polymorphic microsatellite markers, suggesting that they were unlikely to have experienced severe genetic bottlenecks (Forstmeier *et al.* 2007). There is significant genetic and morphological differentiation among captive populations between Australia, Europe and North America with further differences between regions, in particular in Europe (Zann 1996; Forstmeier *et al.* 2007). It is clear that there have been regional differences in the direc-

tions of the domestication process, which might have arisen from differences in sources of wild stock, in climatic conditions and in show standards for size (Zann 1996). Researchers on zebra finches thus do not use a genetically uniform stock and it is essential to give information on the origin of birds used in every study.

There are many colour morphs of zebra finches. The wild type or grey morph is shown in Figure 43.1. The most frequently found colour mutant is fawn. This morph was discovered in wild birds in 1927 and formed the breeding stock from which many of the other colour morphs were developed (Zann 1996). Aviculturists have bred about 30 main morphs mainly for show competitions and most are mutations of all or particular parts of the plumage (for a list of morphs see Appendix 1 in Zann 1996). In research laboratories mainly wild-type and fawn birds are used. The colour mutation fawn is sex-linked and this has been used in the past to sex very young offspring (Birkhead *et al.* 1989; Kilner 1998). Imprinting studies have shown a strong effect of plumage colour on mate choice (eg, Immelmann *et al.* 1978) and this needs to be considered in studies on sexual selection and mate selection. Ideally, one would want to have birds of the same colour morph, but this is difficult to achieve since most colour mutations are recessive and unexpected colour morphs may appear in later generations.

### Use in research

The zebra finch is widely studied by biologists in the laboratory and field. It is one of the most popular caged birds in the world. It is hardy, easy to keep and one of the most readily bred aviary birds. Zebra finches are inexpensive to buy. They are widely used in research with the number of publications steadily increasing each year, reaching over 100 publications per year in recent years (Figure 43.2). Research using zebra finches focuses mainly on the neural basis of song learning, but also sexual selection, development of sexual preferences and physiological studies such as endocrinology and toxicity testing.

**Figure 43.2** The number of publications per year containing 'zebra finch' in the title, keywords or abstract is steadily increasing (searched on Web of Knowledge 24 October 2007).

The zebra finch genome was the second avian genome to be sequenced to 6X coverage in 2007, using initially one male bird from a North American captive breeding population (University of California in Los Angeles, UCLA). The availability of extensive genomic information is likely to be a great catalyst for further studies of the species.

### General husbandry

Although zebra finches are one of the most commonly used experimental bird species, it is surprising that very little work has been conducted on their welfare. The following account is based on 'good practice' advice from a number of laboratories and organisations (eg, Joint Working Group on Refinement (JWGR) 2001) who have many years of experience in working with this species. In most cases, however, there are no systematic scientific studies to evaluate the impact of common husbandry practices on the birds' welfare. Future work into the welfare of captive zebra finches is needed to refine guidelines for their husbandry.

### Enclosure

Enclosures for captive animals need to allow as much natural behaviour to be performed as possible (Young 2003). In the wild, zebra finches regularly flock in trees and forage on the ground and therefore require the space to carry out such movements. In the wild, the birds are highly sociable, maintaining close contact to each other and hence in captivity can be maintained at higher densities than many other species. The size of the enclosure needs to take these needs of the birds into consideration.

The size of the enclosure and the layout of the enclosure furnishings should be organised to maximise space for movement. The size of aviary should be such as to permit birds to perform horizontal flight and, if space is limited, width can be compromised in order to defend sufficient length for free flight. Spacing of the perches should be such as to encourage the maximum flight distances possible, while satisfying the need for a comfortable roost. Due to their social nature, zebra finches can be kept at relatively high densities in large flight cages or aviaries. For scientific reasons, it may be necessary to hold birds under standardised conditions in smaller cages either individually or in pairs. Although the effect of separation from conspecifics on isolated zebra finches has not been studied, many sources recommend minimising the time zebra finches are not kept with others (eg, JWGR 2001).

Zebra finches can be kept in standard cages with solid sides on all but the front. It is recommended that cages should be made of an easy-to-clean material to provide a hygienic environment for the birds. Cages can be stacked or mounted on wall brackets. Zebra finches can also be kept in aviaries constructed with a frame of steel or treated wood and covered with wire mesh of  $\leq 10$ mm width or vertical bars not more than 12mm apart. Aviaries can be indoors. Zebra finches in the wild, however, experience a wide range conditions and can be exposed to freezing temperatures (Meijer *et al.* 1996). Thus they can also be kept outdoors

**Table 43.1** Minimum enclosure dimensions and space allowances for zebra finches as good practice recommended by the BVA(AWF)/FRAME/RSPCA/UFWA Joint Working Group (JWGR 2001) and the European Commission (2007).

	Minimum enclosure area (m <sup>2</sup> )	Minimum height (m)	Minimum number of feeders
Single bird or breeding pair	0.5	0.3–0.4 <sup>1</sup>	
Up to 6 birds	1	1	2
7–12 birds	1.5	2	2
13–20 birds	2	2	3
Per each additional bird above 20	0.05	2	1 per 6 birds

<sup>1</sup> BVA(AWF)/FRAME/RSPCA/UFAW joint working group report (JWGR 2001) recommends a minimum height of 0.3 m whereas the European Commission (2007) recommends 0.4 m

throughout the year provided they have sufficient protection from wind and rain such as shrubs and access to an indoor area with supplemental heating in winter (JWGR 2001).

There are hardly any data on the effects of enclosure size on the welfare of zebra finches. In a study involving very small numbers, Jacobs *et al.* (1995) found reduced activity, in a number of behaviours, in cages with an area of 0.11 m<sup>2</sup> compared to cages with an area of 0.22 m<sup>2</sup> (the latter cage size is approximately current practice). There is a large gap in our understanding of the effects of enclosure size on zebra finch behaviour and physiology. Nonetheless, several organisations have provided guidelines on what they consider best practice for space requirements of groups of various sizes (summarised in Table 43.1) and these may become legally binding in a number of countries.

### Environmental provisions and enrichments

Zebra finches normally feed on the ground and therefore require solid flooring. The floor can be covered with a paper liner or some substrate, such as bark chips, wood shavings, hemp core or sand which gives the birds a softer and more varied substrate and makes foraging for spilled seeds more challenging. Bark chips have the advantage that they maintain a hygienic floor litter, but do not work well under the dry conditions usually encountered in laboratory bird rooms. Floor substrate should produce as little dust as possible under the conditions usually encountered in bird rooms in order to keep dust levels low for the benefit of the birds and of the staff working with the birds.

Wild zebra finches spend much time perching in trees. Perches of a variety of diameters and at different heights should therefore be provided. In captivity, they prefer to perch high up in the cage and to approach the food by moving to progressively closer perches. Care needs to be taken not to overcrowd the space with perches that would restrict the birds' flight movements. Furthermore, care

should be taken not to place perches over food and water dishes to prevent fouling. Often doweling rods (ca. 0.5 cm in diameter) are provided as perches, but these are not recommended as they are too hard. Sandpaper perch covers should not be used as they can abrade the feet and provide a route for infection. Softer wood or a variety of natural branches (apple, aspen, birch, cactus wood, cherry, elm, maple, mountain ash, pear, pine, poplar and willow) are good alternative perches. Natural branches in a range of diameters (0.5–2 cm), which are often less rigid than artificial perches, allow the muscles of the feet and body involved in balance to be properly exercised and help to keep the claws in good trim. There are also artificial perches that are not of a constant diameter and are attached to the cage wall at only one side giving them the springiness of a natural branch. Perches that sway when the birds land and take off, as well as commercially available swings designed for zebra finches, help mimic the movement of trees in the wild and cause the birds to exercise a variety of muscles and use the wings for balance. Zebra finches like to sit close together and therefore perches and swings should be of sufficient length to allow at least two birds to sit on them. Perches need to be replaced, or cleaned where possible, possibly every 6 weeks to provide a hygienic environment (see Hygiene section).

Zebra finches will use both sand and water baths, sometimes using the bowl communally. In the authors' experience, baths once a week help to keep their plumage in good condition. Baths are usually provided for a few hours per day, water should be 0.5–1 cm deep and if size allows, a flat stone can be placed in the water bath, to help prevent the bath tipping over. Since zebra finches are prolific nest builders and also build roosting nests outside the breeding season, provision of some nest material to non-breeding birds may help provide good sensory stimulation. Jacobs *et al.* (1995), using a very small sample size, suggested that simple enrichments such as a larger number of perches, twigs, sand and water baths may result in increased frequency of a number of behaviours. Zebra finches with little opportunity for exercise can become obese (Birkhead *et al.* 2006).

An obvious way to stimulate captive birds is to increase foraging time and, like many other animals, they will work for food even if it is freely available (contra freeloading). Zebra finches can be provided with additional sprays of *Panicum* millet and these can be placed so that the birds need to increase their effort to feed from them. Seed spillage or intentional scatter feeding on the ground can encourage natural foraging behaviour (JWGR 2001). Mixing seeds with husks also increases foraging time and effort, but birds provided with mixtures with the highest husks:seed ratio for their entire lifetime had low foraging efficiencies (effectively starving) and produced small and few broods as well as having a poor survival (Lemon & Barth, 1992; Lemon 1993), therefore extreme caution is needed when applying this feeding method.

### Feeding and watering

In the wild, zebra finches forage on a wide variety of seed types and sizes (Zann 1996). Captive birds do best on a diet of foreign finch seed mixes (largely millet and canary seeds).

Food can be provided in feeders mounted on the cage wall or in petri dishes provided on the ground but the latter result in a lot of seed spillage. The daily requirement for seed by domesticated zebra finches under standard laboratory conditions is about 3 g. Seeds should be provided in at least two feeders per cage and, if birds are kept in social groups, provisioning of several dishes is recommended (see Table 43.1) to avoid monopolisation of the food by dominant birds at the expense of subordinates. To assist the breakdown of seeds in the gizzard it is essential that birds are given fine oyster shell and other grit, and this should be available separate from the seeds, so that the birds can control their intake.

To balance the diet, zebra finches should, once or twice a week, be given good-quality greens such as dandelion leaves, the darker outer leaves of lettuce, chickweed, spinach, watercress or vegetables (eg, grated carrots, cucumbers) and fruits (eg, apples, oranges and bananas). Several vegetables and fruits may have to be tried to see what appeals to the individual finches. Greens, vegetables and fruits form an important source of dietary carotenoids that positively influence the bird's health and affect bill coloration (Blount *et al.* 2003a; McGraw *et al.* 2003). Sprouted seeds should also be given to birds to satisfy the need for greens. In order to germinate the seeds, normal finch mix can be soaked in clean water, thoroughly rinsed after 24 h and then soaked in water again. After 48 h rinse again, drain thoroughly and place on paper towels in a flat tray in a warm and dark place. Depending on temperatures, seeds will sprout in 24–36 h and sprouting of over 60% indicates that the seeds are relatively fresh. The sprouted seeds can be fed at any stage but are best in the first 36 h. Zebra finches also like soaked seeds (seeds are soaked for a day in clean water and rinsed) and live insect prey, such as mealworms or cricket nymphs (again one may need to try different live insects to see what appeals the individual finches). Birds should always also have access to some form of calcium as this is an essential mineral. A good source of calcium is cuttlefish bones, positioned so that the birds have access to the softer side. These have the additional benefit of helping to keep the birds' bill in good trim. Other good sources of calcium are crushed sea shells or domestic chicken egg shells (it is recommended to microwave domestic chicken egg shells for a few minutes to kill any bacteria that may pose a health risk) or commercially available calcium supplements can be provided in the drinking water.

Any potential deficits in the diet can be corrected with supplements. Supplements can be added in liquid form to the birds' drinking water or in powder form to the grit. Because finches remove the husk from all seeds before consumption, any food additives on the seed surface are likely to be discarded before eating. Protein-rich foods such as cooked domestic chicken eggs or commercially available protein supplements, live insect prey and greens should be provided regularly but in small amounts and in several separate dishes to prevent birds overeating protein-rich food that can cause diarrhoea.

Special attention should be paid to diet during breeding. Egg formation is a very demanding process both in nutrients and energy requirements. Protein is of paramount importance in egg formation. Zebra finch females use protein

stored in muscle tissue to contribute to egg formation and build these stores up over several weeks prior to breeding. Females fed *ad libitum* with a protein-enriched diet from 2 weeks before breeding produced larger eggs, larger clutches and had a higher breeding success than birds on a control diet (Selman & Houston 1996). Good sources of protein are boiled chicken's eggs or commercial protein supplements. Dietary calcium is also important for egg formation. Females with *ad libitum* calcium (calcareous grit, cuttlefish bone and fine oyster shell) provided regularly throughout pre-breeding and breeding laid eggs with stronger shells compared to females on a calcium-deficient diet (Reynolds 2001). Calcium may also be given as a supplement in drinking water and the manufacturer's guidelines should be checked for proper dosage. Pre-laying females supplemented with carotenoids mixed into their drinking water and with carotenoid intakes raised to the upper range of that which their normal seed diet provides, formed eggs with higher carotenoid content in the yolk. This was found to result in higher hatching and fledging success and in more brightly coloured males compared to offspring from females on a control diet (McGraw *et al.* 2005). Rearing and conditioning supplements and greens and fruits are a good source for additional carotenoids.

The quality of the rearing diet affects growth and development. Compared to nestlings on a diet of mixed seeds with *ad libitum* low-protein (7%) commercial conditioning food, nestlings on a mixed seed diet enriched with high-protein (34%) commercial conditioning food and 1 g of minced hard-boiled hen's egg per day per family, grew faster and reached larger adult size (Boag 1987). Compared to nestlings that received 1.5 g of conditioning food per family once a week (conditioning food is the main source of dietary antioxidants), during their first 15 days of life, nestlings that received daily 1.5 g of conditioning food per family had higher plasma levels of antioxidants in adulthood, which have beneficial effects on the birds' health, bill coloration and immune functions (Blount *et al.* 2003a, 2003b) and had a greater reproductive performance as an adult (Blount *et al.* 2006).

Zebra finches should have access to clean drinking water on a daily basis. Birds would naturally drink from open water surfaces on the ground, but they also easily accept commercially available drinking bottles. The latter can be mounted externally to the cage, which will reduce stress to the birds at water changes. When switching from one kind of water container to another, both should be provided for a while. Although, in captivity, zebra finches (providing they are healthy) can survive several months without water on a diet of dry seed, this can result in severe bill deformation and poor plumage (Sossinka 1972b).

### Social housing

Zebra finches are gregarious birds during both the breeding and the non-breeding season, and therefore can be kept in high densities in large aviaries (see Enclosure section). When introducing unfamiliar birds, or regrouping birds, the groups need to be carefully monitored for social compatibility, unusual weight loss or signs of pecking. Whilst breeding

in groups, care should be taken that an excess of nesting sites are provided as birds will compete for and actively and aggressively defend these. Breeding in several smaller aviaries may be preferable to breeding all together in one large aviary to minimise levels of aggression. In breeding populations, male-biased sex ratios may cause social instabilities which could result in more aggressive behaviours, weight loss, reduced body condition and poorer immune functions, as have been for example observed in other captive finches (Greives *et al.* 2007).

### Identification and sexing

The most common method to individually mark zebra finches is to use split leg rings. If coloured leg rings are required for individual identification it is important to be aware that the colour of the rings may have profound effects on their social behaviour, mate attractiveness, longevity and offspring sex ratio (Burley *et al.* 1982; Burley 1986, 1988; Swaddle & Cuthill 1994; Cuthill *et al.* 1997); although not all studies have confirmed these effects (see eg, Hunt *et al.* 1997; Rutstein *et al.* 2004, 2005). In some studies, females preferred males with red leg rings and with symmetrical arrangements of multiple colours and disliked males with green leg rings and with asymmetrical arrangements of multiple colours and the same colour preferences were found for captive and recently caught wild females. Males most prefer females with black leg rings and least prefer females with light-blue colour rings. Zebra finches do not appear to distinguish between un-ringed birds and those with orange leg rings. Ring colour also affects intra-sexual dominance interactions with red-ringed males being socially dominant over green-ringed males. Hence, it is best to use colours that have less impact on the birds' behaviour and where different colours are unavoidable, to provide a sufficient number of different food sources to avoid dominant birds monopolising the food (JWGR 2001).

The zebra finch is sexually dimorphic and from 2–3 months of age the sexes can readily be distinguished on the basis of plumage markings (Figure 43.1) and the fact that only the male sings. In addition, males have a redder beak colour, whereas the beak of females is more orange, which may help to determine sex in pure white colour varieties. Before reaching the mature plumage, the sexes may be distinguished by using certain varieties where colour inheritance is sex-linked (Birkhead *et al.* 1989; Kilner 1998) or by taking a small drop of blood or a growing feather to use in a molecular sex determination (Griffiths *et al.* 1996).

### Physical environment

Zebra finches can withstand a wide range of temperatures (but it is important that extremes are avoided). The flight areas of outdoor aviaries should be protected from wind and driving rain in the winter months and suitably shaded areas provided for the summer. Hessian sacking or other garden centre windbreak materials can be used around bird flights to provide protection. Various species of dense

shrubs in the outside flight areas, avoiding poisonous varieties, have been used to provide zebra finches with shelter and a secure retreat. Outside the breeding season, zebra finches are known to protect themselves from lower night temperatures by building nests. Birds kept indoors do well when the temperature is maintained between 20 and 25 °C, and it may be worth considering a slightly reduced night-time temperature where the heating system allows.

It is unlikely that minor fluctuations in relative humidity levels would stress captive zebra finches. Humidity levels between 40 and 80% are typically recommended, and colonies have been maintained at ca. 40–55% for many years without mishap.

Most zebra finch colonies are kept at cycles of between 14h:10h and 12h:12h of light:dark. Provision of shorter days a few weeks before breeding may increase the percentage of birds breeding (see Perfito *et al.* 2007). Lights should gradually fade on and off at the start and end of each day avoiding sudden changes from dark to light and *vice versa*. Light levels should be of an appropriate brightness and as bird vision works well in light levels suitable for humans, around 500 lux should suffice. Light levels that are constantly low (below 20 lux) can cause the birds to become stressed. The visual system of birds differs from that of humans in the way that birds perceive light in the UV range and in that they have a higher temporal resolution. The latter means that captive birds may perceive the flicker emitted from conventional low-frequency fluorescent lights (100 Hz in Europe, 120 Hz in the USA). The flicker rate of the light can affect female mate choice behaviour in captive birds, possibly due to non-specific stress effects or impaired discrimination ability of visual signals (Evans *et al.* 2006). Therefore the type of fluorescent tubes needs to be carefully chosen. High-frequency fluorescent tubes (>30 kHz) that mimic the daylight spectrum (ie, with some UV component) are preferable. It is also worth considering whether there needs to be an emergency lighting system in case of power failures, as birds will not forage in the dark.

Adequate air circulation is essential to prevent accumulation of dust and gases (eg, carbon dioxide, ammonia); in the authors' bird rooms there are about 13–15 air changes per hour. This is for the benefit of the birds but also the health of staff working in these rooms. This should be achieved without causing draughts. Bird house ventilation ducts should be fitted with filters of a suitable size to remove fine dust and dander before venting outside. The build-up of feathers and dust on ventilation ducts can be remedied by regular vacuuming.

Birds should not be housed near any equipment that emits low frequency vibrations and white noise. Environmental white noise can erode the strong pair bond in zebra finches, with females subjected to this challenge showing no greater preference for their chosen male than for strangers; presumably because the noise prevents the female from hearing the calls that allow her to recognise and locate her mate (Swaddle & Page 2006). Playback of conspecific vocalisation showed that it influences the breeding schedule and clutch size in zebra finch colonies presumably through social stimulation (Waas *et al.* 2005). Playing music may be an acceptable method for managing the auditory environment by masking

potential auditory stressors, helping them feel more settled when unexpected sounds occur or introducing auditory stimulation, but more research in this area is required (reviewed in Patterson-Kane & Farnworth 2006). If playing music in bird rooms it is suggested to use classical or easy listening music played not above a conversational level (about 60 dB) and only during the birds' active periods (Patterson-Kane & Farnworth 2006). The potential positive and negative effects of playing music, however, need to be carefully monitored when introducing it.

## Hygiene

Hygiene measures in the bird room should take account of both birds, and the people working in the facility. Access to the unit should be restricted to essential staff and protective clothing, masks, footwear/shoe covers and hand-washing facilities should be used to create a viable barrier.

The accommodation should be cleaned and sanitised before each batch of birds arrives, and should be decontaminated when all the stock is exchanged. Internal bird flights and cages should have the substrates regularly changed; the length of time between changes will depend on the stocking density. Waste substrate and seed from birdcages should, where possible, be vacuumed with low-noise vacuum cleaners fitted with high-efficiency particulate air (HEPA) filters, which help avoid the displacement of fine dust particles into the air. Perches should be removed and washed in disinfectant. Perches can then be rinsed in fresh water and left to dry before re-use. Cage walls and wire need periodic cleaning. All food, water and grit containers should be regularly sterilised. Floors and walls of the bird laboratory room should be cleaned and disinfected.

## Health monitoring, quarantine and barrier systems

Occasionally individuals need to be singly housed in a 'hospital cage' because of illness or injury. A 'hospital cage' should contain a heat source that the bird can move towards or away from. A good heat source is a 25W tungsten bulb with a temperature of about 24 °C. Hospital cages can be provided within the same room, but if there is concern about a contagious disease, the bird needs to be kept in isolation with separate air ventilation or appropriate filters to protect the stock. Hospital cages should provide a good supply of food and fresh water in shallow dishes on the floor for easier access.

All staff should be aware of the normal behaviour of zebra finches and able to recognise when they are ill and need attention (see Health section). All birds entering the unit should be health screened and should be quarantined for at least 28 days before being added to stock (long enough for many common diseases to manifest themselves). Quarantine, health screening and monitoring protocols should be agreed with the attending veterinarian. All deaths must be recorded and, where there is a cause of concern, *post-mortem* examinations should be undertaken to identify the cause whenever possible.

## Breeding

Zebra finches breed readily throughout the year in indoor aviaries. Captive birds as young as 3 months are physiologically ready to breed, but for best results they should be at least 6–9 months old. For best breeding results, birds older than 4 years, particularly females, should be avoided. Little is known about variation in breeding success in relation to the birds' age and experience (but see Williams & Christians 2003). Under the relatively constant environmental temperature of captive breeding facilities, productivity may show seasonal variation with day length, more clutches being produced in summer and autumn (Boruszewska *et al.* 2007).

For best breeding results, young birds should be allowed to express mate choice, choosing their own partners from a small mixed-sex group. If particular pairings are required, most male/female couples in good condition will breed when placed in the same cage. Pair bond formation between unfamiliar birds can start immediately after introduction where the male performs a characteristic courtship dance and direct song towards the female and the female carries out an acceptance posture (for more details see Zann 1996). A sure sign of an established pair bond is when the male and female sit close to and preen each other.

Captive birds need to be provided with suitable nesting sites. Different types of nesting sites are available from wicker baskets, half coconut shells, to re-usable wooden or single-use cardboard nest boxes. Commercially available nest boxes typically have linear dimensions of at least 10 cm and an entrance hole of at least 4 cm diameter. Nest boxes mounted externally to the aviary mesh are convenient since the nest can be checked with minimal disturbance to the breeding birds. Birds need to be provided with suitable nesting material, but not in great excess. Usually the birds will start to build a nest almost immediately. Coconut fibre is a good nesting material. On a foundation platform, males and females together build an enclosed nest chamber (Figure 43.3), but when offered nest boxes they often build much less complex structures. The inside of the nest chamber is lined with some softer material. In captivity, feathers, cotton wool, fine sisal string or moss can be used. It is important that there is no risk of the birds getting their toes caught in the nesting material. When using nest boxes, the bottom of

the nest box can be filled with floor substrate to allow the bird to sit level with the entrance hole. Provision of nest material should stop once the clutch is complete as otherwise birds may continue to add nest material over the eggs and lay another clutch on top ('sandwich clutches').

The onset of breeding can be promoted by provision of soaked seeds, and greens and/or spraying a fine mist of water over the birds, but these measures are not essential. Also, good nutrition will affect the birds' breeding behaviour (see Feeding and watering section). Usually within a week, the nest is finished and the females start laying. In captivity, around the time when the third egg is laid or even earlier, the birds start sitting on the eggs and this onset of incubation is earlier than in wild birds, resulting in a larger hatching asynchrony than in wild birds. Both sexes help to incubate the eggs and keep them covered for close to 100% of the time (Gorman & Nager 2003; Gorman *et al.* 2005). After approximately 2 weeks of incubation, the eggs will start to hatch. The newly hatched nestlings are blind and only have a few areas of soft down. At hatching a rearing food (see Feeding and watering section) should be provided together with the regular seed mixture.

Like most estrildines, zebra finch nestlings are slow developers and they spend longer in the nest and take longer to reach adult weight than other granivorous species, such as fringillids and ploceines (Zann 1996). Nestling zebra finches are very hardy and 4–5-day-old chicks can endure periods of up to 36 h without food and warmth, presumably entering some form of torpor. Nestlings are fed by both parents and store seeds in their crop; the crop of newly hatched nestlings (day 0) is empty and parents only start feeding the next day. First only the right side of the crop is filled and only later when larger quantities need to be stored, the left side of the crop also fills. Nestlings start to make soft begging calls from the third day onwards, feathers start to break through by 6–7 days and eyes open fully by day 10–11. Nestlings can be individually marked using non-toxic pens on the skin and tufts of down, and marks may need to be renewed regularly. From around 8 or 9 days old, nestlings can be ringed with leg rings. To avoid birds leaving the nest prematurely, regular nest checks should be stopped when the birds are about 2 weeks old. When the birds are around 18 days old, they will leave the nest for the first time. Around day 35 the

**Figure 43.3** Zebra finches build nests when suitable nest support and nest material are available (nest on the left). Similar nests can be built inside nest boxes, which might be more suitable for outdoor aviaries and, when mounted from the outside, minimise disturbance to the breeding birds. (Photo: R. Nager.)

birds will become independent and feed independently, although they will continue to beg for a while longer. Around this time the bill colour starts to change from black to a lighter colour (which will eventually turn orange or red) and the post-juvenile moult into the adult plumage begins.

For best breeding results, birds should be kept at lower densities than in standard holding accommodation, and should be maintained in an equal sex ratio and with an excess of nest sites provided. When zebra finches breed in groups, both extra-pair paternity and intra-specific brood parasitism can occur (Birkhead *et al.* 1990). Under good conditions, zebra finches may breed continuously; but it is best not to allow them to produce more than two successive broods before a period of non-breeding. At the end of breeding, the nest should be removed. If two successive clutches are desired, young need to be removed from the cage when independent. If they are left with the parents, they may interrupt the next clutch and the parents may chase off the young birds and pluck their feathers. If a particular behavioural study, for example on song learning, requires that young are raised by females alone, this is possible. In this case it is best to delay removing the male until day 5 as there is no evidence for memorising the father's song before that age, and a reduction of the brood size can be considered (Royle *et al.* 2002). Zebra finches can also be raised from the egg stage onwards by Bengalese finches. Both inter-specific cross-fostering and female-only rearing will affect the behavioural development of the chicks. If pairs fail to feed their chicks at first, particularly first-time breeders, the nestlings can be helped through that period by some hand feeding.

It is important to keep detailed records on the breeding activity of individual birds and pairs. This prevents breeding between close relatives, allows the elimination of poor breeders and efficient rotation of the stock used in breeding. Several pedigree software packages are now available for this purpose, such as ZooEasy or LaoTzu's Animal Register.

## Laboratory procedures

### Handling

If specific individuals need to be captured and handled on a regular basis, it may be preferable to keep them in small cages where they are more easily and rapidly captured. This is less stressful to the individual bird as well as for other birds in the group. In large cages, a bird net with padded edges will be required to catch birds. Switching off the light can help to catch the bird more quickly in the dark. Once in the hand, birds should be kept with the back inside the palm of the hand, its head between the index and second finger and the wings gently closed against its sides so that the bird's chest remains free.

### Training and habituation for procedures

Zebra finches are believed not to habituate easily to handling and, compared to many other cage birds, they do not become very tame and are not as inquisitive. Nonetheless,

zebra finches will work for food, and can learn to respond to light and colour cues and to discriminate between different songs and sounds. Rewarding zebra finches after disturbance is an effective and simple way to improve their habituation to handling (Collins *et al.* 2008). Suitable rewards are small pieces of fruit, salad and live insect prey. Providing cover, eg, by an opaque cloth over part of the cage, where birds can take refuge when humans are present, however, can lead to increased fearfulness over time (Collins *et al.* 2008).

### Monitoring methods

Body temperature can be recorded using small temperature probes (<0.5mm wide) that are carefully inserted into the rectum. Blood for haematological, hormonal and biochemical analyses can be collected from three points: right jugular vein, ulnar vein and the medial metatarsal vein. As these are all superficial veins they can be punctured with a sterile needle or lancet and anaesthesia is not necessary. Blood collection should only be carried out by trained and experienced staff. Bleeding can be stopped by pressure from a swab. The vein, in particular the jugular vein, may be more easily recognisable in a well exercised bird with small fat deposits, which would reduce the duration of handling the bird. The quantity of blood that can be safely collected from healthy individuals is limited to 10% of circulating blood volume (which is about 0.1 ml for a 16 g zebra finch) and less if the same bird is re-sampled in less than 3–4 weeks (maximum of 1% of circulating blood volume or 0.01 ml for a 16 g zebra finch per 24h) (Morton *et al.* 1993). There are non-destructive methods to collect a sample of the crop content (Zann & Straw 1984) and of semen (Pellatt & Birkhead 1994).

### Administration of substances

Some drugs can be mixed with food or drinking water. Since zebra finches usually remove the husk of the seeds before ingesting them it is unlikely that they would ingest any drugs on the outside of the seed, unless de-husked seed is used. These methods can be useful for administering substances to a large number of birds, but do not permit accurate control of dosage. Suitably-sized oesophageal tubes can be used for individual birds, which allows for more accurate dosing. Injections in small passerines like the zebra finch are difficult and hazardous. Subcutaneous and intramuscular injections can be given with a 27G needle and a 1 ml insulin syringe, but great caution is necessary. A small amount of alcohol with 10% glycerine is normally used to prepare the site before injection. When the needle is removed, a dry cotton-tipped applicator is placed over the site to apply gentle pressure and stop any bleeding.

### Anaesthesia and analgesia

General anaesthesia can be achieved using gaseous or injectable anaesthetics. Gaseous anaesthetics have the advantage

that dosage is easily changed during the procedure, and recovery can be extremely rapid. They require special equipment for precision delivery. The most commonly used gaseous anaesthetic for birds is isoflurane. This agent has proved safe and extremely useful in many avian species and it is the recommended choice for anaesthesia. Ketamine has been used as an injectable anaesthetic in birds, but recovery is often troublesome, with the bird flapping and thrashing due to involuntary excitement. Hence, ketamine should be mixed with an equal volume of xylazine, which has strong muscle relaxing as well as weak analgesic properties. The reader should refer to specialised textbooks on avian anaesthesia (eg, Samour 2000) for drug dosages, methods of delivery and monitoring of anaesthesia.

## Euthanasia

Zebra finches can be euthanased by overdose of gaseous or injectable anaesthetic. Exposure to a rising concentration of carbon dioxide in an enclosed chamber has also been used but the humaneness of this method is controversial. Birds

can also be killed by neck dislocation by an experienced person but this may not be ideal as evidence from studies in poultry indicate that this does not always lead to immediate loss of brain function. See also Chapter 17.

## Common health and welfare problems

### Health

Zebra finches can be affected by a range of infectious and non-infectious diseases (see Dorrestein 1996; Jones & Slater 1999). An ill bird is normally less active than usual, and may sit in a corner in a huddled position, fluffed up, and with dull, slit or closed eyes. It is best to place ill birds in a hospital cage (see Health monitoring, quarantine and barrier systems section) and to seek prompt veterinary attention. If a contagious disease is suspected, ill birds should be immediately isolated. A summary of common infectious diseases of the zebra finch is given in Table 43.2. It is important to remember that some of these diseases can affect humans and due care is essential. Ectoparasites such as feather lice and

**Table 43.2** Some infectious diseases of zebra finches

Disease	Comments
<b>Viral</b>	
Avian pox	Uncommon. Conjunctivitis, blepharitis. Self-limiting but may be fatal. Common in some species. Torticollis, depression, weight loss
Paramyxovirus	Severe pancreatitis on <i>post-mortem</i>
Papovavirus	Common in some aviaries. Deaths amongst nestlings and young birds, developmental abnormalities, beak deformities. Hepatocellular necrosis on histopathology
<b>Bacterial</b>	
Enterobacteriaceae	<i>E. coli</i> septicaemia can be a problem in new shipments (stress-related). <i>Citrobacter</i> , <i>Salmonella</i> and <i>Yersinia</i> have also been reported
Mycobacteria	Tuberculosis (usually due to atypical <i>M. avium</i> ) can affect finches, but it is not commonly encountered
<i>Campylobacter</i>	More common in tropical finches such as the Bengalese. Inactivity, yellow droppings and high mortality amongst fledglings. Can be treated with appropriate antibiotics
<i>Chlamydophila</i> (Psittacosis)	Rare. Conjunctivitis, debilitation, diarrhoea. May see hepatomegaly on <i>post-mortem</i>
<i>Pseudomonas</i>	Usually associated with poor hygiene. Foul-smelling diarrhoea
<b>Fungal</b>	
Gastric yeast	<i>Macrorhabdus ornithogaster</i> (formerly Megabacteria) is commonly found in finches. Not too clear whether it can be a primary pathogen but it can certainly result in a chronic, debilitating condition. Affected birds are fluffed up, constantly hungry and progressively lose condition
<i>Candida</i>	Associated with poor hygiene and unbalanced diets. Crop candidiasis is seen as a distended, thickened crop with a white covering of the mucosa. Can also cause diarrhoea and moulting problems
<b>Parasitic</b>	
Protozoans	Various coccidian species can affect finches. <i>Isospora serine</i> (atoxoplasmosis) causes debilitation, diarrhoea and sometimes neurological signs, but is not very common. Other <i>Isospora</i> species (causing diarrhoea and weight loss) are more frequently encountered. Trichomoniasis causes respiratory symptoms, regurgitation and emaciation. <i>Cochlosoma</i> is not uncommon in Bengalese finches and can cause problems in other varieties. <i>Toxoplasma</i> can also be found in finches
Helminths	Both tapeworms and roundworms can be a problem but they are rare in well managed aviaries and tend to be associated with the feeding of live food
Arthropods	<i>Cnemidocoptes</i> mites can cause abnormal crusting and deformities on the base of the beak. Air sac mites ( <i>Sternostoma tracheacolum</i> ) can cause respiratory signs but are rare in finches

mites are a potential health problem in bird rooms. They can spread quickly and have an adverse effect on the birds' condition. Infected birds should be isolated and treated, and the affected bird housing should be isolated and thoroughly cleaned with compounds that are safe to use around birds.

Bald patches in the plumage could indicate presence of a pathogen or be the result of abnormal behaviour (see next section). Claws and beaks may overgrow, although they should usually be maintained naturally by the inclusion of a whole cuttlefish bone in the aviary. If claws grow too long or the beak overgrows, then the bird should be caught and these appendages trimmed with a nail clipper taking care not to clip too much. Birds that have been ringed should be monitored to ensure that their legs have not outgrown the ring, which could result in swelling of the foot, gangrene and necrosis.

Breeding females can become egg bound. This may occur for a variety of reasons (eg, a calcium deficiency, low environmental temperature, fatigue, oversized egg, etc) but the result is that the bird is unable to pass the egg through the oviduct. Affected females become hunched and fluffed up and immediate veterinary treatment is essential.

Readers may refer to Roszkopf and Woerpel (1996), Tully *et al.* (2000) or Chitty and Lierz (2008) for further information on epidemiology, diagnosis, treatment and prevention of diseases in birds.

## Behaviour

The most common abnormal behaviour observed in caged zebra finches is feather pecking resulting in bald patches in their plumage. This can be caused by self-harm, by other individuals or by environmental conditions. If persistent feather peckers are identified they may need to be removed from the group. Environmental conditions that could trigger feather pecking are overcrowding and a shortage of nest materials for breeding birds.

Breeding birds can produce 'sandwich clutches' (see Breeding section) when too much nesting material is provided for too long. Females may also lay a large number of eggs on the cage floor and in most cases don't incubate the eggs. In both cases, females will have an increased egg formation effort, which is costly to the female, without any breeding output.

## Acknowledgements

The authors thank Dr Michael Wilkinson (Deputy Named Veterinary Surgeon, University of Glasgow) for compiling the list of infectious diseases of zebra finches in Table 43.2.

## Pigeons and doves

Anthony McGregor and Mark Haselgrove

### Biological overview

#### General biology

Doves and pigeons make up the family Columbidae within the order Columbiformes. While there is no scientific distinction between the terms dove and pigeon, in practice 'dove' tends to be used for smaller species, such as turtle doves and collared doves, and 'pigeon' for larger species, such as the wood pigeon. There are currently 313 known species (Cramp 1986) within the order Columbiformes, over 300 of which are Columbidae. The majority of these species are arboreal. However, they are found within most habitats and there are both cliff- and ground-nesting species. Species vary greatly in size and in plumage colour. The smallest species measure little more than 150 mm in length, while the largest can reach up to 850 mm (Goodwin 1983). Their diet consists mostly of fruit or seeds, although invertebrates are consumed by some species that otherwise specialise as fruit or seed eaters. A common feature among species is bi-parental care, in which both sexes incubate eggs, produce crop milk and provision young. In addition, all species drink water by sucking it up without lifting their heads.

The most commonly used species for research purposes is probably the domestic pigeon, and the various varieties bred from it (eg, White Carneaux). The rock pigeon (*Columba livia*) is thought to be the ancestor of all domestic and feral pigeons. The other common species used in research is the Barbary dove (*Streptopelia risoria*), also known as the ring-dove, although Hutchison (1999) points out that, in fact, this is a domesticated variety of the African collared dove (*Streptopelia roseogrisea*). There is little sexual dimorphism between the sexes (but see below for differences in behaviour) and individual pigeons have been recorded as living for 30 years (Hutchison, 1999). Biological data are provided in Table 44.1.

#### Social organisation

Feral pigeons are colonial breeders and forage in flocks (Cramp 1986). Aggressive competition for food and partners is often observed where they occur in high densities (Murton *et al.* 1974; Johnston 1992). Although the feral (domestic) pigeon is socially monogamous, frequent pair copulation

and intense mate guarding by males suggest a degree of sperm competition (Lovell-Mansbridge 1995). However, when male partners are experimentally removed, females showed no tendency to approach other males or to engage in extra-pair copulations (Lovell-Mansbridge & Birkhead 1998). Higher levels of aggression from cuckolded males may have selected against extra-pair copulations. For example, pair bond structure in females paired with aggressive males is poorer, leading to delayed breeding in these pairs (Erickson and Zenone 1976), which subsequently affects reproductive fitness. Alternatively, Trivers (1972) suggested that one cost of cuckoldry is the withdrawal of parental care by the male. In pigeons and doves, where bi-parental care is important not only in provisioning young, but also in producing crop milk, the cost of extra-pair copulations for the female is potentially high.

#### Reproduction

Many aspects of reproductive behaviour and endocrinology have been studied in the Barbary dove and the main findings are summarised briefly here.

#### Courtship and pair bonding

The male Barbary dove expends considerable time, energy and physical resources on its own offspring, participating in both the incubation of the eggs and in rearing chicks by producing crop milk for feeding the offspring. This resource provisioning by the male is mediated by the synchrony of breeding behaviour in male–female pairs, since reproduction is successful only when the male's physical condition is synchronised with egg laying. The purpose of courtship behaviour, therefore, is to bring about the synchronisation of the physical condition of the pair (Lehrman 1965; Lovari & Hutchison 1975).

Courtship behaviour in the male Barbary dove is characterised by a transition from initial aggressive interactions (chasing, bowing and kah-calls) to nest-orientated behaviour (nest display and cooing), and changes in hormonal states accompany these behaviours. There is a change from testosterone-driven aggressive behaviour to oestrogen-dependent nest-orientated behaviour as courtship progresses (Hutchison 1999). Since the male dove has no oestrogen circulating in the plasma, testosterone is converted to

**Table 44.1** Standard biological data (Hutchison 1999).

	Body weight	Body temperature (cloacal)	Resting respiration rate
Pigeon	350–550g	40–41 °C (104–105.8 °F)	25–30/min
Dove	130–180g	40–41 °C (104–105.8 °F)	40–42/min

oestrogen by the enzyme aromatase in the preoptic area and hypothalamus (Hutchison 1991).

Hutchison (1999) notes that courtship patterns in doves and pigeons perform a number of functions, such as identification of sex and reproductive condition of females. The initial aggressive courtship by the male consists of chasing, with the body horizontal, and a kah-call, and may alternate with bowing (in doves) or head nodding (in pigeons). In doves, the male will lift his head, inflate the crop and coo as the head is lowered towards the floor. The feet are stamped between bow-coos. In pigeons, depending on the species, the beak can nearly touch the ground or the breast, and in some types, crests may be fanned out or the tail fanned. The pupil of the eye contracts in both doves and pigeons showing the iris. If the male meets another male, the encounter may result in wing-boxing. However, if opposite sexes meet, the female will alternate between retreating from and approaching the male, and this leads to nesting activity, attempted mating and full copulation 1–2 days after pairing.

#### Nest building, ovulation and incubation

Both doves and pigeons build rudimentary nests consisting of a few twigs with grass or hay collected by the male and placed in the nest by the female. The female Barbary dove increases wing-flipping (vibration of the wings) when sitting on the nest 4–5 days before egg laying. This behaviour in turn stimulates the male to bring nesting material to the female.

The time course of the transitions in male courtship behaviour has retarding or accelerating effects on the female's ovarian development. Persistent aggressive courtship patterns by the male are associated with a delay in egg laying and nest soliciting in the female. However, provisioning of nesting material by the male accelerates the female's ovulation.

In both pigeons and doves, females lay two eggs. The first egg is usually laid in the afternoon, with incubation occurring immediately afterwards. Incubation behaviour is performed by both sexes, although the male usually incubates in the mid-afternoon (Hutchison 1999). Ovulation involves the hormone prolactin, but in the Barbary dove at least, progesterone mediates the initiation of incubation behaviour and egg-laying in the female. During incubation, prolactin levels increase and the milk cells lining the crop begin to proliferate to form crop milk in readiness for hatching of the young. Young are fed with crop milk within the first hour of hatching. The crop milk becomes mixed with seeds as the young get older.

#### Breeds and supply

Barbary doves have probably been domesticated for centuries and are available as caged birds throughout the world. The wild-type African collared dove (*Streptopelia roseogrisea*) is slightly smaller than the Barbary dove and is confined to Northern Africa, south of the Sahara, and western central and south western Arabia, occurring in acacia thorn scrub. The collared dove (*Streptopelia decaocto*), which has recently spread across the north-west of Europe into Britain, is occasionally used as a laboratory bird. It is slightly larger than a Barbary dove and with darker coloration. The courtship and incubation behaviour are very similar to those of the Barbary dove.

There are over 200 breeds of domesticated pigeons, and within each breed there may be a number of colours and markings. In pigeons there are four main colours: red, black, blue and brown, and many plumage types: fantails, feathered feet and crests. 'Croppers' have the ability to inflate the crop, while 'tumblers and rollers' tumble and roll while in full flight. Because of the genetic variety available, checks should be made to ensure that the strain or breed selected does not show abnormal behaviour when selecting a strain for use in the laboratory.

Barbary doves and especially different strains of pigeons are available from bird dealers, while a useful source of domestic pigeons is pigeon racers. As they are domesticated species, there is no need to obtain free-living birds. In fact, obtaining pigeons from the wild may import diseases into the laboratory.

#### Uses in the laboratory

The pigeon is the standard avian animal when comparison between mammals and other phyla are made in physiology and anatomy; it has a similar status to the 'white rat' in laboratory studies. Pigeons have been used extensively in visual and auditory physiological research (eg, Granda & Maxwell 1979; Erichsen *et al.* 1982). Particularly important in some of these studies is the strong lateralisation of brain function that occurs in birds (eg, Güntürkün *et al.* 1998). The sensory basis of mechanisms that allow the domestic (homing) pigeon (*Columba livia*) to display the remarkable ability to return to its loft from unfamiliar sites has been studied extensively over the past 50 years (eg, Papi 1992; Bingman 1998; Wallraff 2001). The pigeon is known to use olfaction, magnetic fields and the position of the sun in the sky for long-range homing (Walcott 1996). Less well studied are the mechanisms behind homing in the birds' familiar area. Visual landmarks are thought to be important (eg, Braithwaite & Guilford 1991; Wallraff *et al.* 1993), and how the pigeon learns and uses information about landmarks is becoming clearer (eg, Biro *et al.* 2004). The other major laboratory use for pigeons is in experimental psychology in studying visual discrimination, cognition and learning. Pavlovian and instrumental conditioning tasks in conditioning chambers are used extensively with pigeons in experimental psychology (eg, Haselgrove *et al.* 2005; McGregor *et al.* 2006). In addition, pigeons have been valuable in work on toxicology.

Since the 1960s, the endocrine basis of the reproductive behaviour of the Barbary dove has been studied. More recently neuroendocrine studies have focused on the androgen-metabolising brain enzymes, the aromatase system (Hutchison 1991) which forms oestrogen in brain neurones. Brain aromatase levels providing oestrogen for nesting behaviour are high in doves and are regulated by environmental as well as endocrine factors. The male dove has provided a model for studying this system. The control of prolactin secretion and its role in maintaining incubation behaviour and crop milk production is also being extensively studied in the Barbary dove (Lea & Sharp 1991; Horseman & Buntin 1995).

Because the domestic pigeon and the Barbary dove are the most commonly used species in the laboratory, the following sections on Laboratory management and breeding and Common welfare problems will be primarily concerned with this species. Where other species are discussed, this will be made clear in the text.

## Laboratory management and breeding

### General husbandry

#### Housing

##### *Indoor*

The European Commission (2007) has recently produced updated guidelines on minimum standards of housing that include the housing of pigeons (see also the revised Appendix A to the European Convention for the Protection of Vertebrate Animals used for Experimental and other Scientific Purposes (Council of Europe 2006) and Joint Working Group on Refinement (JWGR 2001a)). If pigeons or doves are to be housed indoors, it is recommended that both the quantity and quality of space provided is sufficient to allow the bird to engage in a range of behaviours including, if possible, flight. Pigeons housed either individually, or in pairs in small cages are often unable to extend their wings fully. Such housing, therefore, should not be considered appropriate for long-term housing. Wherever possible, pigeons and doves should be housed in an aviary large enough to permit flight. JWGR (2001a) recommends pens (7 m × 3 m × 3 m high) or tunnel aviaries (20 m × 7 m × 3.5 m high). If the provision of an aviary is not possible, access to a room in which exercise flights can be conducted is recommended during the morning and/or late afternoon. There is a circadian rhythm in bird activity, with more calling and feeding in the morning than the afternoon. Long, narrow pens (eg, 2 m × 1 m) can also be recommended as these permit short flights.

In laboratory cages, there is a build-up of white 'dust' (keratinised scales) from the feathers and skin of doves and pigeons. Cages should be cleaned at least once a week: wiping with a damp cloth removes this dust. In addition, it is essential to have frequent air changes – fans bringing fresh air into the laboratory, and extraction fans to clear laboratories of dust. Wolfensohn and Lloyd (2003) recommend at least 10 air changes per hour, although the UK Home Office recommends 15–20 (Home Office 1989).

##### *Outdoor*

If pigeons and doves are to be housed in an outdoor aviary, then consideration must be given to the provision of ventilated, but draught-proof, covered shelters. If necessary, a supplementary heater may be used. The environmental provisions and enrichments described in the next section outline some of the steps that may be taken to further enhance this environment.

#### Environmental provision and enrichment

Nesting facilities, nesting material and perches (allow 20 cm per dove, 30 cm per pigeon) are necessary in cages when birds are paired and in aviaries. In aviaries, shelving on which the birds can display courtship can be provided. A flat tray with clean water for bathing will be used frequently by both sexes. Pigeons also seem to enjoy a shower, and a fine mist of warm water can be sprayed at individual birds with a commercial plant sprayer. If birds are caged indoors, it is advisable to use 'daylight' strip lighting controlled by a time clock. Fourteen hours of light will induce and maintain sexual activity and breeding behaviour. Birds housed in cages can benefit from the provision of toys such as bells and mirrors that can be hung from the cage by chains.

#### Social grouping

Doves and pigeons can be maintained as single-sex colonies, but usually the sexes are mixed to prevent excessive aggression. It is advisable to monitor groups closely when first acquired to ensure that birds do not bully or injure others. If housed in pairs, males should not be caged together as they may fight.

#### Laboratory feeding and dietary requirements

Food can be provided either in open bowls or in hoppers attached to the side of the cage or aviary. Since some birds consume preferred foods selectively, it is essential that food hoppers are replenished each day with fresh food. Females can be discouraged from nesting in the food trays by providing covered nesting boxes positioned well away from the food. Foraging can be encouraged by scattering seed upon the floor. In addition, hand feeding provides an excellent method to habituate the birds to contact with humans, which is desirable if the birds are to be handled regularly.

Domestic pigeons and many doves are omnivorous (JWGR 2001a; Redrobe 2002). Consequently, vegetable proteins alone will not provide sufficient nutrients and amino acids for these birds. Thus, a supplement such as turkey starter crumbs or chick-rearing meal should be given. Grains commonly fed to pigeons are kaffir corn, maple peas, hemp, maize, vetch, millet, wheat, oats and barley. Some green food, chick-rearing meal, shell, grit and salt are usually given. Kaffir corn, wheat, maize, millet, finely ground oyster shells and starter turkey crumbs can be fed to doves. Turkey crumbs typically contain vitamins A, D<sub>3</sub> and E supplements, ash, methionine, copper(II) sulphate, lasalocid sodium and may contain dimetridazole to control protozoal diseases. If

starter turkey crumbs are not used, vitamin supplements should be used. Adult pigeons require approximately 28 g of food per day, and pigeons which have only limited exercise should not be fed *ad libitum* otherwise they tend to become overweight. Body condition can be monitored by regular weighing.

Minerals play an important role in bone growth and egg-shell formation, and are an essential supplement. Calcium and phosphorus are required in relatively large quantities and can be given as crushed shells, for example crushed oyster shell, or as powdered or liquid supplements added to the water (although it may be hard to meet daily requirements in this way). It is also usual to consider a vitamin supplement, as sufficient vitamins do not occur in cereals and legumes. Insoluble grit plays a key role in the digestive process of the pigeon and dove as it is stored in the gizzard and used to grind and break down seeds and other fibrous matter before chemical digestion.

### Water

Fresh water should be provided daily. To prevent the birds fouling the water, the containers should either be covered or, if the birds are housed in a cage, the container should be mounted on the outside of the cage. Some birds do not drink when first caged individually. This problem can be avoided by providing the water in see-through reservoirs. Birds which still refrain from drinking can be encouraged to do so by gently immersing their beaks in the water.

### Identification and sexing

Individual birds can be identified for life if ringed at fledging with numbered and/or coloured, split plastic rings. Although the males of some strains of pigeon have distinctive colouring (eg, red chequers, mealies and silvers, which show black flecking), in general, the plumage of the male and female pigeon or dove will have the same form throughout the lifespan of the bird, making sexing a difficult task. In the domestic pigeon, the eyes of the young male are more widely spaced than in the female. In adults the male may be more heavily built than the female and the head rounder with larger wattles and ceres than the female who will tend to have a slighter build and a flatter head.

Hutchison (1999) suggests that domestic pigeons can also be sexed by their behaviour. Males strut, bob up and down and emit a double 'coo', while females emit only a single coo. In addition, males turn 360° circles, fan out their tails and drag them along the floor whilst courting a female. At about a year old, once doves and pigeons are sexually mature, the sex of the birds can be determined using observations of courtship behaviour. Each bird is placed in a cage with a known sexually active male. If the unsexed bird is female, it will retreat from the sexually active male and, usually after 5 minutes, the known sexually active male will display nest soliciting and the female will approach the male. If the unsexed bird is a male, aggressive courtship behaviour (chasing, bowing, pecking, kah-calls and wing-boxing) will be displayed. However, it is important to note that identification of sex by either observation of behaviour or external anatomy requires considerable experience before

these criteria can be used with any degree of accuracy, and even then, should not be regarded as an entirely accurate method of identification. More reliable methods of sexing doves and pigeons before the birds are sexually mature include DNA sexing by commercial laboratories (using a blood sample or tissue from a growing feather), or by visually examining the gonads by laparotomy under general anaesthesia.

### Transport and quarantine

Information on the transport of laboratory animals has been provided by Laboratory Animal Science Association (2005). The Live Animals Regulations Manual (2007/2008) provides comprehensive information concerning international regulations for air transportation of animals, and is available from the international air traffic association website<sup>1</sup>. For establishments in the UK, transport of non-human vertebrates within Europe must comply with regulations set out by The Department for Environment, Food and Rural affairs<sup>2</sup> and the Home Office code of practice (Home Office, 1989). See also Chapter 13 on transport.

Providing there is adequate ventilation, pigeons and doves may be transported for short distances in wicker baskets or in cardboard boxes. It is not advisable to give them water continuously as the plumage may become damaged. After a journey of 1–2 h birds should be given food and water. Upon arrival in the laboratory, it is recommended that incoming birds should be health checked by a vet and any treatments and disease control procedures necessary should be undertaken (eg, to control internal and external parasites).

### Breeding

#### Condition of adults

A 14 h light/10 h dark regime induces sexual activity in adult male and female doves. If, however, artificial light is not used to induce sexual activity, it is best to pair doves in February or March in northern latitudes. To reduce aggression in the male, it is advisable to introduce the female to a male who has already established a perching and nesting site. Doves and pigeons can form pair bonds and mate for life, therefore separating breeding pairs may cause distress. However, if the birds are kept in an aviary, breeding can be unsuccessful due to competition for the females from intruder males. Placing pairs in separate cages prevents this interference and allows the behaviour of the pair to be monitored. When the birds are sexually active and behaviourally compatible, egg-laying should occur about 10–12 days after pairing. However, if no eggs are laid within 20 days then the birds should be paired with different partners. Pigeons should be allowed to rest and should not be bred all year round. In particular, they should be allowed to moult normally in the autumn.

<sup>1</sup><http://www.iata.org>

<sup>2</sup><http://www.defra.gov.uk>

### Nesting and incubation

When birds are paired, nesting material (straw and twigs), as well as earthenware nesting bowls or papier maché nest pans, should be provided. Filling the nesting bowl with sand or newspaper prevents cracking of the eggs. The male sits for shorter periods, usually in the afternoon. Earthenware pans should be disinfected between broods.

### Hatching

Hatching occurs 14 days after the beginning of the incubation period, in the dove. In pigeons, hatching occurs after 17 or 18 days of incubating. If pairs are compatible, about three to four broods are produced on normal day length during the reproductive season, which is until the end of September in northern latitudes. Maintained on artificial light, pairs will produce young at about 2-monthly intervals for 1–2 years.

### The young

Squabs are incapable of locomotion and do not leave the nest for the first 8–10 days. Both the male and female produce crop milk to feed the young for approximately 10–12 days after hatching. The crop milk, as mentioned earlier, becomes mixed with seeds as the young get older. The parents then continue to feed the squabs grain, until fledging occurs at between 21 and 24 days. Young birds should not be allowed to breed until they are at least 36 weeks old. Squabs must be able to grip the substrate with their feet to prevent 'splayleg'. Birds that hatch with splayed legs, or develop them, will never walk, and must be humanely killed. It is usual to leave the parents with the young for the first month. The young birds are then ringed and caged.

### Reproductive problems

Egg binding may be caused by calcium deficiency, infection or malformation of the oviduct, or soft-shelled or broken eggs. Egg binding can be very serious and signs may include depression, droopy wings, abdominal straining and weakness or paralysis of one or both legs. A hard swelling can usually be felt in the lower abdomen. A lukewarm bath may help the egg pass. Soft-shelled eggs are almost always due to a deficiency of calcium in the diet. During breeding, pigeons and doves have a particularly high requirement for calcium, which should be freely available. Females that continually lay soft-shelled eggs should not be used for breeding.

### Laboratory procedures

#### Handling

Pigeons and doves can easily lose feathers if they are improperly handled. To avoid this, quickly grasp the bird from behind around its body and wings (Figure 44.1a). An inexperienced handler may have to use both hands used at first, but with practice, an adult pigeon or dove can be both caught and held with one hand, leaving the other hand free to open wings, check feather condition, etc (Figure 44.1b). Avoid pointing the cloaca towards the person, as the bird may choose to defecate, particularly if it is not habituated to humans. Pigeons housed in an aviary or in large groups can be caught with a net, and dimming the lights can ease capture. However, if the birds are accustomed to hand feeding, pigeons and doves will fly to the hand. A number of pigeons can be transported a short distance (such as

**Figure 44.1** (a) An experimenter handling an adult pigeon, using two hands. (b) Holding a smaller bird, giving the handler more freedom.

between an aviary/holding room and a nearby laboratory) at the same time by gently placing them head first into individual measuring jugs. The pigeon will typically remain in the jug without attempting to escape.

### Behavioural training

Pigeons are frequently used in experiments designed to investigate the psychology of learning and memory. Usually, they are housed individually or in pairs before tests in conditioning chambers in which visual or (less frequently) auditory stimuli are presented to the bird, along with food reward. Prior to the tests the animal is caught, placed in either a cloth bag, or plastic jug for weighing before being placed into a dark, or dimly illuminated chamber. Before training begins, there is usually a period during which the bird settles.

A less stressful procedure for housing, weighing and testing pigeons in the laboratory has been described by Huber (1994). The pigeons are, in this case, housed in outdoor aviaries with perches, a pigeon loft for nesting and hatching eggs, water, but no food. They enter the experimental chamber directly from the outdoor aviary through connecting channels to obtain food. After an acclimatisation phase of several days, the birds enter the channels daily. The animals are weighed automatically on a scale in the floor at the rear of the chamber.

### Recording body temperature

Temperature may be taken by inserting, to a depth of not more than 2 cm, a cloacal thermometer, or thermister into the cloaca. The average body temperature of the dove and pigeon is 40–41 °C (Hutchison 1999).

### Collection of blood sample

In adult birds, blood samples may be collected from the brachial vein, which runs parallel to the external aspect of the humerus, on the underside of the wing. Puncture immediately above the elbow joint is not recommended, as haemostasis can be difficult to achieve at this site. Application of pressure with the thumb at the proximal humerus can help to raise the vein, making it clearly visible. Once the route of the vein is located, feathers can be parted by lightly wiping the injection area with cotton wool soaked in surgical spirit. The blood volume in birds in general is approximately 7 ml/100 g body weight. For a single sample, 0.5 ml/100 g of body weight can be drawn safely (see also JWGR 1993).

### Administration of substances

As with the collection of blood, it is not necessary to pluck the feathers when administering substances by injection. Lightly wiping the injection site with surgical spirit and parting the feathers will provide sufficient access to the skin.

- Oral administration. Solid or liquid oral preparations are best administered in the drinking water or in the feed. However, oral gavage may be necessary for unpalatable substances, or under conditions in which a precise dose is necessary. Take care to avoid the trachea when inserting a tube or substance into the oesophagus. The trachea in the pigeon is located behind the tongue and should be identified before carrying out the procedure. Catheters to be inserted into the oesophagus should be lubricated to avoid damage to either the oesophagus or the pharynx. This procedure requires two people, and firm but gentle restraint of the bird. Sharman *et al.* (2001) recommend a maximum oral dosing volume of 10 ml/kg.
- Subcutaneous injection. The most common site for subcutaneous injection is under the loose skin in the back of the neck. The maximum dose is 2–5 ml/kg (Sharman *et al.* 2001).
- Intravenous injection. Frequently used sites include the ulna, right jugular and medial metatarsal veins. One should aim to use the smallest gauge needle possible for injecting pigeons and doves intravenously. Sharman *et al.* (2001) recommend that the injected volume be no more than 5 ml/kg. It is essential to ensure that the bird is adequately restrained.
- Intramuscular injection. Intramuscular injections can be given into the pectoral muscles. Pigeons possess a renal system that can move the blood flow from the lower extremities to the central circulation. Injection into the thigh muscle, therefore, is not recommended as drugs may be eliminated quickly by the kidneys. Intramuscular injections are painful and can affect mobility. They can also result in death of living tissue (necrosis), it is therefore preferable to administer substances subcutaneously, wherever possible. Intramuscular administration of large volumes should be divided between different injection sites, and the total dose should not exceed 0.05 ml/kg (Sharman *et al.* 2001). Care must be exercised so as to not inject into blood vessels. This can be achieved by refraining from inserting the needle too deeply and, prior to depressing the plunger, withdrawing it slightly to check for signs of blood.
- Intraperitoneal injection. Substances should not normally be administered to pigeons or doves by intraperitoneal injection as the substance can easily enter the air sacs and disrupt their function.

Further guidance and recommendations of the administration of substances to birds can be found in Harrison and Harrison (1986); Richie *et al.* (1994); Sharman *et al.* (2001); JWGR (2001b).

### Anaesthesia and analgesia

#### Anaesthesia

The inhalant anaesthetic, isoflurane, has become the preferred agent for both short and long anaesthesia due to its reliability and the rapid recovery from its effects. Prior to anaesthesia, the pigeon must be fasted for 6–8 h to empty its crop and minimise regurgitation. Ophthalmic ointment

should be applied to the eyes to prevent the drying of the corneas.

Induction of anaesthesia can be achieved with either a face mask, or an induction chamber at 4% isoflurane, and 1–2l/min flow. Once induction has occurred, anaesthesia should be maintained using endotracheal intubation if the bird is over 100g (Redrobe, 2002; Wolfensohn & Lloyd, 2003). Redrobe (2002) recommends flushing with oxygen every 5 minutes to prevent hypercapnia. Air exchange is very efficient in birds, and the depth of anaesthesia can change rapidly when using gas inhalants. However, maintenance anaesthesia may be set initially at 2–3% isoflurane and 1–2l/min flow. Responses should be monitored to maintain a light to medium depth of anaesthesia, and concentration of isoflurane adjusted accordingly. The relationships between responsiveness and the depth of anaesthesia were reported by Abou-Madi (2001), and a selection of these are shown in Table 44.2. Birds lose heat rapidly during anaesthesia and a heated blanket may not provide sufficient thermal support to prevent a decrease in body temperature. A heat lamp may be employed during surgery, but care must be taken not to overheat the bird. Body temperature should be monitored with a rectal thermometer.

Wolfensohn and Lloyd (2003) state the importance of flushing with oxygen at the end of anaesthesia to prevent reabsorption of anaesthetic. Warmth and subcutaneous fluids should be provided during recovery from anaesthesia. The wings can be controlled during recovery by wrapping the bird in a towel, taking care not to restrict breathing. The bird should be monitored during recovery in a dark, or dimly lit, quiet area. A smooth recovery can be produced by administering analgesics immediately after surgery, but they can also be administered preoperatively for a smoother induction. Indications of pain in birds can include agitation and restlessness, loss of weight, appetite and variations in the preening of a painful site. Opioids (eg, butorphanol, 1–4 mg/kg subcutaneously) and non-steroidal anti-inflammatory drugs (eg, carprofen, 5 mg/kg, or meloxicam, 0.2 mg/kg) can be administered as analgesics.

**Table 44.2** Levels of anaesthesia (after Abou-Madi, 2001).

Response	Light anaesthesia	Medium anaesthesia	Deep anaesthesia
Voluntary blinking	Slow or absent	Slow or absent	Absent
Muscle relaxation	Moderate–good	Good	Absent
Breathing pattern	Rapid and deep	Slow, deep, regular	Slow, shallow
Palpebral reflex <sup>a</sup>	Present or slow	Slow, intermittent	Absent
Pedal reflex <sup>b</sup>	Present or slow	Slow, intermittent	Absent

<sup>a</sup>The palpebral reflex can be elicited by running the finger along the eyelashes.

<sup>b</sup>The pedal reflex can be elicited by squeezing the toes between the thumb and forefinger.

## Euthanasia

Injectable agents such as sodium pentobarbital can be administered intravenously into the medial metatarsal vein to bring about death (150 mg/kg). Injection may also be given intrahepatically, with the injection site under the sternum along the ventral midline. However, intracoelomic injection should be avoided because the crysallisation of barbiturate drugs may cause pain and distress to the animal. Cousquer and Parsons (2007) provide excellent details on locating the medial metatarsal vein and other advice on euthanasia.

Exposure to carbon dioxide is widely used for the euthanasia of mammals, but its applicability to birds remains controversial as exposure to the gas can result in distress in some animals (JWGR 2001a), and there are other satisfactory alternatives (see 2006 report by the Animal Procedures Committee<sup>3</sup>). The authors' observations, however, suggest that a rising concentration of carbon dioxide introduced into an induction chamber does not result in any noticeable aversive response in the pigeon. Whichever method is used, death must be confirmed with dislocation of the neck.

## Common welfare problems

### Health and disease

#### Prevention of disease

In outdoor aviaries or lofts, primary prophylaxis may be aided if wild birds such as sparrows, pigeons and wild doves are prevented from entering or perching on top of aviaries. When contact with wild birds is limited, doves and pigeons are usually free of infectious disease, particularly if they are sourced from a reputable supplier. Transmission of endoparasites occurs where there is poor hygiene, overcrowding and warm, moist conditions. Therefore, as secondary prophylactic measures, keep drinking water clean and remove faeces weekly, so as to break the life cycles of these parasites.

#### Health monitoring and signs of disease

Hygiene is of prime importance since infections can spread rapidly from one bird to another. Clinical signs of disease are not always obvious. One useful method of monitoring the health of birds is to keep regular records of the weights of individual birds. Birds may initially be examined in the cage or on a perch. Redrobe (2002) lists criteria for monitoring health in the perching bird: can it perch?; are its feathers ruffled?; is it alert and responsive?; is its respiration normal?; is there feather loss, or a change in quality of feathers, beak and nails?; is the bird standing with equal weight on both legs and are the wings held at equal lengths? The authors would also recommend observation for changes in faeces. Abnormalities in any of these factors may indicate problems with the bird's health.

<sup>3</sup><http://www.apc.gov.uk/reference/schedule-1-report.pdf>

Feeding is a good time for health monitoring. If hand feeding, the opportunity may be taken to inspect the feathers which, in a healthy bird, should feel silky to the touch. Redrobe (2002 p. 171) lists common clinical conditions that may be detected when the animal is being handled.

Later signs of illness include the bird remaining in a moribund state on the perch or floor of the aviary, crouched with feathers fluffed out and head down. Birds in this state will not respond to a loud noise such as clapped hands.

More specific information on the diseases most likely to occur in captive pigeons and doves, their diagnosis, and appropriate treatments follows (Davis *et al.* 1971; Keymer 1991). A particularly good source of information on disease and pathologies in pigeons is Cousquer and Parsons (2007). Other sources include Nepote (1999), Redrobe (2002), Rupiper (1998a, 1998b) and Tudor (1991).

#### Endoparasitic infections

The following may occur in pigeons:

1. *Trichomonas gallinae* is a flagellated protozoan which causes 'canker', 'diphtheria' or, particularly in falconry, 'frounce'. The domestic pigeon is considered the primary host of *T. gallinae*, although it also occurs naturally in a wide variety of species. Infection is spread from parents to squabs during feeding, and through contamination of the drinking water. There are thought to be more than 20 strains of *T. gallinae*, varying in virulence, which infect domestic pigeons. The immune response associated with the disease includes yellow round lesions on the epithelium of the mouth, oesophagus and crop, with accompanying diarrhoea and loss of appetite (Hutchison 1999). However, as Frank<sup>4</sup> points out, with breeders and racers at least, the widespread use of antibiotics in the 1970s and 1980s led to the near eradication of those strains that produce these symptoms. In addition, milder strains of *T. gallinae* are thought to enhance immunity against more virulent strains, making detection of the presence of *T. gallinae* by presence of symptoms more difficult. However, in the most virulent strain (Jones' Barn) death occurs in almost 96% of infected non-immune birds, through the necrosis of liver and other internal organs<sup>5</sup>. Therefore, if infection is suspected treatment is necessary. Infection may be confirmed by a swab taken from the crop lining and the contents inspected under magnification. Hutchison (1999) recommends treatment with dimetridazole 500 mg/l in the drinking water for 7 days. However, others have questioned the efficacy of nitroimidazole class drugs in eradicating *T. gallinae* from pigeons (eg, Munoz *et al.* 1998), while others have called for higher doses for nitroimidazoles for effective treatment (Franssen & Lumeij 1992). Cousquer and Parsons (2007) point out that carnidazole (Spartrix: Harkers) is the only licenced nitroimidazole available in the UK. Administer 10 mg tablets for 5 days.

<sup>4</sup>Frank, K.H. (2005) Canker! <http://www.albertaclassic.net/trichomonas/trichomonas.php>

<sup>5</sup>Chalmers, G. (2005) Canker revisited. <http://www.albertaclassic.net/trichomonas/trichomonas.php>

2. Roundworms (*Ascaridia columbae*) and hairworms (*Capillaria columbae* and *C. longicollis*) may infect the duodenum and upper part of the small intestine. *A. columbae* average about 2–6 cm in length and 1 mm in thickness, and reproducing worms are generally detectable by visible ova in the faeces. In severe infections the gut wall may be thinned and transparent, and may occasionally rupture. *Capillaria* species are smaller, at around 2.5 cm in length and much more slender than *A. columbae*. Ova in the faeces may only be detected with microscopy. In both infections, birds are likely to lose weight chronically, develop diarrhoea and suffer a general loss of condition. For *A. columbae*, Hutchison (1999) recommends treatment with piperazine citrate dissolved in the drinking water at a dosage rate of 2 g/l given for 2–3 days, with administration of liquid paraffin to facilitate elimination of the worms. However, piperazine is considered an older treatment and worms may now be resistant to its effects. It is more common to treat both worm infections with levamisole hydrochloride or fenbendazole at 20 mg/kg of bodyweight. Walker<sup>6</sup>, however, points out the negative side effects of these treatments, such as vomiting and loss of condition, and recommends avermectins such as moxidectin at 10 mg/l of drinking water.
3. Coccidia are a widespread and important group of protozoa, causing the problematic coccidiosis condition in poultry, sheep, dogs, cattle and rabbits. Coccidiosis is most commonly caused by parasites of the genus *Eimeria*. Species in this genus are unusual in having a high degree of host-specificity. In pigeons *Eimeria lab-beana* and *E. columbarum* are most common, and affect pigeons at 3–4 months of age most severely. Many birds have a low level of the disease, but affected birds have a greenish diarrhoea, and become emaciated and stunted. Diagnosis is through the number of oocysts present in the faeces and is necessary to distinguish the symptoms from those of salmonellosis, trichomoniasis, worm infestation and gut infection. Treat with sodium sulphadimidine, 15 ml of the solution in 4.5 l of drinking water. This should be given in the place of the normal drinking water for 5 consecutive days.

#### Ectoparasites

Ectoparasites, such as ticks, mites and lice may result in feather loss, anaemia, and the stunted growth of squabs. Therefore affected birds should be inspected for the causal organisms.

Some species of lice such as the long feather louse, *Columbicola columbae*, and coxyc louse, *Campanulotes bidentatus*, are common and may cause irritation and damage to the feathers, but feed only from feather dust after attaching themselves to the feather shaft. Very small feather mites such as *Falculifer rostratis* may cause irritation if present in large numbers. If anaemia accompanies skin irritation then the red mite, *Dermanyssus gallinae*, may be suspected. It should be noted that these mites do not breed on the birds

<sup>6</sup>Walker, C. (2005, Sept, 14) Parasitic control. [http://www.auspigeonco.com.au/Articles/Parasite\\_control.html](http://www.auspigeonco.com.au/Articles/Parasite_control.html)

but in cracks and crevices from which they emerge at night. Moxidectin, used for worm infestations, has the advantage of killing any blood-sucking mite. The cage or aviary should be sprayed at the same time as treatment to the bird. Bromocyclen in the form of a dusting powder may be used as a general treatment for most lice and mites. An alternative is a synthetic pyrethroid such as permethrin, sprayed directly on to the bird at 10–20 ml/l of water.

#### Bacterial and viral diseases

Below is a non-exhaustive list of diseases that may occur in pigeons. Cousquer and Parsons (2007) and Redrobe (2002) discuss a wider range of less common diseases.

1. Salmonellosis, also known as paratyphoid, is usually caused by *Salmonella typhimurium* and is the most common bacterial infection of pigeons. The organisms can be transmitted in the faeces, crop milk or infected eggs. Clinical signs of infection are extremely variable. Young pigeons often show stunted growth, are underweight and listless, and are affected by diarrhoea. Affected adults may lose weight and develop diarrhoea and swelling of the joints. Swelling and necrosis of the inner eye, known as panophthalmitis, may occur. Isolation and identification of the *Salmonella* microorganisms, usually from faeces or blood, is the only certain means of identifying presence of the disease. In the UK positive tests for *Salmonella* must be reported, under the Animal Health Act (1981)<sup>7</sup>, to a local Veterinary Laboratories Agency (VLA) laboratory in England and Wales and to the local Divisional Veterinary Manager in Scotland. Because *Salmonella* is a zoonosis, the risk of a pigeon infecting humans should not be underestimated and strict hygiene measures are essential in handling infected birds. Hutchison (1999) notes that treatment is unlikely to be satisfactory, since a proportion of birds in a loft are likely to remain carriers after treatment, with the result that the disease may flare up again. She does, however, recommend chlortetracycline in the drinking water, made up fresh each day, at 120 mg or more per litre, for 5–7 days. However, more recent advice from Cousquer and Parsons (2007) recommends that the most severely affected birds be culled and the remainder treated with an antimicrobial, to be determined by culture and sensitivity tests, for 10–14 days.
2. *Chlamydophila psittaci*, formerly known as *Chlamydia psittaci*, is an intracellular bacterium that causes ornithosis in pigeons and respiratory psittacosis in humans. In pigeons it can be associated with other diseases such as trichomoniasis, pox and herpes virus infections. Symptoms in birds include diarrhoea, weight loss and egg infection, and may only appear if the animals are under stress. Humans that have come into contact with infected birds may show influenza-like symptoms that may indicate psittacosis, which may develop into pneumonia. Therefore if human and pigeon symptoms coincide ornithosis may be suspected. Infection is spread through inhalation or ingestion of nasal discharges or through faeces. The currently favoured treatment is doxycycline or a chlortetracycline-medicated feed. If antibiotics are not available, or ineffective, the birds should be killed and a thorough disinfection of the aviary and cages should be carried out before restocking.
3. Newcastle disease is rare in pigeons. However, there is a strain which occurs in pigeons called avian paramyxovirus type 1 (APMV-1). According to Wallis (1983) the pigeon strain of APMV-1 causes green watery diarrhoea, clearly audible upper respiratory sounds and some sneezing. This may be followed by lack of coordination, twitching and paralysis of the legs. In the UK, occurrences of APMV-1 and Newcastle disease must be reported, under the Animal Health Act (1981), to a local DEFRA office. Amendments to the Act in 2002 and under the Avian Influenza and Newcastle Disease (England and Wales) Order (2003)<sup>8</sup> extended previous powers to protect the public from outbreaks of Newcastle disease in poultry. There is no treatment. Inactivated and live vaccines are now freely available for use under veterinary supervision, although only healthy pigeons should be vaccinated.
4. Pigeon pox or so-called diphtheria is common especially in young birds. The incubation period is usually 1 week. Squabs are infected by their parents. Mosquitoes and other blood-sucking parasites may also play a role in transmission. Therefore prevention may be facilitated by a clean cage or aviary. Swellings develop on unfeathered areas of the body, particularly around the eyes, beak and legs. Affected birds lose weight and a few young birds may die following spread of the virus to the mouth and throat. Removal of scabs or swellings is not recommended because this is likely to spread infection by releasing viral particles. An infected pigeon is not dangerous to humans. Pigeon pox may occur in doves. There is no treatment, and with care, birds will recover. Vaccination is recommended in previously infected populations.
5. Avian influenza has received high media coverage since the zoonotic nature of the deadly H5N1 strain was discovered in Hong Kong in 1997. On that occasion six people died from contact with infected chickens. However, it has been widely reported that should the H5N1 strain mutate to allow transmission between humans then a pandemic, killing millions, would be likely (Webster & Walker 2003). H5N1 is only one strain of many that vary in their pathogenicity. Low pathogenic avian influenza (AI) infection does not always produce clinical symptoms. However, in the UK, AI is a notifiable disease under the Animal Health Act (1981) and associated amendments, and must be reported to a local DEFRA Animal Health Office if suspected. In birds, clinical signs include respiratory illness, swollen head and loss of appetite. In poultry, high pathogenic AI causes multiple organ failure, rapid death within 48 h, and is spread through a population very quickly. The disease is spread through contact or faeces, and is not airborne. However, there is little evidence that pigeons are a major factor in the spread of the disease.

<sup>7</sup>[http://www.opsi.gov.uk/RevisedStatutes/Acts/ukpga/1981/cukpga\\_19810022\\_en\\_1](http://www.opsi.gov.uk/RevisedStatutes/Acts/ukpga/1981/cukpga_19810022_en_1)

<sup>8</sup><http://www.opsi.gov.uk/si/si2003/20031734.htm>

Perkins and Swayne (2002) showed that pigeons were resistant to the Hong Kong strain that killed poultry and waterfowl so readily (but see Klopfleisch *et al.* (2006) for evidence of artificial H5N1 inoculation effects in pigeons). In addition, with low pathogenic AI, pigeons are not thought to shed viruses post-inoculation (Panigrahy *et al.* 1996). However, AI has a high mutation rate, and the situation for pigeons may change very quickly. The best recommendation is to keep laboratory pigeons under cover and out of contact with wild birds.

### Vitamin deficiency

Vitamin A deficiency may occur in caged doves and pigeons, especially young birds kept on a deficient diet with no green food or yellow seeds such as maize that contain carotene, the precursor of vitamin A. Symptoms include 'rattling' respiratory sounds, resulting from degeneration of mucous membranes in the mouth, and eye infections. Affected birds will lose weight and may move in an uncoordinated way. Birds should be given an oral preparation of vitamin A.

### Risks to humans

#### Health and hygiene

Handlers should wear appropriate protective clothing at all times, to avoid potential health risks from handling birds. The authors recommend the use of disposable examination gloves and a face mask as a minimum. Cuts and grazes should be covered, and hands and arms washed thoroughly with disinfectant after handling.

#### Sources of allergens for bird handlers

Humans may develop pigeon-breeders disease, a form of hypersensitivity pneumonitis caused by inhalation of antigens of pigeon (or dove) origin. It is characterised by a diffuse inflammation of the lower respiratory tract. T-lymphocytes recognise a wide range of proteins from pigeons and can induce T-cell proliferation. It has also been found that feather mites are a source of allergens for pigeon handlers, with allergic rhinitis being the most common reaction. Dry skin may also occur.

### Acknowledgements

The authors would like to thank Claire Richardson for helpful comments, and Jemma Dopson and Guillem Esber for providing the photographs for Figure 44.1.

## The European starling

Melissa Bateson and Lucy Asher

### Biological overview

#### General biology

The European starling (*Sturnus vulgaris* L.), henceforth the starling, is a medium-sized song-bird with a length of about 20 cm, belonging to the family Sturnidae, sub-order Oscines, order Passeriformes. Starlings are native to most of temperate Europe and western Asia. Northeastern populations migrate in autumn, with some birds over-wintering in Iberia and Africa. Starlings were introduced to Australia (late 1800s), New Zealand (1862), North America (1891) and South Africa (1890); the species is currently estimated to inhabit 30% of the earth's land area, excluding Antarctica (Feare 1984).

#### Use in research

##### Benefits

Starlings are a readily available and robust species, settling fast in captivity and usually remaining in good health. Their gregarious nature allows group housing at relatively high densities, and they have simple dietary requirements. For many experimental purposes starlings are an ideal size, being large enough to handle easily, but small enough to allow natural behaviour such as flight in captivity (eg, Witter *et al.* 1994). Being naturally inquisitive, starlings are easy to train on operant tasks using autoshaping procedures (eg, Bateson & Kacelnik 1995). Starlings can readily be brought into breeding condition by manipulation of day length, and will both sing and court in captivity (eg, Heimovics & Ritters 2006; Meaden 1979). However, they are hard to breed in captivity.

##### Types of research

Due to the range of benefits outlined above, starlings are currently among the most popular passerine bird species used in laboratory-based biological research (Asher & Bateson 2008). They were first used for studies on avian infectious diseases over 25 years ago (Cooper & Needham 1981; Cooper 1987), and are currently a widely used model species in many areas of behavioural research including foraging decisions, mate choice and social learning (eg, Fernandez-Juricic *et al.* 2004). Starlings have been useful

subjects for the neurobiology of both hearing and song learning/production (eg, Langemann & Klump 2001). They have also been important for understanding the environmental (photoperiod and temperature) control of breeding and moult and endocrine control of reproduction and the stress response (eg, Dawson 2001; Nephew & Romero 2003). Visual and auditory discrimination testing have been performed on starlings (eg, Swaddle & Ruff 2004) and studies of flight mechanisms and aerodynamics (eg, Ward *et al.* 2004). The widespread use of starlings in laboratory experiments has led to a recent increase in research on the laboratory welfare of this species (eg, Maddocks S.A. *et al.* 2002; Matheson *et al.* 2008).

#### Size range and lifespan

Basic biometric data for free-living British starlings are shown in Table 45.1. It is important to realise that the mass of individual birds will vary depending on time of day (a bird can lose 10 g on a long winter night (Tait 1973)), season (birds can be as much as 15 g heavier in winter than summer), current diet (birds eating more plant food will have a longer gut (Al-Joborae 1979)), and cage size (birds will lose flight muscle in smaller cages). In studies where control of weight is important, birds should be weighed at the same time of day (preferably before it is light in the morning when the gut is empty), and baseline weights should be established immediately prior to the start of a study (eg, Barnett *et al.* 2007).

Free-living adult starlings (ie, at least 1 year of age) have an average annual survival rate of around 45%, with most birds dying during the annual breeding season. However, survival should be much higher in captivity where birds are protected from starvation, hypothermia, predation and certain diseases. Maximum recorded longevity for free-living birds vary between 15 years 3 months (North America) and 21 years (Germany) (Klimkiewicz 2007).

#### Social organisation

Starlings do not have a strong social structure, but are gregarious throughout the year, tending to form larger and denser feeding flocks in winter. They form communal roosts in winter that can comprise up to one million birds.

Dominance hierarchies are established in captive flocks, with males dominant to females and adults to juveniles. Birds may jockey to defend preferred perching positions or feeding sites, and fighting involving grappling with feet and bill stabbing can occasionally occur. During the breeding season birds will defend a territory immediately around the nest site with males chasing away other males up to 10m from the nest. Both monogamous and polygamous mating systems have been reported. Pair bonding does not occur until the weeks immediately before laying. Both sexes feed the young.

## Reproduction

Starlings are cavity nesters and are usually colonial breeders with nests as little as 1 m apart. Females breed at 1 year of age, males not till 2 years. In England, first clutches are initiated between early April and late May (Joys & Crick 2004). Eggs are pale blue or white-spotted and 30 mm × 21 mm and 7g (BTO Nest Record Scheme data). They hatch asynchronously, with the last egg hatching up to 24h after others. Basic reproductive data are shown in Table 45.2. Chicks grow fast, reaching their adult weight within two weeks of hatching.

Starlings go through a complete moult once each year, following breeding, with juveniles moulting their distinct grey-brown, spotless, plumage at the same time. New feathers are tipped with white or buff giving a spotted appear-

ance that is less apparent by the following breeding season as the pale feather tips wear off.

## Normal behaviour

Starlings are opportunistic and adaptable foragers, but forage predominantly on the ground in open areas of short grass. They are adapted for terrestrial foraging with powerful legs for walking and a strong, pointed bill for probing into the substrate to locate soil invertebrates. Probing behaviour involves the bird pushing its closed bill into the soil, opening its bill to create a hole whilst rotating its eyes forwards to gain binocular vision of the contents of the hole (Figure 45.1). Hawking of flying insects has also been observed. Starlings often feed up to 20 miles from their winter roost sites, and have relatively long and pointed wings adapted for fast flight across open country. Starlings can be tame and approachable in gardens, but are generally more wary in rural areas.

Starlings are highly vocal, with both sexes singing, except in the breeding season when only the males sing. They have a complex song, incorporating mimicry, and are open-ended learners extending their repertoire throughout life.

## Sources

The vast majority of starlings used in laboratory research are caught from the wild either as adults or juveniles (Asher & Bateson 2008). The advantage of juveniles is that they are easier to catch and may adapt to captivity better. However, they also typically have higher parasite loads, and are more prone to developing symptoms of avian pox following capture. A number of methods can be used to catch starlings. Walk-in traps and funnel traps can be very successful, especially if live decoy birds are used. However, the ethical and legal considerations of the latter strategy need to be carefully considered. Mist nets and baited spring-loaded whoosh nets have also been used successfully. Adult birds can easily be captured roosting in nest boxes prior to the start of the breeding season.

Hand raising chicks is extremely time-consuming, but can be achieved successfully provided chicks are at least 4 days old at the time they are taken from the nest. Hand raising chicks of less than 4 days is reported to be unsuccessful.

Captive breeding is generally unsuccessful (but see Meaden 1979). Starlings will attempt to breed if housed in mixed-sex aviaries with nest boxes. However, the chicks usually die soon after hatching due to the lack of availability of appropriate food. A possible solution to this problem is

**Table 45.1** Biometric data for free-living British starlings (British Trust for Ornithology 2005). Cells show: mean ± sd (range).

Variable	Male	Female	Juvenile
Wing length (mm)	132.6 ± 3.1 (135–137)	129.5 ± 3.3 (132–135)	130.2 ± 4.2 (122–136)
Mass (g)	86.95 ± 9.97 (76.00–100.0)	82.50 ± 9.27 (72.00–95.00)	81.83 ± 7.59 (70.00–95.00)

**Table 45.2** Reproductive data for starlings.

Variable	Mean ± sd	Range
Clutch size (number of eggs)	4.60 ± 0.94	2–9
Incubation (days)	12.38 ± 1.61	10–16
Fledging (days)	20.50 ± 3.25	15–26

**Figure 45.1** Distinctive probing behaviour of a starling. From left to right the bird searches for indication of a prey item; lowers its head pushing its closed bill into the soil; it opens its bill to create a hole whilst rotating its eyes forwards; then raises its head to complete the movement. Reproduced from *The Starling* by Feare, Christopher (1984), by permission of Oxford University Press (www.oup.com).

to use a large portable aviary that can be moved around natural pasture during the night so that a constant supply of fresh invertebrates is always available to the birds.

### Conservation status

The International Union for the Conservation of Nature and Natural Resources places the starling in the category of Least Concern. However, the number of starlings has fallen rapidly in the UK since the early 1980s (Robinson *et al.* 2005) leading to upgrading of the species' UK conservation listing to Red (>50% population decline). Starlings are rated as SPEC category 3 (declining) in Europe. In the UK, starlings are protected under the Wildlife and Countryside Act 1981, which makes it illegal to intentionally kill, injure or take a starling, or to take, damage or destroy an active nest or its contents. In England, a licence is required from Natural England to catch and hold starlings. In the USA, starlings are not protected under American wildlife conservation laws due to their status as both an introduced species and an agricultural pest.

## Laboratory management

### General husbandry

#### Enclosures

Captive starlings are successfully kept in a wide variety of enclosures of different sizes and shapes. Where possible, group housing in large, outdoor aviaries is always preferable. Advantages include reduced feather damage, greater space and lower maintenance, but individuals are less easy to inspect and capture. Where birds have to be kept in smaller cages, a minimum space requirement of 1 m<sup>3</sup> for a singly housed bird was recommended by the Joint Working Group on Refinement (JWGR 2001b). However, this latter volume was not chosen on the basis of any scientific evidence, and represents a much larger cage than the median of 0.42 m<sup>3</sup> revealed by a review of current practice with this species (Asher & Bateson 2008). Within the volume range of 0.14–1.00 m<sup>3</sup> measurements of stereotypic behaviour patterns show that the environmental enrichment present in a cage may be more important in determining starling welfare than cage volume (Asher 2007). Thus, while larger cages are preferable if all else is equal, there is currently little evidence to suggest that welfare of birds is significantly greater in cages of 1.00 m<sup>3</sup> volume than in smaller cages down to 0.14 m<sup>3</sup>. At all volumes, long-shaped cages that allow for flight are preferable to squarer cages or taller cages (Asher *et al.* 2009).

#### Environmental provisions

Cages should be equipped with adequate perches for all birds so as to reduce competition (Boogert *et al.* 2006). Plenty of high perches should be provided because birds will tend to spend most of their time on the highest perch available. In aviaries it is advantageous to have some moving perches since this will help maintain agility. In smaller cages, par-

ticularly when birds are singly housed, perches should be fixed because birds seem more fearful of moving items in this environment. Perches of varying thicknesses and textures (natural branches are ideal) will help maintain healthy claws and feet and provide a variety of substrates for bill-wiping (Witter & Cuthill 1992). Perches should not be located directly over food and water dishes to avoid fouling and possible spread of pathogens.

Bathing is probably important for feather maintenance (Brilot *et al.* 2009) and appears to be a strong behavioural need in this species. Starlings will attempt to bathe in their drinking water unless suitable baths are provided. Trays of bathing water at least 20 cm in diameter and not more than 3 cm deep should be provided, and will need to be replaced daily due to fouling.

Nest boxes should not be provided in mixed-sex aviaries because they are likely to provoke aggressive nest defence and may encourage unsuccessful breeding attempts.

#### Environmental enrichment

Provision of environmental enrichment reduces the incidence of behavioural stereotypies in starlings, and may be more important in determining the welfare of caged starlings than cage size *per se* (Asher 2007; Bateson & Matheson 2007). Starlings will choose to work for food by searching for it in a substrate such as sand even if the same food is freely available (Inglis & Ferguson 1986; Bean *et al.* 1999). This contra-free-loading behaviour may suggest a behavioural need to perform natural foraging techniques (Kacelnik 1987), which can be met in captivity by providing a substrate for starlings to probe. Ideally the entire floor of the enclosure should be covered with a substrate such as bark chippings, but if this is not possible, trays of bark chips or turf should be provided that are large enough not to allow aggressive defence by a single bird (Gill 1995; Gill *et al.* 1995).

Protective foliage cover in the form of evergreen trees or branches is likely to reduce perceived predation risk in starlings and may be important in reducing anxiety (Lazarus & Symonds 1992) and encouraging birds to use other available enrichment.

#### Feeding/watering

Starlings are omnivores eating both animal (predominantly insects and their larvae, but also other non-insect invertebrates) and plant material (soft fruits in autumn and seeds and cereals in autumn and winter) at all times of year. In captivity starlings can be kept indefinitely on commercial poultry or game bird starter crumbs or dry cat or dog food, provided the protein content is at least 30%. This diet should be provided *ad libitum* and can be supplemented with live invertebrates (eg, mealworms) and low-sucrose fruit such as apple pieces, cherries and grapes; the Sturnidae are unable to digest sucrose (Avery *et al.* 1995). Live insect prey can be placed in the probing substrate to encourage natural foraging behaviour. Insoluble grit does not appear to be required by starlings.

Drinking water should be available at all times, and should be changed at least once a day. Use of gravity dispensers for both food and water will help to reduce fouling.

An adequate number of feeders and water bottles should be provided to reduce aggressive interactions.

### Social housing

Captive starlings prefer to be in proximity to conspecifics (Vasquez & Kacelnik 2000), and can be housed at relatively high densities as long as adequate roosting perches and food dishes are provided so that all birds can use these simultaneously (Boogert *et al.* 2006). Groups of 4–12 birds are recommended. It is better to keep several birds together in a larger cage, even if this is at a reduced space per bird.

It is feasible to house starlings individually for experimental purposes; however, if possible auditory and visual contact with other birds should be maintained.

### Identification and sexing

#### Individual identification

Starlings can be individually identified with leg rings (bands) of either plastic or aluminium. Ring size 'C' (diameter 4.3 mm, weight 0.14 g) is usually appropriate for a starling. Split plastic rings are fitted with the tool provided with them, whereas metal rings will require specialist ringing pliers (Redfern & Clark 2001). Rings should be large enough to move freely on the starling's leg but not too large to fall over its foot. Rings are available printed with numbers and also in a range of colours to aid identification of birds without the need for catching. Up to two rings can be accommodated on each leg if a large range of colour combinations is required.

#### Sexing

Starlings are sexually dimorphic and can be accurately sexed from external features alone (see Table 45.3). Juveniles can be more difficult to sex based on plumage; however,

98% can be correctly classified based on iris colour alone (Smith *et al.* 2005a).

### Physical environment

#### Temperature and humidity

Starlings can withstand a wide range of temperatures and humidity as evidenced by their geographic distribution, and will thrive in outdoor aviaries (in the UK climate) provided that some shelter is available. Inside it is typical to maintain laboratory temperatures at 14–20°C; however, deviations from this range are unlikely to cause problems. Ambient temperature is known to affect foraging decisions (Bateson 2002) and fat storage (Cuthill *et al.* 2000).

#### Photoperiod

Photoperiod is extremely important in starlings because, like other temperate-zone species, they use the shape of the annual change in day length to control the time of breeding and moult (Dawson 2007). The short days of winter render birds photosensitive such that when days lengthen, the neuroendocrine changes leading to gonadal maturation and breeding are stimulated. Starlings held on 11L:13D will retain mature gonads indefinitely. Prolonged exposure (>30 days) to long days results in a photorefactory phase, gonadal regression and finally moult. In starlings held on 13L:11D the gonads will remain regressed indefinitely and birds will never come into breeding condition. Moult duration can be reduced from 119 days for birds held on constant long days of 18L:6D to 92 days by gradually reducing day length by 1 h/week from 18L:6D to 12L:12D; however this acceleration is bought at the expense of reduced final feather quality (Dawson 2004). Following a period of long days, photosensitivity in starlings can be reinstated by a period of 25–35 days of 8L:16D (Goldsmith & Nicholls 1984).

For birds housed indoors, either the daily transition between light and dark should be gradual in order to allow

**Table 45.3** Sexually dimorphic features in starlings.

Variable	Male	Female	Accuracy in juveniles?*
Colour of base of bill	Grey-blue	Salmon pink	100%, but only in the breeding season (when males have yellow bills)
Lightness of iris colour relative to dark chocolate brown pupil	Either dim ring, visible with careful observation or so dark as to be indistinguishable from pupil	Either much lighter with a highly distinct ring or lighter with a clear ring	98% classified correctly using this feature alone
Throat and chest feather length	Mostly long and thin	Range from 50% long and thin, 50% short and wide to mostly short and wide	93–94%
Throat and chest feather tip shape	Range from 50% round, 50% V-shaped to mostly V-shaped	Mostly rounded	81–89%
Mass	Heavier: ≥78 g	Lighter: <78 g	70–72%
Tarsus length	Longer: ≥29.3 mm	Shorter: <29.3 mm	65–67%
Speckling (density of pale feather tips)	Fewer to no spots	More spots	Not a useful trait in juveniles

\* Figures are taken from an analysis in Smith *et al.* (2005a).

birds to find a roosting site for the night, or a dim nightlight should be provided.

#### Quality of light

The frequency at which a flickering light source is perceived as continuous is believed to be higher in birds than in humans (>100Hz vs. 50–60Hz), leading to concern that starlings may be able to perceive the flicker from conventional low-frequency fluorescent lights (100Hz in Europe and 120Hz in the USA) and cathode ray tube monitors. In preference tests, starlings prefer high-frequency (>30kHz) over low-frequency (100Hz) lighting, indicating that they can detect a difference (Greenwood *et al.* 2004). Myoclonus is induced in starlings exposed to fluorescent lighting and cathode ray tube monitors flickering below 150Hz (Smith *et al.* 2005b). Birds are less active and have higher basal corticosterone levels under low frequency lighting, suggesting that they may find it more stressful (Smith *et al.* 2005c). Starlings also show changes in mate choice in low- and high-frequency lighting, becoming less consistent in the preferences in low-frequency conditions (Evans *et al.* 2006). It is therefore recommended that, if natural light is not available, rooms are lit with high-frequency fluorescent lights.

Most birds, including starlings, have an additional retinal cone type tuned to UV wavelengths meaning that if they are housed in laboratories without UV light they may be deprived of visual information usually available to them in the outside world. There is some evidence to suggest that starlings may prefer a light environment containing UV (Greenwood *et al.* 2002), and that being housed in a UV-deficient light environment causes higher basal corticosterone levels and changes in behaviour (Maddocks A.A. *et al.* 2002). It is therefore recommended that starlings are housed in rooms with full-spectrum lighting.

#### Hygiene

The main disadvantage of starlings as an experimental animal is the large quantities of droppings (faeces and urates) they produce. The floor covering will need to be replaced daily in smaller cages, but in larger aviaries less frequent cleaning will be necessary. Cleaning can be stressful for birds, particularly those in cages, but stress can be reduced if husbandry is conducted as quietly as possible, ideally by a familiar person, at a similar time each day (Rich & Romero 2005). It may also help if birds are provided with cover in which they can hide.

Starlings can carry human pathogens and there is therefore a potential risk of infection from their droppings. However, a recent analysis on bacteria present in free-living starling droppings showed that most did not belong to the specific types most often found in humans. The authors concluded that starlings are unlikely to present a major source of infection for humans (Gautsch *et al.* 2000). Nevertheless, appropriate precautions should be taken by humans working with this species. Some laboratories routinely screen incoming starlings for common pathogens including *Salmonella*, *Yersinia* and coccidia.

#### Health monitoring and quarantine

##### Quarantine

Recently acquired starlings should be kept isolated from existing laboratory stock for at least 2 weeks to establish as far as is possible that birds are free from infectious diseases and to allow screening for zoonoses and treatment for parasites (see later in this chapter).

##### Bill and claw trimming

Starlings' claws and bills are adapted for walking and probing in soil and can become overgrown in captivity where they are not naturally abraded. Provision of rough wooden or sandpaper-covered perches can help (Cuthill *et al.* 1992), but usually birds will need to be caught and their bills and claws trimmed with nail clippers every few months. Overgrowth of the upper mandible will result in feeding and preening problems. It is important to check regularly that leg rings have not become too tight (see also Dietary related health problems).

#### Laboratory procedures

##### Handling

Capture by hand is possible in smaller cages. Since birds will not fly in the dark it is often easier to turn off the room lights and use a small torch to locate birds. In larger cages or outdoor aviaries a net (with padded edges) will be necessary. Birds will usually fly towards the light, and an indoor aviary can easily be emptied by turning off the lights and allowing the birds to fly into an adjacent lit room. Starlings can be trained to enter a small transport cage by reinforcing this behaviour with a preferred treat such as mealworms. Cotton drawstring bags are ideal for transporting starlings short distances. A recommended procedure for holding a starling is shown in Figure 45.2.

##### Training procedures

Captive starlings can rapidly be habituated to familiar humans if human visits are associated with beneficial con-

**Figure 45.2** A recommended way to hold a starling: the bird's head is held between the index and middle finger with its back in the palm of the hand. The ring finger, little finger and thumb rest across the bird's closed wings to prevent them from flapping.

sequences such as provision of mealworms or water baths. It is not unusual for well habituated birds to take mealworms directly from humans. However, if birds are to be released to the wild, consideration should be given as to the possible adverse consequences of extensive habituation to humans.

Starlings can be easily trained to perform responses including hopping on perches, flying through mazes, probing holes through paper, going through push-doors, pecking lids off wells/dishes, and pecking illuminated keys or touchscreens. Pecking illuminated keys for food reward can be trained using standard auto-shaping procedures (for details see Bateson and Kacelnik 1995). Other behaviour patterns such as hopping between perches or using their feet to remove the stopper from a food container will need to be trained by gradual shaping with positive reinforcement.

Birds will learn to work for preferred treats such as mealworms without prior food deprivation. However, if birds are being reinforced with their normal diet it may be necessary to restrict their food intake, either by removing *ad libitum* food a few hours prior to the training session, or by feeding a restricted daily ration. If the latter approach is adopted, it is important to monitor birds by daily weighing (eg, Barnett *et al.* 2007). Birds maintained at 90–95% of their free-feeding mass will typically work well in operant experiments, and greater weight reduction is not recommended in this species. Given the possible temporal variation in free-feeding mass (see earlier), new baselines will always need to be established immediately prior to the start of an experiment.

## Monitoring methods

### Weighing

Birds can be weighed either by catching and placing in a cloth bag or clear plastic cone, or by training birds to come to a balance in their cage for mealworms. The balance can either be connected to a computer or read directly (a video camera or binoculars can be used for this in the case of shy birds).

### Removal of blood

For a general review of procedures for removal of blood from laboratory birds (specifically chickens) see JWGR (1993). Recommended procedures for removal of blood from chickens should be extrapolated to starlings with extreme caution due to the large size difference between the species. Ideally, advice should be sought from researchers with first-hand experience with either starlings or another similarly sized bird species. In starlings, small blood samples (of the order of 0.05–0.1ml) are most easily taken from the alar (ie, wing or brachial) vein. Use of the jugular vein is not recommended due to the risks of accidentally puncturing the nearby carotid artery. Use of alcohol for site preparation is not recommended, because it causes cooling, and the consequent vasoconstriction can make the alar vein hard to locate. Up to four 0.1ml samples have been taken in a

60-minute period (with no subsequent resampling) without problems.

## Administration of substances

For general principles and summaries for specific protocols see JWGR (2001a). The easiest injection site on a starling is the pectoral muscle (the largest muscle in the body), but care should be taken, especially if repeated injections are required, because damage to this muscle can cause impairment of flight (Cooper 1983). For substances that can be administered by mouth, feeding birds injected mealworms should be considered as a low-stress approach (eg, Barnett *et al.* 2007).

## Anaesthesia

Starlings can be successfully anaesthetised for up to 2–3h with inhalation agents. Isoflurane, for example, is used at 5% for induction and 1.5–2.5% for maintenance (eg, Bee & Klump 2004). Injectable agents can also be used (Cooper 1987).

## Euthanasia

Alternatives to euthanasia should be considered where possible. It is common practice (and indeed sometimes a requirement of licensing bodies such as Natural England) to release wild-caught starlings following research that does not involve any invasive procedures. Ideally, birds should be given a period (eg, 2 weeks) in a large aviary to build-up and exercise their flight muscles prior to release either near the site of original capture, or at another location frequented by wild starlings.

For general principles of euthanasia, see Chapter 17 and Close *et al.* (1996). A summary of methods of euthanasia appropriate specifically for birds is provided by Close *et al.* (1997). A range of different procedures is used for euthanasing starlings, the most common being cervical dislocation and concussion by striking the head on a hard surface followed by cervical dislocation. The latter methods have the advantage of being quick but require confidence on the part of the handler. Overdose of anaesthetic (eg, pentobarbital injected intraperitoneally) is also possible.

## Common welfare problems

### Health

This chapter is not the appropriate place to present a full review of all the health problems that can occur in starlings, and for more information readers should consult an avian veterinary text (eg, Altman *et al.* 1997; Ritchie *et al.* 1997; Rupley 1997). The internet is also a source of useful sites aimed at pet owners containing health advice specific to starlings. Here we present the most common health problems reported in a questionnaire sent to researchers in both

Europe and North America with extensive experience keeping starlings in the laboratory.

### Dietary related health problems

Hyperkeratosis characterised by raised overgrown scales on feet and legs, overgrown beak and nails and poor feather condition is common in captive starlings (Figure 45.3). In extreme cases scales can grow over the leg rings. Hyperkeratosis appears to be caused by diets that are too low in protein, as is the case for some poultry foods and softbill diets designed for fruit-eating Mynahs. It is important to check the protein content of the basic diet used for starlings (see Feeding/watering section for details).

Haemochromatosis, also known as iron storage disease, is a cause of mortality in some of the Sturnidae when they are kept in captivity, and could be related to dietary factors influencing the bioavailability of iron (Sheppard & Dierenfeld 2002). Cause of death appears to be heart failure or liver disease. Recent feeding experiments with European starlings suggest that a diet containing 34–125 ppm of iron is optimal for preventing accumulation of iron in the liver. Alternatively, adding a phytate (inositol), tannic acid, or both to readily available food stuffs may be a practical alternative to feeding low-iron diets (Olsen *et al.* 2006). However, despite the evidence that European starlings will accumulate iron in their organs, there is no evidence that birds fed long-term on the basic diets recommended earlier in the chapter commonly develop iron storage disease. Therefore, the authors conclude that concerns about haemochromatosis in European starlings are probably exaggerated.

### Parasites and infectious diseases

Parasites and infectious diseases are not thought to be a major cause of mortality in free-living starling populations

(Feare 1984), and captive starlings rarely have disease problems if husbandry is good. However, the species is host to a wide range of parasites with infection rates in free-living birds being higher in juveniles than adults and peaking in the summer, and it is good practice to treat incoming birds for endo and ectoparasites.

Ectoparasites include feather lice, ticks and mites. These can be vectors of disease in addition to producing clinical signs of anaemia, feather loss and skin lesions. Ectoparasites can be treated with ivermectin applied topically to the back of the neck. Starlings are recorded hosts of many endoparasites including nematodes, trematodes, cestodes and acanthocephalans. The gapeworm (*Syngamus trachea*) is a long red nematode that attaches to the trachea of birds. The worms cause bleeding in the throat and can block the trachea. Starlings infected with gapeworm can often be heard coughing. Nematode worms in starlings can be treated with the following drugs: fenbendazole (by addition to feed), flubendazole (by addition to feed), ivermectin (by mouth) and levamisole (by addition to drinking water).

Avian pox is a viral disease that produces wart-like lesions on the bird's head, particularly around the eyes and the base of the bill. Badly affected birds may need to be euthanased, but most usually recover without treatment. It is common for birds to develop the disease shortly after capture from the wild. Juvenile starlings seem particularly susceptible to pox, but survivors appear to become immune, and captive adults rarely develop the disease.

Aspergillosis is a common fungal infection of starlings causing clinical signs ranging from mild debility to sudden death. It is usually secondary to immunosuppression from chronic stress or other primary diseases, and can also occur in the presence of high concentrations of the fungus in the environment. Clinical diagnosis of aspergillosis is difficult and prognosis is poor.

### Behavioural

The most frequently reported abnormal behaviour pattern exhibited by caged starlings is the somersaulting or flipping stereotypy (although incidences of stereotypy are relatively low compared with other captive birds). This appears to be most common in birds housed in small barren cages, and can be reduced by adding enrichment to the cage or returning victims to a larger aviary.

Aggression and persistent harassment can occasionally become a problem in some group-housed birds. This will sometimes result in feather loss. In such cases birds should be carefully monitored and separated if necessary.

Polydypsia leading to watery diarrhoea occasionally occurs in captive starlings. This can be caused by birds trained on operant schedules erroneously associating their own drinking with reinforcement with food. Removing the bird from the operant schedule and adding oat flakes to the diet may help.

Feather damage, including complete loss of the tail, is common in birds housed in wire mesh cages. Although this is unsightly, it is unlikely to be a welfare problem unless birds are about to be released, in which case it could affect flight performance.

**Figure 45.3** A laboratory starling with hyperkeratosis. Note the poor feather condition and specifically the heavy, overgrown bill and thickened scaly legs.

## Further reading

Asher and Bateson (2008) provide a recent review of current practice in laboratory husbandry of European starlings. Feare (1984) is the best general source on the biology of European starlings although is mainly focused on free-living birds. Meaden (1979) provides details of captive care and breeding of many European bird species including the starling, and Perrins (1994) is a good review of general biological information, especially geographical distributions and song.

# Reptiles and Amphibia

# 46 Terrestrial reptiles: lizards, snakes and tortoises

John E. Cooper

## Introduction

I am grateful to my friend and former teacher, Dr Roger Avery, for permitting me to base some of this chapter on his original, excellent, text in the previous edition of the Handbook.

There are four orders and approximately 7000 extant species of reptiles (class Reptilia). The majority of these are lizards and snakes (order Squamata). There are more than 40 species in the order Chelonia that can be regarded as terrestrial; these are called 'tortoises' in Europe, Australasia and elsewhere but in North America they are usually referred to as 'turtles', a term which there encompasses also marine and freshwater aquatic chelonians, but in the UK (and elsewhere) refers only to the marine species. There are just over 20 species of crocodiles, alligators, caimans and their allies (order Crocodylia), and two species of lizard-like tuataras (order Rhynchocephalia), neither of which is dealt with in this chapter.

Much has been published in recent years, in various languages, concerning the husbandry and captive care of reptiles. This is critically relevant to laboratory management. General information about the biology, restraint and treatment of reptiles can be found in various texts. For instance, useful, succinct, summaries for lizards are provided by Schumacher (2003), for snakes by Mitchell (2003) and for chelonians by Raphael (2003). This chapter does not attempt to provide details of the husbandry of individual species. Instead, this chapter outlines and explains the general biological principles underlying successful reptile husbandry.

Many of the requirements of reptiles, and the husbandry techniques appropriate for successfully maintaining them in captivity, are significantly different from those of mammals or birds. With a few exceptions (see, eg, Thorogood & Whimster 1979; Wisniewski 1992), relatively little has been published specifically on the laboratory management of terrestrial reptiles: therefore it is often necessary (and wise) to extrapolate from the experiences of those who successfully keep and breed these species in private collections or in zoos. While some of the accounts tend to be anecdotal, others are based on sound observation and study – see, eg, Divers (1995), Frye (1993), Harling (1993, 1994), Langerwerf (1990, 1991), Rose (1992), Sheriff (1988), Sweeney (1993) and Townson (1994).

## Biological overview

### Anatomy

Reptiles are vertebrate animals that show considerable variation in morphology, especially modifications to limbs, vertebral column and pectoral and pelvic girdles (Davis 1981). There are snakes with vestiges of hindlimbs and lizards that are leg-less; an example of the latter are members of the family Amphisbaenidae (Schumacher 2003). Some indication of the complexity of structures in the cephalic region of squamate reptiles (snakes and lizards) is given in Figure 46.1. The integument of all reptiles is particularly important in terms of biology and health and is therefore discussed in detail in the next section.

### The integument

In almost all reptile species the outer layer of the skin, the epidermis, is thickened (see Figure 46.1) and highly keratinised to form plate-like scales (Figures 46.2 and 46.3), which in places overlap one another (imbrication) (Cooper 2006). The surface of the epidermis is lost periodically, a process known as ecdysis or sloughing, and is replaced by growth of new cells from deeper layers. In snakes, the entire skin is shed, usually in one piece, including the keratinous 'spectacle', which covers the eye. Changes in the spectacle, characterised by an opacity or translucency, are a sign that sloughing is imminent. In lizards the skin is lost in small portions and the process takes place more or less simultaneously over the entire surface of the body. In other reptiles shedding tends to be piecemeal.

Sloughing (shedding) is an important physiological event (Maderson 1965). When reptiles are kept in laboratories it is important that detailed records of sloughing are maintained as a change in frequency, or a failure of/difficulty in shedding (dysecdysis), may indicate ill-health. It is good practice to retain shed skins, in a sealed plastic bag, so that they can be examined in the laboratory as part of routine health monitoring (see section on health) (Figure 46.4).

The 'shell' of terrestrial chelonians consists in most cases of bone, sometimes cartilage, that is covered with connective tissue and highly keratinised stratified squamous epithelium. It is well innervated and sensitive to trauma and

**Figure 46.1** Head of a monitor lizard (*Varanus* sp.), illustrating the detailed scalation. The animal has a clear, shiny, eye, usually indicative of health.

**Figure 46.2** A low-power scanning electron microscope view of the skin of a skink, showing the overlapping scales.

painful stimuli. The care of, and veterinary attention to, chelonians can be very specialised (McArthur *et al.* 2004a).

### Ectothermy and behavioural thermoregulation

Reptiles are ectothermic animals and, apart from rare exceptions, such as brooding pythons, cannot control their body temperature by internal means. This can have profound effects on their health and welfare, especially in captivity where environmental features are usually dictated by the keeper of the animal. The amount of heat produced by reptiles is small and because they have no insulation (hair or feathers) it can be rapidly lost. Without some external source of heat, the body temperature of a reptile will approximate to its immediate surroundings. Many species of reptiles adjust their behaviour to take advantage of external heat sources, usually either direct sunlight or sun-warmed substrates such as rocks, sand or (less frequently) water (Figure 46.5). Typically, a reptile will lie in the sun ('basking') until its body temperature rises to a threshold level ('upper thermoregulatory set point') at which metabolic rate is optimal and it will begin to perform other kinds of behaviour such

**Figure 46.3** Line drawing of *Lacota viridis* head (drawn courtesy of the Edward Elkan Memorial Collection).

**Figure 46.4** A sloughed (shed) skin from a boa constrictor. Regular and complete sloughing is usually a sign of good health in snakes. Under laboratory conditions the sloughing cycle should be monitored and shed skins carefully preserved, in sealed plastic bags, so that they can be examined for parasites and evidence of disease. (Photo: Richard Spence.)

as searching for food, courtship and mating and defensive aggression (Schieffelin & Queiroz 1991).

Basking often involves distinct postures, such as flattening and positioning the body so that the maximum surface area is exposed to solar radiation. When the animal stops basking, these postures are no longer maintained. If it remains in the sun, it may nevertheless drop in temperature because the rate of heat gain has been reduced. If it moves

**Figure 46.5** A mixed group of leopard (*Testudo pardalis*) and hinge-back (*Kinixys belliana*) tortoises in an outdoor pen. This sort of management is popular in the tropics because it is inexpensive and provides natural sunlight (note how the tortoises are thermoregulating in the sunlit area). It offers environmental enrichment but may predispose animals to damage and predation.

into the shade, for example while feeding, it will cool. In both cases a second threshold temperature ('lower thermoregulatory set point') will be reached, and the animal will seek sunlight and resume basking. In small lizards, the rates of heat loss and heat gain are rapid, and as they move from sun to shade and back again, they are often called 'shuttling heliotherms'. This method of maintaining a relatively high body temperature by basking to gain heat (and in very hot environments, actively seeking to cool by spending long periods in the shade or panting) is termed 'behavioural thermoregulation'. It is a major key to understanding many aspects of reptile biology, including how best to provide suitable conditions in captivity.

The actual threshold temperatures (Firth & Turner 1982) vary from species to species, and sometimes amongst individuals of the same species, depending upon various factors (Huey 1982). The mean temperatures recorded in active animals (mean activity temperature (MAT); Pough & Gans 1982) will thus fluctuate. More than 500 species of reptiles for which MATs or similar thermoregulatory data are available were listed in Avery (1982), Meek and Avery (1988) and Peterson *et al.* (1993). Another term used by herpetologists is 'preferred optimum temperature zone' (POTZ) or 'preferred optimum temperature range' (POTR) and published data are available on the POTZ for numerous species of reptile, some of which may be kept in laboratories (Rossi 2006).

It is important under laboratory conditions to ensure that the temperature of different areas in the reptile's environment is properly monitored and recorded. Maximum and

minimum thermometers are the basic tools but digital thermography is increasingly being used (Fleming *et al.* 2003). Thermostats are an important item in any reptile house and should be pulse-proportional so as to regulate energy flow to the heat source.

### Behavioural interactions

Many species of reptile are territorial, and when group housed they may form dominance hierarchies. In nature, animals with low status can usually flee to alternative locations. This option is not available in a small cage, and low-status individuals may be subject to chronic stress (see later) and sustain physical injury. They may be excluded from basking, feeding or retreat sites, and as a consequence fail to thrive. It follows that great care must be exercised if potentially territorial reptiles are kept together in cages. There are, however, measures that can be taken to reduce agonistic interactions. Enriching the environment by increasing complexity and installing refugia (see later) can ensure that individuals encounter one another less frequently, and may actually reduce territory size in some species, eg *Anolis aeneus* (Eason & Stamps 1991). Providing multiple basking and feeding sites and non-communal retreats may also minimise aggression.

### Special senses

Most reptiles other than snakes have colour vision and some can sense the near ultraviolet (UV) (Fleishman *et al.* 1993). All chelonians and many lizards have a parietal eye (pineal organ) situated at the top of the head which is connected to the pineal organ. This has a lens and a retina, but because it lies beneath the scales, cannot form an image. It responds to the wavelength and intensity of light and seems to be concerned with rhythmic behaviour, seasonal reproductive cycles and thermoregulation.

All terrestrial reptiles can respond to vibrations (an important consideration in the positioning of cages as proximity to electrical and other equipment may have adverse effects), and many can hear. Few reptiles vocalise, an exception being some species of gecko. Even the sounds made by copulating tortoises may serve as communication (Galeotti *et al.* 2005).

There are other aspects of reptile senses that differ from those in mammals. Direct olfaction is not well developed, but lizards and snakes have forked tongues, the tips of which can be inserted into the paired organs of Jacobson at the top of the palate. This provides a kind of 'touch-smell' sense, and enables the animals to obtain detailed information about the immediate environment and to make extensive use of communication by pheromones. Such communication is often important in mediating social behaviour (Mason 1992; Alberts *et al.* 1994a) and physiology (Alberts *et al.* 1994b). The 'touch-smell' sense may also enable reptiles to detect the presence of other species, including potential predators and possible prey. Discrimination using this sense can be subtle. Many snakes can use chemical cues to follow the 'trails' of prey, and this is particularly important for those venomous

species that track envenomated victims until they die – so-called ‘strike-induced chemosensory searching’. Pythons and some other snakes have small pits on the side of the head that are sensitive to infrared radiation, and enable them to sense the presence of warm-blooded prey.

UV radiation can be important in social behaviour (Fleishman *et al.* 1993). There is evidence, for example, that secretions from the femoral glands of some desert iguanas selectively absorb longwave UV radiation; deposits from these glands left in the environment will be very obvious to another individual (Alberts 1989; Alberts *et al.* 1994a). Chin glands in certain chelonians may play a similar role (Alberts *et al.* 1994b).

### Size and lifespan

Adult reptiles range in size from lizards that measure 40 mm or less in length and weigh less than 1 g, to snakes that are more than 9 m in length (eg, *Python reticulatus*, *Eumeces murinus*). The largest lizards (*Varanus komodoensis*) reach 3 m in length, and have a body mass of up to 160 kg.

In general, smaller reptiles live for shorter periods than do larger ones. Small lizards characteristically have a maximum longevity of 10 years; larger lizards may live for more than 30 years. Pythons and boas can also live for more than three decades, but the potential longevity of most other snakes is not known. Small species of tortoise have a life-expectancy of 20 years; larger species more than 100. Reptiles are likely to survive longer in captivity than they would in the wild.

### Hibernation and aestivation

Some species of reptile hibernate, others will undergo periods of aestivation when environmental conditions are hot, dry and adverse.

The physiology of hibernation (brumation) is complex and some examples draw attention to the remarkable resilience of certain reptile species to hypoxia (Jackson 2002).

There is much published advice on how best to prepare reptiles, mainly tortoises, for hibernation (see, eg, McArthur *et al.* 2004a). Under laboratory conditions, however, these and other species are usually kept awake during the cold months and not allowed to hibernate (see, eg, Arbour *et al.* 2007), apparently without any adverse effects on health and welfare.

### Sex determination and reproduction

Most reptile species (all chelonians and crocodylians, most lizards and some snakes) lay eggs. Some lizards and certain snakes, particularly but not exclusively those that inhabit cold climates (eg the European common lizard, *Lacerta vivipara*) or high altitudes where incubation of eggs may be retarded (eg certain Central African chameleons) produce live young. In such taxa the eggs are retained in the oviducts until the young are ready for independent existence. Reptiles that produce live young are usually termed ‘viviparous’ or

‘live-bearing’ but the word ‘ovoviviparous’ is sometimes also used.

Fertilisation, in reptiles, is internal, and may follow elaborate courtship behaviour (Hernandez-Divers 2001). Male lizards and snakes have two intromittent organs, the hemipenes: chelonians have one hemipenis (phallus).

Some species of reptiles are sexually dimorphic, showing distinct colour, markings, size or anatomical features such as the presence of femoral pores in certain lizards (Schumacher 2003).

Distinguishing the sex of monomorphic species or (of almost all) juvenile reptiles, can be difficult but various methods can be used (Denardo 2006a). In snakes scale counts often help (male snakes usually have a longer tail, with more subcaudal scales, than do females) and even a sloughed skin can be used to determine this (Cooper & Cooper 2007) (Figure 46.4).

‘Cloacal probing’, using a slender, blunt object of suitable size, is the most frequently employed technique for the sexing of snakes and the larger lizards. If the probe cannot be advanced when gently directed caudally from the cloaca, the animal is female. In males the probe will enter a sulcus which contains an invaginated hemipenis (Frye 1991). Probing is used routinely by herpetologists but the technique needs to be properly learned if damage to animals is to be prevented. Probing is often taught using a freshly dead reptile.

As discussed in more detail in the section on reproduction, sex determination in some species, such as sea turtles, is temperature-dependent (Ewert *et al.* 1994), and this has to be borne in mind when incubating eggs under laboratory conditions. Egg-laying female reptiles usually bury their eggs in soil or sand, or lay them in crevices in rock or bark. Eggs of most species are oval or round in shape and are surrounded by a shell, which may be hard as a result of impregnation with calcium salts, or soft and leathery. In nature the site at which the eggs are laid is important. Protection from predators is necessary but the temperature will affect the rate of development and, in some species, the sex of the offspring. Relative humidity is also relevant. If it is too low, the eggs will dehydrate; if too high, they will drown or become infected by fungi or bacteria.

## Laboratory management

### General

Reptiles are adept at escaping from cages and enclosures. Many species climb or burrow and, by flattening their bodies, can squeeze through small holes or cracks.

The Council of Europe has provided recommendations for minimum housing standards for reptiles used in research (Council of Europe 2006). Some reptiles can be kept satisfactorily in large aquaria, wooden cages with a glass panel or open-topped wooden or fibreglass containers. Certain species appear to require such cages to be only very simply furnished in order to thrive – a ‘clinical habitat’ (Varga 2004) that lends itself well to laboratory research. Others need more specialised accommodation, and may thrive better if the internal construction and ‘furnishing’ of the cage bear some relationship to their normal environment – a ‘natural-

*istic habitat'* (Varga 2004). Thus, sand-burrowing lizards (eg, *Chalcides ocellatus*) remain in far better condition if they have sand in which to burrow, as do arboreal species when provided with branches on which they can climb, for example most *Anolis* lizards. Species that are 'sit-and-wait' predators (eg, many species of snakes and geckos), and herbivorous reptiles, usually need little space. Some species, such as most lizards in the families Lacertidae and Teiidae, will be restricted by smaller cages. In these, they often spend much of their time trying to get out, possibly suggesting that a motivation to range is being thwarted. This has been linked with poor welfare in mammals (Clubb & Mason 2003). The immediate action should be to provide such species with more space but it is important to realise that, in contrast to the situation in other taxa, scientific data on the significance of escape-like behaviour in reptiles is sadly lacking.

### Handling and restraint

Competent handling and restraint are as important for reptiles as they are for other species of laboratory animals. Training of staff is highly desirable and in some countries, such as the UK, may be mandatory before appropriate licences are issued. Inexperienced research workers can learn much from herpetologists.

Smaller lizards and snakes can usually be rested, or restrained gently, on the hand for routine inspection or movement from one cage to another. Many species of snake will support themselves if allowed to move from hand to hand. When restraint of snakes and lizards is necessary, they should be grasped firmly behind the head while supporting the body. Support is particularly important for snakes and legless lizards which become damaged or stressed if they are allowed to 'dangle'. Guidance on handling venomous snakes is provided in Locke (2008). Care must be taken with lizards to ensure that the tail is not grasped or pinned, since certain species can spontaneously shed it (autotomy) (Bellairs & Bryant 1985). Some geckos are particularly fragile; they not only shed their tails extremely readily but their skin is only loosely attached, so that it easily tears away from the underlying tissue.

Large lizards, such as iguanas and monitors, have a powerful, possibly toxic (see later), bite and can also inflict damage with their tail and claws. It is a wise precaution to use leather gloves when handling them.

Chelonians can usually be handled by grasping the 'shell' (carapace and plastron) and land tortoises, in contrast to many species of terrapin and turtle, rarely bite. Restraint of tortoises in order to carry out procedures is less easy. It may be possible to grasp the animal's head but sometimes light anaesthesia is required to facilitate this and other investigative techniques.

Training and habituation of captive reptiles can facilitate handling and thereby minimise stress to both animal and personnel.

### Species used in the laboratory

Reptiles of various species are kept in laboratories. Table 46.1 lists some that are used widely for research, and which

are relatively easy to obtain, maintain and breed. Most of them and certain others can be obtained as captive-bred animals. A very few species of captive-bred terrestrial reptile are produced commercially specifically for research purposes – *Anolis carolinensis*, for example. Other species that are not listed are regularly bred in captivity as part of conservation projects or for the pet trade.

Whenever possible, reptiles for research should be captive-bred and obtained from reliable sources. On occasion, however, animals need to be taken from the wild – either because they are not available as captive-bred specimens or because the research is specifically concerned with free-living reptiles – for example, reintroduction or translocation conservation projects.

It is essential to adhere to relevant legislation. Even common and widespread species of reptile may be covered by national laws, requiring (for example) a licence to take them from the wild or to retain them in captivity. Special legislation may apply to venomous snakes and lizards. International regulations may also be relevant, in particular the Convention on the International Trade in Endangered Species of Wild Fauna and Flora (CITES). Many species are covered by this Convention which controls 'trade' (movement) of live and dead organisms and their derivatives, including blood samples and tissues for DNA analysis (Cooper *et al.* 2006).

Reptiles and other ectothermic vertebrates have played a significant part in scientific research. Cooper (1977) reviewed the role of such species and stressed that they can serve as useful models for studies on the origin and aetiology of human diseases.

Some indication of the value of terrestrial reptiles in research is given in Table 46.1. Lizards have been extensively used in studies of biological rhythms and seasonal cycles (Underwood 1992), control mechanisms for reproductive cycles and comparative endocrinology (Moore & Lindsey 1992), neuroethology (Crews & Gans 1992), regeneration processes (Bellairs & Bryant 1985), brain chemistry, neuropeptide neurotransmitters (Reiner 1992), evolutionary aspects of exercise physiology (Garland 1994) and growth and longevity (Roitberg & Smirina 2006).

Vipers, mambas and cobras are frequently kept in laboratories for the production of venom, or to study the pathological effects of such toxins. The pit organs of some vipers and pythons have been widely studied.

Tortoises have been used in studies of sensory physiology, leading to a better understanding of pain in these animals (Rosenberg 1972) and contributing to the development of what would appear to be more humane methods for euthanasia (Cooper *et al.* 1984; UFAW/World Society for the Protection of Animals (WSPA) 1989, WSPA 1994). Tortoises are popular subjects for research on *Salmonella* and other bacterial pathogens (eg, Arbour *et al.* 2007).

In many parts of the world lizards, snakes and tortoises are kept in laboratories for teaching students and for simple, non-invasive, studies on nutrition, growth or reproduction. All such animals deserve the highest level of care. An important prerequisite is an understanding of the natural history and biology of the species. For some there may be extensive published information – *Iguana iguana*, for example (Jacobson 2003). For others, data may be sparse or largely anecdotal.

**Table 46.1** Some terrestrial reptile species that are frequently kept in laboratories.

Scientific name	Common English name	Studies for which the species is commonly used	Reference
<b>Lizards</b>			
<i>Anolis carolinensis</i>	American anole	A wide range of physiological topics, especially neuroethology and colour change	Harling (1994)

<i>Testudo graeca</i> and <i>T. hermanni</i>	European tortoises	Physiology of the pineal and associated organs	Jackson (1991), British Chelonia Group (undated)

## Temperature and thermoregulation

Many nocturnal geckos and lizards and snakes from the leaf litter or lower levels of tropical rain forests do not routinely thermoregulate. Ideally, they require air temperatures that equate with their natural environments. However, during the day some species warm themselves by (for example) pressing themselves on to the warm rock under which they live and then use the heat obtained to help sustain them at night. Most species of reptile do, however, need to thermoregulate and this can be accommodated under laboratory conditions by providing a diversity of substrate temperatures, using heating pads, lamps or other sources of surface warmth. The provision of radiant heat from a small tungsten bulb enables many species to bask in the light and heat, treating it as though it is natural sunshine. Sources of heat that produce only infrared radiation, such as ceramic bulbs, are usually, but not necessarily, less suitable as they do not provide light, which many basking reptiles use as a cue to prompt thermoregulation. Larger incubator bulbs that give out yellow light are suitable for bigger reptiles (but not those which emit visible light mostly in the red part of the spectrum). The bulb should be positioned so that the animal can approach close enough to be able to warm fairly readily, but not so near that it will burn (Mader 2006a) either from the infrared radiation itself or from a substrate that has been heated by the radiation.

Care must be taken that laboratory cages do not become too hot. There must be areas that are sufficiently cool to enable the reptiles to lose heat as well as to gain it. This can often be achieved by placing the bulb(s) at one end of the cage. The heat should not be switched on for too long; 8–10 h per day is ideal for most species. The longer there is heat provided, the more protracted the period for which the reptile maintains its activity temperature and the greater its metabolic expenditure. Various papers, mainly relating to studies on captive and free-living European common lizards (*Lacerta vivipara*), describe research that is relevant to the care of this and possibly other species under laboratory conditions (Avery 1984, 1994). Avery (1984) has suggested that relatively short daily exposure to radiant heat minimises the risk of respiratory disease caused by the bacterium *Aeromonas*, whilst Guillette *et al.* (1995) postulated that the daily period for which radiant heat is available may affect the immune system.

The air temperature when the heating bulb is switched off may be allowed to vary: this corresponds to the situation in all but the most stable of tropical climates. There is often a tendency to keep the background temperature too high and this may be deleterious for species from desert or montane environments, where high solar radiation during the day can be followed by cool nights. Successful captive husbandry and breeding in environments in which temperatures were carefully controlled and monitored was reported in relation to the Malagasy panther chameleon, *Chamaeleo*

*pardalis* (Ferguson 1994). Similar data are required for other species and those who keep reptiles under laboratory conditions are in a particularly strong position to carry out the necessary studies.

## Light

Light appears to be less important to reptiles than is heat. In general, natural light (in which the greatest energy is in the blue part of the spectrum) usually results in better survival, growth and reproduction than does artificial light (which usually peaks in the yellow), although the reasons for this are not fully understood (Gehrmann 2006). There is some evidence that the duration of the daily photoperiod may be an important factor, controlling reproductive cycles in many species (Avery 1994), and this must be taken into account by those wishing to breed reptiles in captivity.

## Ultraviolet radiation

The importance of UV radiation for many species of reptiles has already been emphasised. When exposure to natural sunshine is not practicable, artificial UV radiation must be supplied. A wide range of fluorescent tubes that will provide this are available commercially. While both middle (UV-b) (290–320 nm) and long (UV-a) (315–400 nm) wavelength UV appear to be important to reptiles, it is the former that is of prime importance in converting vitamin D; UV-a is believed to be more of value in encouraging recognition of food and mates (Rossi 2006). It remains true, however, that despite many reports of UV radiation resulting in improved reproduction in captive reptiles (mainly lizards), most studies remain empirical (Gehrmann 1994).

There are several important considerations when using UV sources:

1. UV emission from fluorescent tubes usually decreases with time; the tubes have a relatively short useful life.
2. Exposure must be direct: normal glass blocks UV radiation.
3. The intensity of UV radiation declines rapidly, so the tubes must be close to the animals.
4. Broad-spectrum tubes (designed to mimic daylight or sunlight) are of limited usefulness.
5. Tubes designed to improve plant growth (which have peak emission in the blue part of the spectrum) usually emit little UV radiation.
6. Fluorescent and mercury vapour sunlamps, sometimes used for tanning in humans, emit a wide range of UV wavelengths, but may damage the retinae or skin of both reptiles and laboratory personnel. They are best avoided.

## Relative humidity

Laboratory environments often have drier air than the microhabitats of free-living reptiles. This may prove deleterious, even to desert species, as these spend much of their natural lives in humid burrows. The relative humidity in rooms housing reptiles, or in individual cages, can be increased in many ways. Spraying the inside of cages with water from a mist nozzle is effective but, unless it is automated, can be labour-intensive. One very simple measure is to furnish cages with living plants, transpiration will then add water to the local atmosphere. High humidity zones can be created within the cage by the use of 'humidity boxes', usually made of plastic (Rossi 2006). On a larger scale, dripper systems and waterfalls can be used.

Various diseases of the skin, scales, the shell in tortoises, and the respiratory system, may be induced or exacerbated by too high or too low humidity (Cooper 2006). In the case of the latter, Gram-negative bacteria such as *Aeromonas* and *Pseudomonas* and certain fungi are likely to multiply excessively under damp conditions (Frye 1991).

Limited data are available on the humidity requirements of reptiles: much of the available information is based upon observational and anecdotal evidence. This is another field which would benefit from input from those who work with reptiles in the laboratory.

## Ventilation and air changes

Optimum ventilation for laboratory reptiles can be difficult to achieve. Too little ventilation results in inadequate diffusion of oxygen into, and carbon dioxide out of, a cage and can also increase humidity, leading to condensation. Too much ventilation, on the other hand, can make it difficult to control the temperature and keep the relative humidity high. The optimum ventilation for a particular cage design must sometimes be determined by trial and error; there is increasingly a tendency to specify the number of air changes in order to conform with research protocols and, ostensibly, to promote health and welfare. These are not necessarily the most appropriate for a given species (Cooper & Williams 1995).

## Environmental enrichment

Many species of terrestrial reptiles can be kept successfully in relatively plain cages; provided that the space is adequate for reasonable movement, such containment seems to satisfy their behavioural requirements although there is an absence of research in this area. As discussed earlier, however, some species thrive better in cages or enclosures that mimic the natural environment (Figure 46.5). The welfare of the reptile is likely to be enhanced if accommodation is appropriate to the species (Varga 2004).

There are many species of reptile that clearly benefit from environmental enrichment. When, for example, small European lacertid lizards are kept in plain unfurnished cages, they tend to spend long periods motionless, often basking at length beneath the bulb that is provided for thermoregulation. Creating an area of spatial diversity, even simply by adding a number of wooden blocks, results in a dramatic change in behaviour. The lizards then bask for only relatively short periods, interspersing this with periods of movement (presumably looking for food) amongst the

blocks, behaviour that is much closer to that seen in the field (Avery 1994).

### Training and habituation

Training and habituation of reptiles is possible to a limited degree. It may facilitate procedures and reduce risks to staff. For example, lizards can be taught to feed at the same location each day. Snakes can learn by association and some species, eg, iguanas, recognise cause and effect relationships. Habituation has been studied in some reptiles (Xavier *et al.* 2006) but needs further research.

The importance of 'good stockmanship' cannot be over-emphasised. Those who tend captive reptiles, especially technicians, should exhibit an empathy with their charges and, preferably, have personal experience of herpetology.

### Refugia (hiding places)

Most species of reptiles, like almost all metazoan animals, have periods of the day when they are active. When they are not active, they seek some kind of refuge – in burrows, under rocks or in crevices, high in trees, or amongst dense vegetation (many terrestrial chelonians). Failure to provide a refuge for captive reptiles may be stressful (Hernandez-Divers 2001). The problem appears never to have been systematically investigated.

In contrast to physiological measures of stress, which have received some preliminary study (Guillette *et al.* 1995; Kreger & Mench 1993), there is as yet no totally reliable behavioural means of defining or measuring stress in the diverse species of reptile (Greenberg 1995; Warwick *et al.* 1995). Captive reptiles should always be provided with a refuge that mimics places where they would hide in nature. Given a choice, snakes prefer an opaque refuge to one with transparent walls, although the latter are more convenient from the standpoint of the reptile-keeper (Chiszar *et al.* 1987). It is best not to disturb individuals in the refuge except in extreme necessity. For similar reasons, as a general rule, it is preferable not to alter the internal arrangements of a cage once an individual has become familiar with it, especially under laboratory conditions where standardisation of procedures is so important. This is because many reptiles learn the immediate topography of their enclosure and can become stressed when it alters (Chiszar *et al.* 1995). On the other hand, many herpetologists and veterinarians would argue that a novel environment can encourage chemosensory behaviour and thereby promote welfare. The relationships between refugia and other elements of cage design are important. Small lacertids such as European wall lizards (*Podarcis muralis*), for example, behave more naturally if one or more of the refuges is placed near to their basking places (Avery, unpublished observations).

### Hygiene

It is usually a basic tenet of captive management of animals that cages should be cleaned regularly in order to minimise

build-up of parasites or other pathogens. This can be particularly important where infections might compromise research. Hygiene is also important to reduce the risk of spread of zoonotic infections. However, there are indications that cage-cleaning for certain reptiles should not be too frequent. Some of the chemicals in faeces can act as pheromones and may be used for communication. Some snakes, for example, thrive less well in clean cages than in cages containing some faeces and leaving a small amount of faecal material in a cage every time it is cleaned reduces the incidence of escape behaviour (Chiszar *et al.* 1980). In contrast, certain species of gecko avoid contact with their own faeces, probably to minimise exposure to parasites (Brown *et al.* 1998).

Disinfection of cages should be preceded by thorough cleaning. The choice of a disinfectant is important. Some can be toxic, especially to small reptiles. Disinfectants have different modes of action (Slomka-McFarland 2006). Under circumstances where quality disinfectants are unavailable or prohibitively expensive, hot water is an easy and cheap alternative, preferably followed by drying in the sun or in a hot-air oven.

There is evidence for some mammalian species that irregular husbandry can be a stressor. While there are few equivalent unequivocal data for reptiles, consideration should be given to regular cleaning routines.

### Diet and feeding

Reptiles as a class eat a variety of foods though many species have narrow food preferences. Lizards are predominantly carnivorous (a few species are herbivorous), and snakes are almost entirely carnivorous. Chelonians vary: as a general rule, terrestrial species (land tortoises) are primarily vegetarian while freshwater aquatic species (terrapins) are carnivorous. Calvert (2004) provides a useful and succinct review of the nutrition of captive reptiles.

Reptiles have relatively low metabolic rates and high net food-conversion efficiencies. Over-feeding is often as much of a problem as under-feeding, and can lead to a range of pathological conditions (see later). Small and medium-sized lizards, and most chelonians, need feeding daily. Large lizards and many snakes should be fed less frequently: some large snakes probably feed in nature less than once per week or once per month. The essential requirements are a regime and diet that will ensure the maintenance of bodyweight in non-breeding adults, and normal growth by juveniles. Many reptiles cease feeding spontaneously from time to time, especially just prior to skin-shedding.

Many insectivorous and carnivorous reptiles feed only on items that are moving. Live vertebrates should not be used as food unless there is no alternative (see later) and even invertebrates should be used in a way that is sensitive to the fact that they too are living animals. There are many methods to simulate the movement of non-living prey: these include placing them in a Petri dish on an automatic shaker, or employing tongs to shake the prey, or dragging the food item around the vivarium so as to create a scent trail for the snake/lizard to follow.

Some snakes refuse to feed in captivity. They can be force-fed (Cooper & Jackson 1981), often now referred to as

'assisted feeding', but it is preferable to try to coax them to feed spontaneously first. One technique, often successful with pythons and boas, is to condition them always to feed in the same place, which may be marked with scent of potential prey from time to time to reinforce the association. Other ruses include hiding the food in a tube or another unexpected location.

Most authorities concur that the diets of captive reptiles should be as varied as possible, as this helps to reduce nutritional disorders that are so commonly encountered in captivity (Frye 1991, 1994, 1996; Calvert 2004). This injunction applies to herbivorous as well as insectivorous or carnivorous species. Because tortoises, iguanas and other herbivorous reptiles feed with apparent relish on soft leaves and fruits, it is sometimes not appreciated that their diets in nature are usually very varied, and often include insects, molluscs and other invertebrates which may be swallowed deliberately or accidentally and usefully contribute to the animal's nutrient intake.

Insectivorous reptiles will often take only living prey. Invertebrates can be purchased from dealers who breed the animals for the pet trade or propagated within the laboratory animal facility. It is important to ensure that such animals are from a reliable source and health checks on them may be advisable as they can be a source of infection, including iridoviruses that can affect both invertebrates and reptiles (Marschang *et al.* 2005).

The most commonly used cricket is *Acheta domestica*, but species that do not stridulate are increasingly becoming available and are often preferable in animal houses. Crickets that are not eaten within a few hours should be removed as they are nocturnal and are likely to nibble the appendages of lizards if allowed to remain in the cage and increase the risk of autoinfection with parasites. There may also be an ethical issue as far as the crickets are concerned.

Mealworms and are larvae of the beetle *Tenebrio molitor* are easy to breed, although other species are increasingly becoming available, including 'giant mealworms' which are suitable for larger species of reptiles. They should not form a major part of the diet of any reptiles, however, because they contain far too high a concentration of phosphorus ions relative to calcium ions. Sooner or later, reptiles fed a diet of mealworms succumb to disorders caused by mineral imbalance (Frye 1991, 1996). Many reptile keepers 'preload' or 'gutload' mealworms and other invertebrates with calcium, and sometimes other minerals, vitamins and plant material, by adjusting their diet immediately prior to using them as food. Finke *et al.* (2005) evaluated four dry commercial gut-loading products for improving the calcium content of crickets.

Invertebrate prey can also be dusted externally with minerals to increase dietary intake but care must be taken to ensure that the invertebrate is ingested quickly as some species, especially crickets, quickly groom and remove the dust.

An increasingly large range of dietary supplements is available commercially, some formulated specifically for reptiles. They all contain vitamin D and calcium; some are very finely ground, so that the particles adhere readily to the cuticle of invertebrate prey. Almost all captive reptiles

need dietary supplementation: the only possible exceptions are those kept in large, open outdoor enclosures, with exposure to natural sunlight and a varied diet. In some studies and locations (eg, the tropics) it may be acceptable to allow the reptiles to eat insects that have flown into the enclosure from outside.

Many reptiles are susceptible in captivity to mineral deficiencies or imbalances. These may result from a faulty diet (Calvert 2004) or from insufficient exposure to appropriate ultraviolet radiation. There are four main reasons why problems associated with calcium arise so commonly:

1. Inadequate calcium in the diet.
2. Calcium: phosphorus ratio is too low.
3. A dietary deficiency of vitamin D<sub>3</sub>.
4. Inadequate exposure to UV radiation, which in many species is necessary for dermal synthesis of cholecalciferol, the metabolic precursor of vitamin D. It is important to note that it is UV-b light in the range 290–320 nm, that is of prime importance in converting vitamin D. The amount of UV-b that is available to the reptile can be measured using an appropriate meter.

The value of natural (solar) lighting must not be overlooked. In many reptile collections in the tropics, including some used for research purposes, sunlight is the only source of UVB-b and the animals appear to fare very well.

Mineral deficiencies or imbalances can give rise to osteodystrophic disorders (Frye 1991), referred to by Mader (2006b) as the '*metabolic bone diseases*'. These are characterised by a range of skeletal lesions, fibrous osteodystrophy (Figure 46.6), impaired locomotion and, in chelonians, abnormalities of the carapace. Problems of mineral imbalances may also occur in larger reptiles fed on day-old chicks or rodents, especially when neonatal rodent pups ('pinkies') are used.

**Figure 46.6** A green iguana (*Iguana iguana*) with metabolic bone disease. The swelling of the lower jaw is a sign of fibrous osteodystrophy. A balanced diet will usually prevent the development of this condition under laboratory conditions.

Various vitamin deficiencies are recognised or suspected in captive reptiles. Hypovitaminosis A was the first to be properly described and documented. In chelonians it can produce characteristic ocular lesions. Other effects may include retarded healing of wounds and predisposition to infectious diseases (Cooper *et al.* 1980). Studies have been carried out on the vitamin A requirements of some species – chameleons, for example (Abate *et al.* 2003).

It is not only a deficiency of vitamin A that can cause disease in captive reptiles. Hypervitaminosis A may result from excessive administration resulting in skin lesions (Cooper 2006).

In nature, most vertebrate prey is taken alive. The question of whether it is acceptable to feed living mammalian or avian prey to snakes and large lizards in captivity raises important ethical and sometimes legal issues. Many large reptiles will feed on dead animals; others quickly learn to do so. It is the animal that persistently refuses to feed on anything but living prey which creates a dilemma. Some authorities take the view that feeding living prey may be acceptable as a last resort (if the predator would otherwise starve to death) but that the prey animal should be removed from the cage immediately if the predator takes no interest in it, in the interests of both predator and prey. There are also legal considerations; however, in the UK, for example, the offering of live prey is not, *per se*, illegal but may provide grounds for a criminal action.

How much to feed laboratory reptiles is an important consideration (see earlier). Condition scores play a crucial part in monitoring nutritional status (see later).

Underfeeding will result in weight loss, 'poverty lines' and weakness. However, such findings can also be the result of providing an adequate but unsuitable diet, or because a reptile is unwell and unable to feed, or is unwilling to do so on account of stressors, including territorial or other aggression. Too low an ambient temperature or other adverse environmental factors may also be a cause of decreased feeding behaviour and food intake.

Over-feeding of captive reptiles can result in a range of pathological changes, including hepatic lipidosis (Divers & Cooper 2000). Some information on food intake of captive snakes in relation to body weight is provided by Kirkwood and Gili (1994).

Laboratory reptiles should always be provided with water. Dehydration can rapidly prove fatal in reptiles, in part because it leads to renal damage and the development of visceral gout (Figure 46.7). Some species will use water for bathing as well as for drinking. Snakes may immerse themselves in water when sloughing is imminent. How water is presented is important. Some lizards and chelonians will drown if they fall into a water container from which they are unable to escape. Chameleons will not usually drink from a waterbowl: they should be provided with water in the form of drops on foliage, using a spray.

### Recognition and marking

The marking for identification of captive reptiles is important both for scientific and legal reasons (Cooper & Cooper

**Figure 46.7** Post-mortem appearance of a Jamaican boa (*Epicrates subflavus*). The kidneys are white as a result of deposition of urates (visceral gout), possibly because of dehydration.

2007). It has long been recognised that many individual reptiles can be identified by a combination of their size, colour, pattern and, in certain lizards, the state of the tail (since this may have been broken off in the past, and be at various stages of regrowth). It is possible to build up databases of sets of pictures of individuals – eg, of the plastral markings of tortoises.

When individual reptiles cannot be recognised visually, it may be necessary to mark them. Methods for snakes were reviewed by Lang (1992). Clipping ventral scales is simple and effective, but the animal must usually be handled in order to see the marks. Implanted transponder tags, commonly termed microchips, are routinely used in zoos and in the pet trade in many countries and may be a legal requirement for certain species as part of enforcing legislation – eg, for tortoises that are traded in the European Union under EC Regulations 338/97 & 865/2006 (Cooper & Cooper 2007). Transponders are also regularly used in field studies (Germano & Williams 1993). There are correct and incorrect methods of implanting microchips, most dictated by factors such as practicability and welfare, some by legal regulations. A useful review insofar as reptiles are concerned is to be found at the website of the British Veterinary Zoological Society<sup>1</sup>.

### Welfare and welfare assessment

As a general rule, the application of the Five Freedoms will do much to promote the welfare of captive reptiles (Rayment-Dyble 2004). As with all species that are kept in the laboratory, the assessment of welfare of reptiles is of great importance. Over 20 years ago, guidelines for the recognition of pain, distress and discomfort in laboratory mammals were first formulated in the UK (Morton & Griffiths 1985). Little comparable advice appears to have been devised for laboratory reptiles, although very general criteria/guide-

<sup>1</sup><http://bvzs.org.uk>

lines for recognising pain, distress and discomfort have been developed by WSPA (1994) and Warwick *et al.* (1995).

Some reptile behaviour is considered to be associated with stressors and stress (Hernandez-Divers 2001). Stereotypy, for example, is well recognised in captive reptiles: it has received little scientific attention in these species in contrast to the situation in domesticated mammals and birds (Mason & Rushen 2006).

There are limited data on the physiological effects of handling and restraining some species of reptile (eg, Kreger & Mench 1993). Chelonians readily defaecate when handled or contained and, indeed, these 'stress faeces' (Josseaume 2002) are used in some research studies.

A useful review of current thinking concerning stress in reptiles can be found in Denardo (2006b), and Hernandez-Divers (2001) provided a very useful introduction to reptile ethology, including examples of normal and abnormal behaviour patterns. Interactions between stress and other aspects of reptile metabolism were discussed by Guillette *et al.* (1995).

In summary, there is an urgent need for more research on the welfare of reptiles and the formulation of protocols to aid research workers, animal technicians and laboratory animal veterinarians.

## Reproduction

### General considerations

Breeding reptiles in captivity demands care and attention to detail, and is usually time-consuming (Wright 2004). Many species require either a natural seasonal regime of temperature and photoperiod (and occasionally also rainfall), or artificial regimes that mimic seasonality (Chiszar *et al.* 1994). Most temperate species require the 'priming' effects of cool-induced hibernation or quiescence in order to promote breeding, eg, *Lacerta vivipara* (Gavaud 1991). Social behaviour often has a modulating effect on the development of reproductive condition, for example in *Anolis* lizards. Successful reproduction may depend on the correct social context (Hernandez-Divers 2001). In the leopard gecko (*Eublepharis macularius*), for example, females will lay only if sexually mature males are present. In the American anole (*Anolis carolinensis*) courtship displays by males facilitate ovarian growth in females, whereas aggressive interactions, which may occur if more than one male is present, may inhibit ovarian development (Crews *et al.* 1994).

Most reptiles are oviparous. Under laboratory conditions the eggs should be removed immediately after laying, because they need a carefully controlled environment for successful development. In addition, the hatchlings may be eaten by the adults. Gecko eggs, however, should not be removed, because they are laid in such a way that they adhere to hard surfaces such as rocks or the walls of a cage. They can be protected by taping a small plastic container over them until they hatch. Temperature, substrate, substrate moisture and relative humidity of the surrounding atmosphere are particularly important. Unlike the eggs of birds, reptile eggs should not be moved or turned during incubation.

### Role of temperature

All reptile species have an optimum temperature for incubation of their eggs. This is usually lower than the mean activity temperatures maintained by adults. Eggs incubated at temperatures that lie outside the optimum have lower levels of hatching success, and may be associated with developmental abnormalities (see later).

There are many species of reptiles in which the sex of an embryo depends not on sex chromosomes but on the temperature during the early stages of incubation (Table 46.2). Three general patterns are seen (Lance 1994):

1. Higher temperatures produce males, lower temperatures produce females; this applies in many species of lizards and in alligators.
2. The opposite effect: higher temperatures produce females, lower temperatures produce males eg, in many chelonians.
3. Intermediate temperatures produce males, higher and lower temperatures produce females. This occurs in the leopard gecko (*Eublepharis macularius*), the snapping turtle (*Chelydra serpentina*) and some crocodiles.

In most of the species that show temperature-dependent sex determination (TSD), the transition from production of one sex to production of the other takes place within a comparatively narrow range of temperatures (intersexes are rare). In American alligators (*Alligator mississippiensis*), however, intermediate temperatures result in the production of a mixture of males and females. The actual temperatures that are important for producing changes in the sex ratio vary from species to species, and sometimes geographically within a species. Fluctuating temperatures may produce different results from constant temperatures. Table 46.2 lists lizard species shown to exhibit TSD. Because of the com-

**Table 46.2** Lizards, terrestrial chelonians and crocodilians that have unequivocally been shown to have temperature-dependent sex determination (TSD). There are many other species which are likely to have TSD. Most reptile species have not been studied in sufficient detail to know whether their sex determination is genetic, environmental or temperature-dependent. The data in this table are mostly from Ewert *et al.* (1994), Lang and Andrews (1994) and Viets *et al.* (1994).

Lizards	<i>Agama agama</i> , <i>A. caucasia</i> <i>Dipsosaurus dorsalis</i> <i>Eublepharis macularius</i> <i>Gekko japonicus</i> <i>Hemithelyx caudicinctus</i> <i>Tarentola boettgeri</i> <i>Phelsuma madagascariensis</i>
Chelonians (terrestrial species)	<i>Testudo graeca</i> , <i>T. hermanni</i> <i>Terrapene ornata</i>
Crocodilians	<i>Alligator mississippiensis</i> , <i>A. sinensis</i> <i>Caiman crocodilus</i> <i>Crocodylus palustris</i> , <i>C. johnstoni</i> , <i>C. moreletti</i> , <i>C. niloticus</i> , <i>C.</i> <i>porosus</i> , <i>C. siamensis</i> <i>Gavialis gangeticus</i> <i>Paleosuchus trigonatus</i>

plexity of responses, no attempt has been made to provide crucial temperatures. The implications of TSD for the breeding of those reptile species in which it occurs are profound; in management programmes for sea turtles, sexing by endoscopy is increasingly being used to ensure an even mix of sexes when juvenile animals are returned to the sea.

### Substrate

The eggs of many reptiles may be incubated on damp tissue paper, *Sphagnum* moss, peat, sand, polystyrene foam or other substrates. The medium most frequently used, however, is vermiculite. Made primarily for insulating buildings, vermiculite is cheap, relatively non-toxic and absorbent; it contains sufficient air-filled spaces among the granules that diffusion of air can readily take place. Whatever medium is employed, it should be used only once. There has been much discussion about the extent to which eggs should be buried in the substrate. Packard and Phillips (1994) recommended that eggs of species with flexible shells should be half-buried; those with rigid shells should be placed in small depressions at the surface of the medium.

### Health and diseases

The aim in captivity is to provide reptiles with good welfare, of which physical health is a vital component. Under laboratory conditions it is particularly important to establish health profiles for the animals so as to help ensure consistency of research results, to detect early signs of disease and to promote welfare (see later). The diagnosis and treatment of reptile diseases are primarily the remit of the veterinarian, preferably one with experience of reptile medicine and surgery (Frye 1994). A useful table of differential diagnoses is to be found in an Appendix to the BSAVA Manual of Reptiles (Girling & Raiti 2004). The animal technician and research worker, who are familiar with the behaviour and natural history of the species, have an important part to play in health monitoring.

### Health monitoring

Health monitoring involves the regular and routine investigation of live reptiles, *post-mortem* examination of any animals that die or have to be culled, and laboratory studies on samples from live reptiles, dead reptiles and their environment. Relatively little has been published on the health monitoring of laboratory reptiles but methods used for lizards, snakes, chelonians and other species in zoological collections and conservation programmes (Woodford 2001) can be usefully adapted. Cooper (1989) wrote a paper specific to laboratory reptiles and amphibians.

The exclusion of infectious disease is facilitated by the use of quarantine, whereby incoming reptiles are kept separately prior to their introduction to the colony. During this period the animals should be screened for pathogens and, if possible, health monitored. Subsequently, as in other fields

of laboratory animal science, there is a need to maintain the reptiles' status by having efficient barrier systems, with rules to which all staff adhere.

An essential aspect of monitoring the health and, to a certain extent, the welfare of captive reptiles is the assessment of body condition. This is not always easy or straightforward; for example, some reptiles go through normal, cyclical, periods of fat deposition or loss. Essentially, however, body condition scoring (BCS) implies that laboratory reptiles are weighed and measured on a regular basis. How these data are processed may depend on the species: formulae are available for Mediterranean tortoises (eg, Jackson 1991; Hailey 2000; Willemser & Hailey 2002).

Newer books do not necessarily supersede older works. Often the latter contain sound, basic information which can be of great value to research workers and animal technicians. Scientific literature about reptile diseases goes back to the seminal work of Reichenbach-Klinke and Elkan (1965): although now over 40 years old, their book remains a useful guide to some aspects, especially parasite identification. More recent publications that provide up-to-date information on medical and surgical treatment include Frye (1991) and Mader (2006c). It is important to remember that not all relevant texts are in English. For example, excellent sources of information on lizards, snakes and tortoises are the relevant chapters in the German work *Krankheiten der Heimtier* (Gabrisch & Zwart 2005).

### The effects of captivity on health

Captivity imposes physical, behavioural and physiological constraints on reptiles. Confinement in a relatively small space, often in close contact with others of the same species, can precipitate infectious or non-infectious disease and compromise welfare (Arena & Warwick 1995). This is an important ethical, often legal, consideration when reptiles are kept in laboratories. Examples of health problems that are due to, or exacerbated by, captivity are given later, under Non-infectious diseases.

### The influence of temperature on health

The immune responses of reptiles, both humoral (production of antibodies) and cellular, are temperature-dependent and therefore less effective at lower temperatures (Guillette *et al.* 1995). Some species respond to bacterial (and perhaps other) infections, or the introduction of bacterial pyrogens, by spontaneously seeking higher body temperatures the so-called '*behavioural fever*' (Ramos *et al.* 1993). For these reasons, many authorities suggest that sick reptiles undergoing treatment should be kept warm or assisted in doing so by providing a temperature gradient and given the opportunity to maintain high body temperatures by basking for longer periods than usual (Frye 1991).

As mentioned elsewhere, adverse or fluctuating temperatures can affect the survival and health of neonatal reptiles. An increased prevalence of developmental abnormalities may be indicative of such a situation (Figure 46.8).

## Non-infectious diseases

Reptiles kept in the laboratory are particularly prone to non-infectious disease, largely because they are confined in captivity and therefore more likely to encounter physical insults. The latter include trauma (physical damage to rostrum (Figure 46.9) or limbs, often associated with cage design or insensitive management), electrocution (from poorly maintained electrical circuits), burns (from proximity to badly positioned bulbs or heaters) and drowning (deep water containers from which lizards and chelonians, in particular, cannot escape). Non-infectious insults can readily lead to infectious disease – for example, a wound may become infected with bacteria.

One of the most common problems in captive reptiles is damage to the rostrum, caused by the animals colliding with the walls of the cage or enclosure, especially when they are trying to escape (a behaviour that can develop into a stereotypy). Attempts to reduce the incidence of such lesions include giving individuals as large a cage as is practicable,

**Figure 46.8** A developmental abnormality, an undershot jaw and hydrocephalus, in a captive-bred king snake (*Lampropeltis* sp.). Such anomalies can have a genetic aetiology, often associated with inbreeding, or follow temperature fluctuations during incubation.

providing refugia (see above) and avoiding disturbance and stress whenever possible. Painting or otherwise marking vertical glass surfaces so that they are opaque can also sometimes reduce the incidence of collisions. Some materials are particularly damaging, eg, wire mesh, which should be screened with protective partitions made from other materials. Treatment is by cleaning the wound (Frye 1991) followed by standard medication and prevention of further trauma. Burns, usually caused by an animal being able to get too close to the hot surface of a bulb or heating pad, can also be treated (Mader 2006a). In lizards and snakes, that shed their skins regularly, the area of the burn can become a site of incomplete ecdysis and a focus for infection.

Chelonians in captivity often have overgrowth of the highly keratinised edges to the mouth, because the diet is softer than that in the wild. Treatment is by burring the beak back to normal anatomy, and prevention by ensuring that the diet is as varied as possible and contains harder material, such as fibrous plants. Overgrowth of the claws, also caused by insufficient abrasion, may occur in chelonians and large lizards.

Snakes in captivity often fail to slough properly (dysecdysis – see earlier). There can be many reasons for this, including poor health, malnutrition, dehydration and endocrine imbalances caused by failure to provide the correct photothermal stimuli that cue seasonal cycles of reproduction and activity (Avery 1994). A dysecdytic snake can be helped to shed by soaking for about an hour in warm water.

Other non-infectious diseases include poisoning, genetic/congenital/developmental abnormalities and metabolic disorders associated with old age and/or dietary imbalances. Poisoning can result from overdosage of medical agents, prolonged exposure to toxins (eg, insecticidal preparations) or ingestion of toxic material in the food (Fitzgerald & Vera 2006). Developmental abnormalities may be present at birth (congenital) or appear later in life. They may or may not have an underlying genetic basis. Environmental factors may play a part in producing some abnormalities, especially during incubation of eggs. All such anomalies should be investigated and documented and specimens retained for study (Bellairs 1981; Cooper *et al.* 1998).

**Figure 46.9** Chronic damage to the rostrum of a water dragon (*Physignathus* sp.) due to repeated rubbing on the glass sides of its cage.

## Infectious diseases

Many infectious agents can cause morbidity (ill-health) or mortality (death) in captive reptiles. While some organisms appear to be frank pathogens, many others are opportunists that take advantage of an injured or immunocompromised animal. Host–parasite relations are still poorly understood in reptiles but knowledge of these is often the key to the prevention or control of infectious disease. Experimental work on reptiles is yielding useful information about inflammatory and other responses in reptiles (Tucunduva *et al.* 2001).

### Bacteria

Numerous pathological conditions in captive reptiles are caused by bacteria, especially Gram-negative species such as *Aeromonas* and *Pseudomonas* (Cooper & Jackson 1981). Pneumonia, often coupled with a septicæmia, is one such example. Necrotic stomatitis ('mouth rot') is another; it is not a single disease entity, but a syndrome that may be caused by a wide range of bacteria (Cooper & Sainsbury 1994). Necrotic dermatitis ('scale rot') shows a similar pattern, as does 'shell rot' in chelonians. 'Blister disease' of snakes and lizards, characterised by fluid-filled vesicles on the skin, is often a result of a non-infectious factor, adverse humidity: the lesions can quickly become secondarily infected by bacteria.

Subcutaneous abscesses are often seen in lizards and snakes and are usually due to bacteria (Figure 46.10). The pus of reptiles is semisolid, often laid down over several weeks in concentric layers, and needs to be removed surgically.

*Salmonella* is of particular importance under laboratory conditions because of the zoonotic risk (see later). The genus consists of over 2400 serotypes, a number of which (some termed 'Arizona' – *S. enterica arizonae*) may be isolated from captive reptiles, including those kept for research purposes, and may cause pathological lesions and clinical signs of

**Figure 46.10** A subcutaneous abscess in the hindlimb of a green iguana. The pus in such a case is likely to be semi-solid and needs to be removed surgically. This is a male animal and the row of femoral pores is very apparent.

disease (Cambre *et al.* 1980; Onderka & Finlayson 1985; Gene & Loeschner 2002).

Many other bacteria may cause disease in captive reptiles (Cooper 1999) including *Neisseria* species, especially *N. iguanae* (Plowman *et al.* 1987; Barrett *et al.* 1994) and *Mycobacterium* species (Soldati *et al.* 2004).

Any breach in the skin may permit the ingress of bacteria which can then cause a localised infection, such as an abscess or cellulitis, possibly followed by bacteraemia and septicæmia, often with fatal results (Cooper 1999).

Most bacterial diseases may be treated with standard antibiotics following sensitivity testing and appropriate palliation (Rees Davies & Klingenberg 2004; Carpenter 2005; Mader 2006c). Reliable pharmacokinetic data are available on a number of antibacterial agents such as enrofloxacin (Young *et al.* 1997).

The eggs of reptiles may be infected with and may spread bacterial and other diseases. The *post-mortem* examination of reptile eggs was detailed by Cooper (2004).

### Fungi

Austwick and Keymer (1981) provided a useful earlier review of mycotic infections of reptiles. Reports in recent years include those by Nichols *et al.* (1999), Bertelsen *et al.* (2005) and Paré and Sigler (2006). Fungal infections appear to be less prevalent in terrestrial reptiles than in aquatic species but the pattern is not straightforward, particularly as 'new' organisms, such as the *Chrysosporium* anamorph of *Nannizziopsis vriesii* (CANV), become recognised as important emerging pathogens of reptiles (Paré & Sigler 2006).

Mycotic infections need to be diagnosed early, using a variety of clinical and laboratory techniques (Cooper 2006), as they are often difficult to treat successfully (Frye 1991).

### Viruses

The importance of viral infections in reptiles began to be appreciated over 25 years ago (Clark & Lunger 1981). Since then great advances have been made, with a range of viruses recognised as causes of disease, in various parts of the world (Gravendyck *et al.* 1998; Marschang *et al.* 2002). A number of these are potentially important in the laboratory maintenance of terrestrial reptiles:

- paramyxoviruses, primarily in snakes but also in lizards (Jacobson *et al.* 2001);
- herpesviruses, in lizards, snakes and chelonians (Jacobson 2007);
- eastern equine encephalitis virus (EEEV) (Essbauer & Ahne 2001; Hernandez-Divers 2006);
- adenoviruses in lizards (Wellehan *et al.* 2004; Julian & Durham 1982);
- poxviruses (or pox-like viruses) in lizards and other reptiles (Stauber & Gogolewski 1990; Jacobson & Telford 1990; Gal *et al.* 2003);
- ranaviruses in tortoises, occasionally lizards and snakes (Essbauer & Ahne 2001; Just *et al.* 2001);
- erythrocytic viruses ('pirhemocytin' or 'toddia') in various reptiles (Paperna & Dematos 1993);

- papillomaviruses, mainly in lizards (Cooper *et al.* 1982; Raynaud & Adrian 1976);
- reoviruses of various reptiles (Gravendyck *et al.* 1998; Drury *et al.* 2002);
- Iridoviruses, possibly acquired from invertebrate prey (Marschang *et al.* 2005).

Captive reptiles can be screened serologically for certain viruses – for example, ophidian paramyxovirus (OPMV) and herpesviruses of chelonians (Mader 2006c). These and other tests, such as polymerase chain reaction (PCR), should be considered an important part of excluding infectious disease from laboratory colonies of snakes, lizards and chelonians.

Stomatitis associated with virus infections in tortoises have been successfully treated but the general rule in laboratory animal work should be to exclude such pathogens by obtaining reptiles from ‘clean’ captive-bred sources and by quarantining and screening incoming stock. The serological testing of snakes for evidence of paramyxovirus infection and PCR testing of chelonians for herpesviruses are two such examples.

### Protozoa

Keymer (1981) provided an excellent review of protozoa of reptiles and Barnard and Upton (1994) produced a practical ‘veterinary guide’ to many of these species. It should be noted that some intestinal protozoa are beneficial – for example, ciliates that aid digestion in tortoises and large herbivorous lizards (Troyer 1982).

Haematozoa (blood-borne protozoa) are not uncommonly seen in terrestrial reptiles, both in wild (free-living) and captive animals. Their classification remains uncertain, as does the understanding of their significance (Davies & Johnston 2000). Their presence in blood smears should be noted during routine health monitoring. Smears should be examined on two occasions, at least 14 days apart, during any quarantine period.

*Entamoeba invadens* has a direct life cycle, with cysts being passed in faeces. Meerovitch (1958, 1961) elucidated the life stages of this protozoon. She concluded that the parasite is usually a commensal in chelonians, where it ingests plant polysaccharides. In snakes *E. invadens* proves pathogenic because they are carnivorous and, in the absence of plant ingesta, the *Entamoeba* obtains its polysaccharide requirements from intestinal mucosal secretions, rendering the gut wall susceptible to invasion. It follows that, in laboratories, herbivorous and carnivorous/omnivorous reptiles should not be kept together and strict hygiene must be practised when moving from one reptile species to another.

The coccidian parasite *Cryptosporidium* is increasingly a problem in reptile collections – eg, in leopard geckos (Deming *et al.* 2008) – and is difficult to treat. It can be zoonotic (McArthur *et al.* 2004b).

### Helminths and pentastomids

All of the major groups of parasitic worms are found in reptiles. Tapeworms (Cestoda) and flukes (Trematoda) are not usually a major problem in captive reptile husbandry,

especially in the laboratory, as they require the appropriate intermediate host as part of their life cycle. The same is true of pentastomids which, although worm-like in appearance, are in fact highly modified arthropods. The life cycles of pentastomids are complex, and, depending on the species of parasite, a reptile may be a definitive or an intermediate host. Most infections of reptiles with pentastomes are asymptomatic (Greiner & Mader 2006).

In comparison, many species of nematodes have direct life cycles and these worms can increase rapidly under suitable conditions. A range of clinical signs and pathological lesions may be seen in infected reptiles. Treatment of the affected animal must be coupled with hygiene and other measures in order to prevent re-infection. Parasitic worms are readily treated with various anthelmintics but care must always be taken as adverse sequelae sometimes result. Ivermectin can be toxic to chelonians (Frye 1991) and should be employed with appropriate caution in all reptile species. Treatment during quarantine, coupled with microscopical examination of faeces, will help to limit and control nematode infestations in laboratory reptiles.

### Ticks and mites

Ticks and other ectoparasites of reptiles can be pathogenic in their own right, causing local or systemic disease, or they may transmit other organisms (Burrige 2001). Ticks (Figure 46.11) can be removed with forceps, but care must be taken that the mouthparts do not remain because they may become a focus for infection with bacteria and other pathogens. Certain acaricides, such as permethrins, are effective in control but, as with all treatment under laboratory conditions, may be contra-indicated in reptiles that are part of an experimental procedure.

Mites, especially the ‘snake mite’, *Ophionyssus natricis*, can be the cause of ill-health or death in laboratory reptiles. Parasitic mites feed on blood, and can transmit viruses, spirochaetes, rickettsiae, bacteria and protozoa. The parasites and their eggs can survive in crevices in the environment for long periods.

**Figure 46.11** Cloacal region of a monitor lizard, showing the presence of tightly-attached *Amblyomma* ticks.

Small and medium-sized reptiles can be treated for mites by isolating them for 24 h in a small cage with a strip of, for example, dichlorvos (Vapona) or trichlorfon, placed out of reach of the animal. However, care must be taken to avoid over-exposure and resultant toxicity, usually characterised by nervous signs. Alternatively, fipronil wipes can be used or ivermectin can be administered topically or by injection. Large reptiles can be treated with proprietary (dog and cat) flea sprays (Frye 1991). Under laboratory conditions, where the use of drugs that have a systemic effect may be contra-indicated, mites can be killed by painting the reptile with vegetable oil, which is then blotted off (Espinosa *et al.* 1998) or trapped with sticky tape and removed.

Routine treatment and quarantine of incoming animals will help to prevent the introduction of mites to a laboratory animal facility. Scrupulous attention to hygiene is then necessary to prevent treated animals from becoming re-infected.

### Health and physiological monitoring

Standard veterinary procedures for reptiles are applicable to those that are kept for research. Imaging is practicable using radiography, ultrasonography, magnetic resonance imaging (MRI) and computed tomography (CT) scanning (Anderson *et al.* 2000; Raiti 2004).

### Collection of samples and laboratory investigations

Samples may need to be taken from reptiles for research purposes, for health monitoring or for diagnostic purposes. Samples can be of many types. Some, such as faeces, can be collected without handling the reptile, while others, such as blood, will necessitate invasive techniques. The most appropriate methods will depend on many factors, including the temperament, size and anatomy of the reptile. Veterinary texts provide useful guidance (see, for example, Hernandez-Divers *et al.* 2004a).

Blood sampling can be an important part of research procedures involving reptiles. It is also a useful adjunct to health monitoring. Specific papers relating to laboratory work are available – eg, on blood sampling of lizards (Brown 2007) – while other texts refer more to pet, zoo and wild animals. Sampling sites depend upon the species and the requirements but include withdrawing blood from a vein (jugular, caudal/coccygeal, brachial, abdominal or subcarapacial), heart orbital sinus or via a toe-nail clip. An excellent review of methods, with clear photographs, is to be found in Hernandez-Divers (2006). However, in order to perfect techniques specific training is necessary, preferably under the supervision of an experienced veterinarian.

The amount of blood and frequency of sampling are important considerations in experimental work where regular bleeding may be part of the research protocol. In some countries, quantity and frequency may be stipulated in regulations designed to promote welfare. Where this is not the case, a general rule is not, on any one occasion, to

remove a sample of blood that is more than 1% of the body weight of the animal. The author's personal guideline for repeat bleeding is to restrict the volume to 0.7% (ie 7 ml of blood per kilogram body weight) and to take this amount from the reptile no more frequently than once a week.

### Reference values

Reference values for blood parameters are available for some species (see, for example, Mader 2006c). These usually include both haematological and biochemical figures. There is a need to expand these databases and those scientists and laboratory animal veterinarians who need to take blood samples from reptiles for other purposes should, whenever possible, prepare smears and carry out haematological and biochemical analyses. Such information is not just of scientific importance: it can also enhance health monitoring and assist in the assessment of welfare.

Laboratory investigation of samples taken from reptiles are covered by a number of authors for example, bacteriology by Cooper (1999), haematology and cytology by Campbell and Ellis (2007) and haematology alone by Diethelm and Stein (2006).

### Methods of treatment

Terrestrial reptiles may need to be treated with medicinal agents either as part of an experiment or for health reasons. Supportive care is always important and useful information is to be found in texts directed at veterinary nurses/technicians (Cooper *et al.* 2003; McBride & Hernandez-Divers 2004; Mitchell 2004). Emergency and critical care have been covered by a number of authors, eg, of chelonians by Norton (2005). Techniques for dosing and injection procedures are described in various publications (eg, Rees Davies & Klingenberg 2004). The dose and the frequency of administration of some agents may need to be based on allometric scaling (Mayer *et al.* 2006).

### Telemetry

Telemetry is a well established procedure in field studies on reptiles and both invasive and non-invasive techniques for attaching a transmitter can be adapted to laboratory research (eg, Ferrell *et al.* 2005).

### Surgical procedures

Both experimental and therapeutic surgery may be carried out on laboratory reptiles. These do not differ significantly from those employed in veterinary practice (Hernandez-Divers 2004a). Under laboratory conditions it is particularly important to minimise invasive techniques. Endoscopy, for example, can be used very successfully in reptiles and often reduces the need to perform traumatic, painful or stressful procedures (Brearley *et al.* 1991; Hernandez-Divers 2004a, 2004b).

## Anaesthesia and analgesia

Anaesthetic methods for reptiles have advanced dramatically in recent years and much has been published in both books and journals (Redrobe 2004; Mosley 2005). Awareness of the susceptibility of reptiles to painful stimuli has prompted studies on analgesia (Greenacre *et al.* 2005). This information is of great relevance to the use of reptiles in research where procedures may be performed that may cause pain.

## Euthanasia

Laboratory reptiles may need to be killed at the end of an experiment, or on welfare grounds because of injury, disease, or old age. Some nations may have local regulations regarding acceptable techniques. Euthanasia of terrestrial reptiles presents special problems (UFAW/WSPA 1989; Cooper 2004), on account of the low metabolic rates of many and the ability of some species to tolerate hypoxia for long periods (Jackson 2002). Useful resumé of methods of euthanasia for reptiles are given by WSPA (1994), British Veterinary Zoological Society (BVZS) (2003), Baier (2006) and Reilly (2001).

Decapitation and cervical dislocation are no longer standard methods, because of concerns that the animal may continue to be aware of painful stimuli for a period after the process. Nevertheless, in the UK, Schedule I of the Animals (Scientific Procedures) Act 1986 continues to permit the use of decapitation so long as it is followed immediately by physical destruction of the brain. Freezing is also no longer advocated by most authorities, again on welfare grounds. The exception is dropping small reptiles (of 1 cm maximum diameter) into liquid nitrogen (BVZS 2003). Other methods that are now considered unacceptable (BVZS 2003) include drowning, overdose of anaesthetic agents by certain routes and use of neuromuscular blockers.

The currently preferred techniques, where practicable, are an overdose of either an appropriate volatile agent, such as isoflurane, or of a barbiturate given by injection (Cooper 2004).

## Zoonoses and other health hazards

Any laboratory animal can present a hazard to those who work with or tend it. The dangers may be infectious, physical or toxic. Pathogenic bacteria that may be transmitted from reptiles to humans include *Salmonella*, *Leptospira*, *Mycobacterium* and *Cryptosporidium* (Frye 1991; Johnson-Delaney 2006). *Salmonella* is always considered a particular hazard, although it is not easy to quantify the dangers, partly because so many serotypes or strains may be involved (Burnham *et al.* 1998).

Under laboratory conditions it is important to draw-up proper risk assessments (see next section). A useful summary of precautions, including reference to the BVZS Guidelines, was provided by Redrobe (2002). Handling animals using appropriate techniques (see Handling and restraint) will lessen the likelihood of physical injury.

A number of species of snake and two species of lizard have traditionally been considered venomous. However, recent research (Fry *et al.* 2006) on monitor lizards and iguanids indicates that other species have saliva which may cause tissue damage (in addition to infection) if the animal bites. It is important, therefore, to be aware of the identity of any snake or lizard that is to be kept in the laboratory. If in doubt, advice should be sought and full precautions put into place.

Details of techniques for keeping and handling venomous squamates are not included here: useful guidelines are provided by Boyer *et al.* (2003), Boyer (2004) and Whitaker and Gold (2006). These animals should be managed only by trained personnel and a proper risk assessment carried out. Venomous species should be handled with appropriate equipment, such as tongs or a snake-hook (Locke 2008). In order to restrain venomous snakes for radiography or injection, they may be induced to enter a rigid transparent plastic tube (Mader 2006c; Locke 2008), of a diameter equivalent to that of the snake. Once the snake is inside, the ends can be closed with bungs. For injection, tubes have small holes drilled at appropriate points so that a needle can be inserted. This technique should not be used for narrow-bodied venomous species such as kraits or mambas, as these may succeed in turning around within the tube.

## Risk assessment

In any work involving laboratory reptiles it is important to carry out a risk assessment. There are five important steps:

1. identify the hazards (anything that may cause harm, such as the animals themselves, chemicals or electricity);
2. decide who might be harmed and how;
3. evaluate the risks (the chance, high or low, that somebody could be harmed and state what precautions are to be taken);
4. record the findings and implement them;
5. review the above and update as necessary.

More information may be found on the (UK) Health and Safety Executive website.

## Other legal considerations

The importance of adhering to relevant legislation when keeping reptiles was emphasised earlier. In many countries reptiles are covered by laws that regulate the use of animals in research. Other statutes may also be relevant, including those concerning conservation of endangered species, welfare, dangerous wild animals and zoonoses (Cooper *et al.* 2006). Where there is no legislation controlling the maintenance and use of terrestrial reptiles for research, it is wise to use and follow established codes of practice. Sometimes specific guidelines are available for example, those produced for field research on reptiles in Canada (Canadian Council on Animal Care (CCAC) 2003) and the USA (ASIH/HL/SSAR 1987); if this is not the case or the guidelines are

inappropriate, the researchers (in collaboration with others) should formulate and use their own.

## Acknowledgements

My wife, Margaret E. Cooper, advised on the sections on legislation and risk assessment. Dr Adrian Hailey, Miss Kristel-Marie Ramnath and Mr Sean Wensley commented on an early draft of this contribution. Miss Nicole Theroulde typed the original manuscript and the Library of the Faculty of Medical Sciences, The University of the West Indies, helped with the references. Two anonymous referees made helpful comments. I am indebted to them all.

## Other sources of information

Herpetological societies exist in many countries of the world. Most publish newsletters, members' information sheets, journals or bulletins, often in different languages and many have their own websites.

The British Chelonia Group produces *Care Sheets*, relating to most of the species of terrestrial chelonians likely to be found in captivity. These are obtainable from the British Chelonian Group<sup>2</sup>.

Journals published in English (and, where appropriate, the associations that publish them) that are of particular relevance to the care and use of reptiles include the *Herpetological Journal* (British Herpetological Society), *Applied Herpetology*, *Copeia* (American Society of Ichthyologists and Herpetologists), *Herpetological Review* (American Society of Ichthyologists and Herpetologists) and *Journal of Herpetological Medicine and Surgery* (Association of Amphibian and Reptilian Veterinarians (ARAV)).

There are numerous websites that provide advice on the care of reptiles in captivity. Some but not all of the information given is sound. A useful list of reference sources for reptile clinicians, albeit with a strong North American slant, was given by Barten (2006). Some websites refer to legislation that affects the keeping and use of reptiles: see Cooper et al. (2006).

## Aquatic reptiles

Simon Tonge

### Biological overview

#### General biology

Aquatic reptiles include representatives from all the major orders of reptiles. Most of the truly aquatic squamates (snakes and lizards) are highly venomous snakes of the family Elapidae and are not suitable for laboratory use, so their maintenance will not be considered further in this chapter. Many other squamates are at least partially aquatic but their husbandry does not differ, at least in the laboratory context, from other more terrestrial taxa so their husbandry is considered elsewhere in this volume. Crocodylians and testudines comprise the bulk of the aquatic reptiles, but the former are generally unsuitable for laboratory usage, when adult, due to their great size and the risks they present to those handling and servicing them.

There are 22 extant species of crocodylians (crocodiles, alligators and caimans) found throughout the tropical, and in some subtropical, areas of the globe. The best current sources of information on crocodylian biology are the Crocodylian Specialist Group website<sup>1</sup> and its subsequent links; also see Trutnau and Sommerlad (2006) and Ross (1989). The species are all rather similar externally, and details of their laboratory maintenance are similarly uniform.

Aquatic testudines are found throughout the temperate and tropical marine and freshwater habitats of the world. Marine turtles are large and highly specialised, belonging to two families. They are not suitable for laboratory usage and are therefore not discussed further in this chapter. Further information on facilities and life support issues relating to aquatic species in general have been provided in Chapters 1 and 4 of Poole (1999).

Freshwater turtles (henceforth referred to as terrapins) comprise nine families and approximately 209 species (Iverson 1992) within two suborders (Cryptodira and Pleurodira) of the order, Testudines. New species are still occasionally described (eg, see Cann & Legler 1994; McCord & Pritchard 2002). Within the constraints of the basic testudine body plan, terrapins show a huge range of morphological variation, from highly adapted, strictly aquatic forms with 'soft' shells, such as the Fly River turtle (*Carettochelys insculpta*), through to secondarily terrestrial species such as the eastern box turtle (*Terrapene carolina*). Some specialisa-

tions are quite bizarre, such as the worm-like tongue lure of the alligator snapper (*Macrolemmys temmincki*) or the leaf-like appendages on the neck and body of the matamata (*Chelus fimbriatus*).

#### Size range and lifespan

Some crocodylians can grow to 7 m or more. Only the very smallest juveniles under 1 m in length can be maintained satisfactorily in the laboratory. Terrapins vary enormously in size. The largest species is probably the giant Asiatic soft shell (*Chitra indica*), which may reach up to 1.8 m in carapace length, and weigh perhaps 200 kg or more. By contrast, Reeve's terrapin (*Chinemys reevesi*) reaches only 12 cm and a weight of 150 g.

Little is known of the lifespan of terrapins or crocodylians, but, in view of their ectothermy and relatively slow growth rates, it is likely that many species live up to 70 years or more, once an individual has achieved the critical size where it is relatively invulnerable to predation. Most species either lay one large clutch of relatively small eggs per annum or several smaller clutches of larger ones, but, in both cases, the majority of hatchlings probably die within their first year of life, mostly as a result of predation.

#### Social organisation

Social behaviour in most terrapins is poorly understood, but ranges from the apparently solitary snappers (Chelydridae) to the highly social sliders (Emydidae), though whether these animals are truly social is something of a moot point as they may simply be gathering at a scarce resource such as a suitable basking site.

Some species are exclusively aquatic, emerging from water only to lay eggs or to move between ephemeral water bodies. Examples of these species include softshells (Trionychidae): the Fly River turtle (*Carettochelys insculpta*), the matamata (*Chelus fimbriatus*) and snappers, Chelydridae. Many more species are partially aquatic, spending a good deal of their time, at least during the day, basking out of the water on rocks, logs or stream banks. Most of the emydid terrapins, including the sliders and cooters (*Trachemys* spp. and *Pseudemys* spp.) fall into this category, along with kinosternids and many chelids. A final category includes those

<sup>1</sup><http://www.flmnh.ufl.edu/cnhc/>

species that have deserted the water and live exclusively on land. The American box turtles (*Terrapene* spp.) are the best known examples, though there are probably several Asian species, mostly in the genus *Cuora*, that have similar lifestyles but which are very poorly known.

Bonin *et al.* (2006) provides the most comprehensive modern review of recent testudines, and should be consulted for a description and brief notes on the biology of particular species. Other important works include those by Pritchard (1979) and Harless and Morlock (1979).

All crocodylians are strictly aquatic, except when basking or nesting. Males are usually territorial and may hold harems in the breeding season. Juvenile crocodylians are not territorial and can usually be kept at high density.

### Sources of supply (conservation status)

One hundred and forty species of Testudines (66% of the total) are currently listed as threatened with extinction (International Union for Conservation of Nature and Natural Resources (IUCN) 2007) and many are very poorly known biologically. However, some species are amongst the best known and most familiar of all reptiles, for example, the red-eared slider (*Trachemys scripta elegans*).

Relations between humans and testudines have been predominantly disastrous for the reptiles. The decline in turtle and terrapin populations over the last two decades has been shocking, mirroring the decline and extinction of many tortoise species a century before. Many species are threatened by direct consumption for food or medicinal purposes, or the taking of eggs, for example, the giant arrau (*Podocnemis expansa*) in South America or tuntong (*Batagur baska*) in Asia. More insidious threats to terrapins are habitat destruction, pollution, the diversion of rivers and lakes and incidental by catch by fisheries. Many species have naturally small ranges (such as the western swamp terrapin, (*Pseudemidura umbrina*) in Australia) and are vulnerable to even minor habitat alteration, because of their narrow ecological niches.

For laboratory purposes, the most commonly used species is the red-eared slider, which is bred commercially in the United States for sale to the pet trade. Juvenile specimens are still available from pet stores but not as widely as was once the case. Occasionally, juvenile softshells (Trionychidae) turn up in shipments of tropical fish, but most species of terrapin are not available commercially.

Ten of the 23 species of crocodylian are listed as threatened (IUCN 2007) but a number of species, for example, the American alligator (*Alligator mississippiensis*) are now farmed for their hides or meat, and are readily available commercially.

### Uses in the laboratory

Because of their relatively expensive (though not complex) requirements in captivity, and the lack of biological information available, terrapins and crocodylians are not widely used experimentally. Studies that have been undertaken include those on heart rate (Bethea 1972), gut passage time (Parmenter 1981), respiratory rate (Jackson 1971), gas uptake

(Bagatto & Henry 1999), heat exchanges during diving (Glidewell *et al.* 1981), heart rate during diving (Belkin 1964) and radionuclide uptake (Peters & Brisbin 1996; Bickham *et al.* 1988; Hinton *et al.* 1992). In addition, more broad-based studies have included environmental sex determination (Yntema 1981; Georges & McInnes 1998), the effects of incubation temperature (Pina *et al.* 2007), behavioural studies (Cloudsley-Thompson 1982) and the construction of heating and cooling curves (Spray & May 1972).

## Laboratory management and breeding

### General husbandry

The great variety of terrapin form and function means that for every 'rule' given in an account of how to maintain them in captivity, it will be usually possible to find a species or individual that is the exception. However, for laboratory purposes, a relatively limited subset of species, mostly emydids, are likely to be used, so it is probable that the following account will cover most species likely to be encountered. If in doubt, refer to the specialised literature contained in such journals as *Sauria*, *The Vivarium*, *Bulletin of the British Herpetological Society* and *Salamandra*; see also Highfield (1996). Recent recommendations can be found in European Commission (2007).

### Housing

The geographical origin of the taxon in question will determine whether the species is kept indoors or outdoors. However, many species from subtropical areas, such as the southern USA, are perfectly capable of withstanding colder weather if kept outdoors further north. They can, therefore, be kept in small ponds, lakes or reservoirs, but extreme care should be taken to ensure that escape is not possible. Accidentally introduced terrapins can cause damage to native invertebrate, fish and amphibian faunas. When kept outdoors, terrapins require access only to deep, unfrozen water in winter, in order to hibernate satisfactorily. Some species, eg, box turtles (*Terrapene* spp.) may not, normally, hibernate in water and will need to be provided with soft soil or leaf litter into which they can burrow. Those species that do not normally hibernate will need to be maintained indoors during winter.

The pond or lake should be surrounded by a solid wall or fence, which will act as a partial sun-trap, thus creating a more suitable microclimate by allowing the terrapins to bask and regulate their own body temperatures. Terrapins can climb, to a certain extent, so wire mesh barriers should exceed 60cm in height and should be sloped inwards to form an overhang. Approximately 30–50% of the enclosure should be land area and the water depth should shelve gently to allow the animals to emerge easily. The land area should include areas of soil, sand or peat (or a mixture) to a depth of 20–30cm, to allow the females to lay eggs when the substrate temperature is high enough.

In most laboratories, terrapins will be maintained indoors and, for ease of maintenance, vivarium conditions should be as simple as possible without compromising animal welfare.

Vivaria can be constructed of glass, metal, plastic or fibreglass, the main consideration being that the surface should be smooth, easily sterilised and waterproof. They should be of an appropriate size, a 'rule of thumb' being that the water area should be at least three times as long, in all dimensions, as the largest inhabitant, and should be sufficient to hold all the vivarium occupants in the water at the same time, with space for them to move freely. Likewise, the land area should be large enough for all the vivarium occupants to be out of the water at the same time (Figure 47.1).

Water depth should not be uniform but should enable the terrapins to immerse themselves completely, and most species will make use of water depths that allow them to swim freely. Juveniles especially need some access to deep water in order to learn to regulate their buoyancy properly. Many species are most comfortable lying on the floor of the vivarium, with their necks extended to the water surface and their eyes protruding out of the water. Comfort and security are also enhanced if the substrate at the bottom of the tank is dark in colour enhancing crypsis.

Land:water ratios in vivaria are usually in the region of 30:70. The terrapins should be provided with metal or wooden rungs to assist emergence from the water onto the land (Figure 47.2). In the wild, many terrapins prefer to emerge on to rocks or branches completely surrounded by water in order to facilitate escape from predators.

Maintenance of juvenile crocodylians is very similar to that of terrapins, although allowance must be made for the extra size of the animals and the consequent need to maintain only like-sized animals together. Crocodylians are also agile climbers so vivaria should have a suitable lid.

#### Environmental provisions

Most crocodylians and terrapins require a background temperature in the region of 22–27°C during the day. At this temperature, they will be active and some feeding will occur. They should also be given access to a basking source positioned over the land area of their vivarium. Traditionally an infrared bulb of an appropriate wattage has been used,

**Figure 47.1** Vivaria for rearing juvenile terrapins. The construction is wood covered with fibreglass. Note multiple hiding places and moveable spotlights.

**Figure 47.2** Cross-section of suggested enclosure for terrapins: (a) heat lamp; (b) ramp; (c) water level; (d) drainage valve.

but bulbs that also emit high levels of ultraviolet-b (UV-b) radiation as well as heat are preferred. This should provide a temperature of approximately 35°C at its warmest point. The temperature gradient thus created will allow the animals to maintain their own preferred body temperatures and will improve feeding rates. For those species that do not normally emerge from water to bask, such as softshells (Trionychidae), the water should be heated to about 26°C. This can be done using thermostatically controlled aquarium heaters that are well protected from the animals.

Many temperate species hibernate during the winter but this does not appear to be obligatory for normal physiological functions in many of those species. Where hibernation is allowed or desired, it should be done at a temperature of about 5°C, either under water or in damp leaf litter. Some species are capable of surviving lower temperatures, even below freezing (Storey *et al.* 1993) but this is neither normal nor recommended. Temperature fluctuations and desiccation should be avoided.

As with most diurnal animals, crocodylians and terrapins are affected by both the quantity (photoperiod and intensity) and quality (wavelength) of light. Natural daylight is the preferred source of light, though if this is filtered through glass, a source of UV light should also be provided (see section on disease). If UV tubes are used they need to be suspended 15–20 cm above the land area of the vivarium (see also Chapter 46), which is impractical for crocodylians hence the preference for high UV-b emitting bulbs described earlier; in any case, these produce higher levels of UV-b with consequent benefit for the animals' vitamin D3 metabolism. A wide variety of UV light sources is available (Gehrmann 1987; Baines *et al.* 2005). Photoperiod and temperature are the major cues for the initiation of reproduction in temperate-region species, but both they and tropical species can be kept perfectly well using 12:12 h day:night ratio. If reproduction is desired, some fluctuation in photoperiod may be required.

Over the last decade, captive animal husbandry has made great strides in the provision of enriched environments for mammals and birds. Less work has been carried out on reptiles and there is a perception that they are more limited behaviourally and therefore less 'in need' of enrichment. This is unlikely to be completely true as many reptiles have been shown to have complex behavioural repertoires. Nevertheless, given that many reptiles, including terrapins and crocodylians, are solitary, 'sit and wait' predators it is unlikely that elaborate enrichment devices are either necessary or effective. If the physical environment is hygienic and complex (in terms of hiding and basking places), the correct social groupings are applied and the diet is diverse and behaviourally stimulating it is unlikely that any further enrichment is required.

### Social grouping

Most terrapins are aggressive to conspecifics to some degree. In softshell and snapping turtles, the level of aggression is usually such that maintenance of more than one animal per vivarium becomes problematic. Most emydids, kinosternids and chelids are more amenable and can be kept in groups. However, where adult animals are concerned, fighting may

occur when animals of the same sex are housed together during the breeding season.

Hatchling crocodylians can be maintained in small vivaria in groups but, with adequate feeding, growth occurs rapidly, and it will become necessary to 'thin' the group in all but the largest vivaria. Crocodile farms maintain high stocking densities (up to 4000 crocodylians in an enclosure measuring 18 m × 90 m metres (Ross *et al.* 1989).

### Identification and sexing

Terrapins are quite easy to identify individually. Many of them have variable markings on their plastral scutes, which can be photographed or even photocopied to provide a semi-permanent record. These markings change with age so regular updating of the photograph or photocopy may be required. Temporary numbering can be applied to the carapace using non-toxic paint, marker pens, nail varnish or even typing correction fluid.

More permanent marking can be achieved using notches filed into the marginal scutes of the carapace. Care needs to be taken not to file too deeply and thereby damage the underlying bony plate. A typical scute code is shown in Figure 47.3 (Swingland 1978; Honegger 1979; Plummer 1979). Microchip transponders can also be used and the usual place of insertion in both crocodylians and testudines is subcutaneously in the left inguinal region at the base of the hindlimb. Crocodylians are usually identifiable visually but can be marked with notches in tail scutes or with a small tag placed in the webbing between the toes.

Distinguishing between the sexes of most species of terrapins is normally fairly straightforward. In many species, there is a sexual dimorphism in size – females usually, though not exclusively, being larger. In males, the tail is often longer than in the female, sometimes up to twice the length. The tails also differ in shape, being tapered and long

**Figure 47.3** Diagram of chelonian carapace, showing suggested method of marking for identification. Right-hand marginal scutes are numbered 1–9 (units). Left-hand marginal scutes are numbered 10–90 (tens). This example shows notching at (a) and (b), indicating no. 34.

in the male and short and somewhat triangular in the female. However, without some experience and lacking animals for comparative purposes, this technique can be confusing. In box terrapins, it can be impossible if the individuals concerned shut the posterior plastral hinge! In some species, there is minor variation in the degree of concavity of the plastron, eg, *Terrapene coahuila* (personal observation), but this is rarely as pronounced as it is in some tortoise species. Finally, some species show other sexually dimorphic traits, such as the presence of long nails on the forelimbs in male *Trachemys scripta* (Gibbons & Lovich 1990) which are used in courtship, or differences in colour between the sexes, as in *Batagur baska* (Pritchard 1979).

Sexing crocodylians is very difficult with animals of less than 1 m in length. For older animals, physical examination of the cloaca (using a finger) to detect the male's penis, is an accurate technique but requires training and experience.

### Physical environment and hygiene

The water area should include some furnishings, such as pipes, slates on bricks and half flower pots, under which the animals can hide. The vivarium should either have a drain or be of easy access with a siphon. The main constraint on good management of terrapins in particular is water hygiene. They are messy feeders and the vivarium may need cleaning after every feed. This can rapidly become an onerous and time-consuming task if the keeping system is poorly designed. Generally, the floor of the vivarium should be kept free of substrate but, for some softshells, the provision of fine gravel allows them to bury themselves, which is more natural behaviour. The presence of gravel affects the ease of cleaning and, in those circumstances, consideration should be given to providing permanent, aquarium-type filtration. For details of appropriate filtration, see Poole (1999) and specialist aquarium publications.

When permanent filtration systems are not being used water changes should occur as often as necessary to maintain hygiene. The vivarium will need to be stripped down completely at regular intervals. It should be scrubbed with a proprietary cleanser such as F10 (Health and Hygiene Pty, South Africa) to kill any pathogens and to remove algal build-up. The disinfectant should be removed by thorough rinsing. Very frequent water changes may result in cooler water temperatures than are desirable for some species, if the water input is directly from the mains supply without some sort of pre-warming, which is why filtration systems are preferable. It should also be noted that mains water can be variable in quality.

### Health monitoring

It is highly likely that newly acquired terrapins and crocodylians will be carrying parasites and potentially harmful bacteria in their guts, so they should be subjected to the usual faecal bacteriology and parasitology screening before being mixed with animals already on site. Wild-caught animals, in particular, should also be screened for external parasites such as ticks, which can be removed manually. Many reptiles carry *Salmonella* spp. asymptotically and cases of

salmonellosis in humans have purportedly been traced back to terrapins kept as pets (Arvy 1998). Therefore, normal hygiene precautions should be performed after handling. The use of gloves, when cleaning out, is possibly advantageous in this regard.

When reptiles are fed correctly and kept in a low-stress environment, medical problems are rare; most problems are ultimately related to poor environment, diet or stress.

### Transport

Sympathetic and sensitive methods of transportation should be used. Most species of terrapin, and all crocodylians, can be transported in strong, ventilated, wooden boxes with a suitable lining of moisture-retaining material such as hay, moss or foam padding for insulation and to cushion against shocks. There is a suggestion in the literature (International Air Transport Association (IATA) 2007) that those species, such as softshells, that risk desiccation when out of water for long periods, can be transported the same way, but with a thin layer of petroleum jelly applied to the shell, if the journey is not longer than 4–6 h, but this technique does not appear to be widely used. For longer journeys, some sort of supplemental watering may be required. Small softshells can be transported in plastic bags in the same way as tropical fish. Care should be taken to ensure that tropical species are not subjected to temperatures below 10°C. This may preclude shipment at certain times of the year. Care should also be taken to ensure that crates are not left in direct sunshine or exposed to temperatures over 30°C for long periods. A suitable design for a crate for air freight can be found in the IATA Live Animal Regulations (2007).

### Breeding

Reproduction in crocodylians is diverse and fascinating, involving complex social behaviours, environmental sex determination and parental care. However, as it is not part of laboratory maintenance, it will not be discussed here.

Some species of terrapin breed readily in captivity; others have never been bred. It is unwise to extrapolate directly between species, and what works for one species may not work for another. Nevertheless, some general trends are apparent. Like most reptiles, the timing of reproduction is controlled by a combination of temperature, photoperiod and humidity, the details of which depend on the local environment to which each species, or population, is adapted.

### Mating systems

Some species exhibit quite elaborate courtship behaviour (eg, the red-eared slider, *Trachemys scripta elegans*) before mating (Gibbons 1990) but, in others, brute force appears to be used to subdue the female. Biting and butting, or ramming, are the primary means by which this is achieved. Vivaria in which breeding terrapins are held should be large enough to allow full expression of this behaviour (proper courtship in *T. scripta*, for example, cannot occur if the water

is too shallow) and should allow the female to be able to gain respite from the attentions of the male. Sex ratios of parity, or slightly female-biased, should be used. If too many males are present, they may spend too much time fighting between themselves or harass the female to the point where they cause her physical harm. However, apparently brutal behaviour leading to obvious injuries appears to be normal in many species, and the females recover.

### Nesting

Terrapins may be quite secretive when nesting. Oviposition may occur at night in many species and is usually completed, at least in small (<1 kg) species, within 1 h. It is often preceded by much restless pacing by the female, apparently looking for a suitable site. She will often choose the warmest part of an enclosure, perhaps directly under a spotlight, but will often dig trial holes and then not lay. Eggs scattered on the surface of the vivarium or laid in the water are usually an indication that the nesting facilities provided are inadequate in some way. It is rarely apparent exactly how the nesting area is deficient! A nesting area of damp sand, peat, or a mixture of the two, with a depth of up to 30 cm, and a substrate temperature of 25°C or more should be provided. Excavation occurs with the hind feet in most species, an exception being the highly endangered Australian chelid, *Pseudemydura umbrina*, which uses its forelimbs.

In emydids, oviposition usually occurs about 60 days after mating, but the pattern is less clear in other families. Clutch sizes vary from a single, large egg in many chelids and pelomedusids, to more than 100 in *Podocnemis expansa*. There is a positive correlation between body size and clutch size. Eggs may be spherical or almost cylindrical in shape, and are normally brittle-shelled.

In situations where terrapins are maintained outdoors, careful searching may be necessary to find all nests. Eggs should be removed from the nesting area as soon as possible after laying. They should be set in a moistened medium, such as peat or vermiculite, with about two thirds of the egg buried. If peat is used, the medium should be moist, but not wet, to the touch. Conventional wisdom has it that the eggs should not be turned or rotated, as this may damage the embryo, but this may be unnecessary (Gad 1988). The eggs should be incubated at a temperature between 28 and 32°C. In some species, the sex of the hatchling is determined by the temperature at which the egg is incubated (Yntema & Mrosovsky 1979; Vogt & Bull 1982): 30°C produces both males and females, but, at higher temperatures, predominantly females are produced, while more males occur at lower temperatures. There is speculation that laying females may deliberately select nest sites at a particular temperature, in order to produce either males or females. However, other species, eg, *Elusor macrurus*, do not show temperature-dependent sex determination (Georges & McInnes 1998).

Emydid eggs usually take 60–90 days to hatch, depending upon the incubation temperature and possibly other factors, as yet unknown. Eggs laid by species from other families may take longer, possibly including a period of embryonic diapause. Some take significantly shorter periods; for

example, *Terrapene coahuila* takes a mean of 46.3 days (Cerde & Waugh 1992) at 29–31.5°C.

### Early development

After pipping, the infant should be left in the incubation chamber until the yolk sac has been completely absorbed. This may take 1–3 days, during which time the hatchling will bury into the substrate and be invisible. Once the yolk sac has been absorbed, the infant can be transferred to a rearing vivarium. This should be similar to the adults' vivarium, but with smaller water depths sufficient to allow the infant to right itself, should it fall on its back, but not too deep that it may risk drowning, and there should be ample provision of hiding places.

Management of juvenile terrapins is similar to that of adults. Similar diets are used for both, though foodstuffs must be more finely chopped. Weight and length should be monitored at regular intervals, at least monthly, and any specimens that are lagging behind the rest should be isolated and given individual attention. It is inadvisable to leave juveniles in the same vivarium as adults, as predation may occur.

### Feeding

#### Natural and laboratory diets

Correct nutritional regimes for terrapins are still a matter of some controversy. Little experimental work has been carried out on the topic, and much of the literature is based on hearsay and/or personal experience, rather than scientific investigation (but see Stancel *et al.* 1998; McRoberts & Hopkins 1998).

The majority of terrapins are predatory animals to some degree. Some species are specialised, such as the big-headed terrapin (*Platysternon megacephalum*) and have not fared particularly well in captivity, while others, such as sliders (*Trachemys* spp.), have an extremely catholic diet. Some exhibit a form of ontogenetic dietary shift, usually becoming more herbivorous with age (Clark & Gibbons 1969). For the majority of species, there is little information on diet in the wild.

Box 47.1 lists dietary items that have been used to feed terrapins. The list is not exhaustive; there are certainly others that have been used subject to local availability. Wild terrapins will feed on almost any animal (alive or dead) that they can overpower, often attacking in groups and developing a feeding frenzy. This is one advantage of keeping terrapins in groups, as this behaviour often stimulates reluctant feeders. Terrapins are unsophisticated predators, biting hard and then ripping prey with the forelimbs. This is one reason why they are messy feeders. Another is due to the rapid disintegration of food items that are not patent, for example, some gelatine-based mixtures, proprietary dog foods, etc.

The author's particular preference is to use whole animal carcasses, usually rodents, fish and chicks. The former are available in a large range of sizes, from tiny pinkies to large, adult rats, and provide bone and roughage though

**Box 47.1** Foodstuffs used to feed terrapins**Lean meat (diced); chopped liver:**

Useful as 'treats' but poor Ca:P ratio precludes regular use. Patency is improved by cooking. Liver is particularly messy

**Rodents, chicks (whole or chopped):**

Excellent, palatable food. Good Ca:P ratio. Fairly patent; chicks can be messy if the internal yolk sac is large

**Insects (giant mealworms, mealworms, crickets, locusts, waxmoth larvae):**

Good 'treat' value, especially when fed live. Poor Ca:P ratio but good roughage content

**Molluscs and crustaceans (prawns, crab meat, snails, mussels):**

Fairly palatable; poor Ca:P ratio unless the shells are included; useful 'treats'. Expensive

**Other animal foodstuffs (dry dog food, earthworms, tinned fish):**

Fairly palatable; poor patency (fish) or low Ca:P ratio (worms) preclude frequent use

**Plants (lettuce, grated vegetables, water plants):**

Good Ca:P ratios; fairly palatable; good roughage. Can be offered *ad libitum*

**Other foodstuffs mentioned in the literature but not used by the author:**

Herrings, sprats, hard-boiled egg, trout pellets, tinned cat and dog food, cockles, lobster meat, squid, tubifex, mosquito larvae, mackerel, commercial terrapin diet

they are often high in both fat and protein so should not be relied upon exclusively. Most terrapins will also avidly pursue live insects, which can also be used to stimulate reluctant feeders. A most important aspect of feeding is to provide variety, as this has great behavioural and nutritional benefit.

Some keepers place vitamin or mineral supplements on food before feeding but, as most terrapins can, or will, feed only in water, the benefits of this practice are dubious. A varied diet of whole animals will provide the majority of the vitamin and mineral needs for most species of terrapin. As with most reptiles, calcium metabolism is of critical importance to health, and an extra calcium supplement to most terrapins is diced or flaked cuttlebone, placed in water.

For those species that are herbivorous a diet of green vegetables, with high calcium content, such as dandelions, chicory, endive, pak choi and watercress, should be offered with the occasional 'treat' fruit such as mango, apple, pear etc.

Crocodylians are exclusively carnivorous. Most species that are suitable for laboratory use will feed very well on laboratory rodents, day-old chicks, or whole freshwater fish and all their nutritional needs will be catered for. Dietary 'treats', such as live insects, can be offered occasionally, for behavioural enrichment. Feeding of live vertebrates, such as fish or frogs, although it may have some benefits, is not essential and is illegal in some areas of the world. Even

where it is technically legal it is a dubious practice ethically.

**Laboratory procedures****Handling**

It is advisable to be cautious when handling terrapins. Some are completely docile, withdrawing into their shell until handling ceases. Others are highly irritable, administering painful bites frequently and rapidly, whilst struggling vigorously. In general, the handler should always be aware of the orientation of the animal and the head should always be pointed away from the handler. Some pleurodires have enormously long necks and are capable of reaching almost round to their rear feet, eg, *Chelodina oblonga*, so care must be taken to keep fingers well out of the way.

Small cryptodire terrapins can be safely picked up by holding the sides of the carapace from above, the legs and neck being too short to reach the fingers. Larger specimens need to be held from behind to avoid the head and forelimbs. However, it should be borne in mind that the hindlimbs are also powerful and can cause loss of grip, as well as scratching the handler. With softshells, the problem is exacerbated because of the slippery carapace, in which case, a damp cloth may be useful. Some terrapins are too heavy and aggressive to be handled by a single person. Terrapins should never be held far above a substrate as they do wriggle or bite without warning, and there is a risk of their being dropped and injured. As a general rule handling should be kept to a minimum and the animals should not be unnecessarily inverted as this is stressful.

Handling crocodylians is not to be undertaken lightly. Even hatchlings can give painful bites, and animals over 1 m in length should always be regarded as dangerous. Small (less than 0.5 m) specimens can be seized from behind (never laterally), grasping the back of the head and then using the other hand to hold the pelvis at the base of the tail. Once held the mouth should be taped shut to remove the bite risk. For details of how to capture larger specimens, see Wise (1994).

**Physiological monitoring**

Chelonians and crocodylians are ectotherms, so relatively little information about the physiological status of the animal can be gained from monitoring the body temperature. Critical thermal maxima for most species occur in the region of 34–38°C. Information about body temperatures is obtained by insertion of a thermal probe into the cloaca, but this is not safely possible in hatchling or small juvenile specimens.

Obtaining blood samples is relatively straightforward. Most crocodylians and chelonians have venous sinuses in the post-occipital region, from which blood can be obtained using an appropriately sized needle (Bennett 1986). The jugular vein is another potential site if the terrapin can be induced to protrude its neck from the shell, and the caudal vein can be productive in larger specimens. In very small

chelonians, direct cardiopuncture, via a plastral suture, may be the only practical way of obtaining blood (Frye 1991) though this is not without risk to the animal so should only be used as a last resort.

Urine may be ejected spontaneously on handling, but otherwise may be obtained by placing the terrapin in a dry, plastic tank, and waiting.

### Administration of medicines and euthanasia

Most bacteria that are pathogenic to reptiles are gram-negatives such as *Pseudomonas* sp. or *Aeromonas* sp. These are usually secondary infections to some other illness or injury and can be treated using antibiotics, but care must be taken to ensure that supportive therapy, such as rehydration and adequate ambient temperatures (30–32 °C), are also in place. Comparatively few antibiotics have been tested in reptiles and some are known to have nephrotoxic effects. Therefore, injection sites should always be in the anterior part of the body, intramuscularly or subcutaneously in the forelimbs. The venous sinuses behind the cranium are also potential sites. Dose rates of 2.5–10 mg/kg for gentamicin are given in Frye (1991), which also contains a very full discussion of antibiotic therapy in general.

Terrapins and crocodylians can be anaesthetised using standard, injectable anaesthetic drugs such as ketamine hydrochloride, propofol or saffan. Volant, inhalant drugs such as isoflurane cannot safely be used to induce anaesthesia but can maintain it provided that this is supported by suitable ventilation. This should only be done under veterinary supervision. Hypothermia should not be used for anaesthetic purposes as there is no evidence that this reduces the animal's sensitivity to pain, merely its ability to move away from it.

Terrapins and crocodylians are tough animals that can be difficult to kill in the laboratory context. Insertion into a freezing environment, or the use of volant anaesthetics such as chloroform have been used in the past, but these are now regarded as either ineffective or potentially painful. The only method of euthanasia now considered acceptable is injection with an overdose of an anaesthetic agent such as pentobarbital followed by pithing to ensure destruction of the brain (Baier 2006).

### Common welfare problems

#### Disease

General veterinary medicine for reptiles is discussed in Mader (2006) and much detailed information on testudines is in McArthur *et al.* (2004). The main constraint on terrapin welfare is adequate water hygiene, as discussed previously. Most other problems are related to inadequate nutrition, lighting or physical environment. For example, necrotic dermatitis ('shell rot') can occur and is often traceable to some sort of inadequate husbandry. It is usually treatable with an appropriate antibiotic. Respiratory diseases, potentially leading to pneumonia, are not uncommon, particularly in terrapins, and can be difficult to treat. If access to adequate

levels of heat and UV light are not sufficient to treat the condition then veterinary assistance will be required. Improvements in the quality of available diets have meant that terrapin diseases that caused difficulties in the past are no longer such a problem.

Vitamin A deficiency (hypovitaminosis A) is probably the most common illness observed in terrapins. It is often found in juveniles after the age of about 6 months. The most obvious manifestation is a swelling of the tissues around the eyes and the airways.

Hyperkeratinosis is also sometimes visible. It is a result of inadequate diet, usually the persistent feeding of red meat. It is fairly easily treated, using multivitamin drops administered orally, and by the addition of supplemental items to the diet, such as earthworms, fish and fresh aquatic vegetation. In the past, some veterinarians have over-reacted to this condition and initiated regular injections of vitamin A as a prophylactic. This should not be necessary if the diet is adequate.

Vitamin B deficiency occurs due to the destructive activity of the enzyme thiaminase, which occurs in frozen fish and molluscs. Chronic nervous system abnormalities can occur, such as nervous tremors, postural abnormalities and blindness. They are easily treated with an injection of thiamin hydrochloride.

Metabolic bone disorders caused by imbalances in the calcium content of the diet are very common and can lead to spectacular shell deformities, which are untreatable (Stancel *et al.* 1998). The imbalances in the calcium content may be a function of poor calcium levels in the diet but can also be caused by a poor calcium:phosphorus ratio. The feeding of large quantities of red meat or insects is a typical cause. Correct calcium:phosphorus ratios are in the range of 1:1 to 2:1. Whole neonate mice are a good source of dietary calcium (Barten 1988). Even if adequate calcium:phosphorus ratios are present in the diet, it is possible that metabolic bone disease may still occur, as vitamin D<sub>3</sub> is required by reptiles in order to metabolise calcium. They can manufacture vitamin D<sub>3</sub> endogenously if given sufficient exposure to a source of UV radiation at about 290–310 nm wavelength. Natural sunlight has this in abundance, but terrapins maintained indoors will require an artificial source.

As a rule, most terrapins are tough, adaptable creatures that cope well with captive management conditions. Those species that are exceptions should not be considered for laboratory use.

#### Reproductive problems

The most common reproductive complication is egg retention (dystocia). The cause of this is often behavioural, perhaps an inability to find or identify a suitable nesting site. Signs include lethargy, reluctance to walk and unsteadiness on the hindlimbs. It is difficult to identify, as it can only be confirmed by X-ray, and can be life-threatening. If warm water enemas and lubrication fail to work, the alternatives are injection with oxytocin (2–10 mg/kg) (Hoggard 2000), following a course of calcium borogluconate injections (10 mg/kg) (Highfield 1996) or surgical removal (Frye 1991).

## Amphibians, with special reference to *Xenopus*

Richard Tinsley

### Biological overview

Amphibians occupy a curious place in the perceptions of many biologists. They are often regarded as a 'minor group', intermediate between fish that are successful in water and the reptiles, birds and mammals that overcame the constraints of life on land; they are considered to represent a tentative experiment in the conquest of land, condemned to an unsatisfactory dependence on damp conditions for survival. In fact, amphibians are highly successful in particular environments with approximately the same number of species as mammals. Many of the specialisations assumed characteristic of higher tetrapod vertebrates are found to be well developed in amphibians (Tinsley 1995). Thus, the immune system has been shown, in an intensively studied anuran such as *Xenopus laevis*, to have virtually all the components found in mammals. Other adaptations of amphibians are unique amongst tetrapod vertebrates.

Amphibians are abundant locally, especially in the tropics but also elsewhere. A visitor from another planet arriving in the Sonoran desert of North America on the first night of the summer rains could be misled into concluding that anurans are the dominant form of vertebrate life in areas that, by day, seem largely uninhabited. On nights when spawning occurs there may be hundreds of toads of half a dozen different species in newly formed ephemeral ponds only a few metres in diameter. Indeed, it is during periods of breeding – in water – that the abundance of amphibians resident in the surrounding area becomes apparent.

Amphibians are exceptional amongst vertebrates in using the skin as a respiratory surface (in addition, in most species, to the lungs and buccal cavity). This has profound implications for many aspects of biology. The skin is a delicate layer that, typically, is kept moist for respiration by extensive mucus secretion; it is highly permeable and well supplied with blood vessels. Amphibians are able to absorb water rapidly through the skin. The kidneys cannot concentrate urine to conserve water. Nitrogenous wastes are eliminated primarily as urea (or ammonia in some amphibians) in very dilute urine. Together, these features prevent measures to restrict water loss. Most amphibians lose water by continuous evaporation from the skin and this confines them to relatively moist environments. The urinary bladder serves as an important water store: this water can be resorbed into the body during dehydration (a process impossible in higher tetrapods).

Amphibians are ectothermic, with body temperature dependent on the external environment, but they can regulate temperature both behaviourally and by evaporative cooling. At very low temperatures, amphibians enter a state of torpor: they seek refuges, their metabolic rate slows, and all physiological requirements are reduced. For small animals in a cool temperate climate, ectothermy may be a distinct advantage: metabolic needs correspond with food availability. In winter, hibernating amphibians do not need to eat until favourable conditions (and prey) return. By contrast, many small mammals need to eat more when cold to maintain constant body temperature even when food is scarce.

All amphibians are carnivorous as juveniles and adults but the larval (tadpole) stage has a wide range of food types including vegetation, microscopic particles and aquatic prey. The diet of post-metamorphic amphibians is primarily composed of small invertebrates but may include young of the same or other amphibian species. With few exceptions, prey capture occurs on land involving terrestrial and aerial targets. Vision is the predominant sense for most species. It is used to detect prey, with movement triggering a feeding response. Prey size appears to be the main determinant of food intake – usually anything that can be taken into the mouth and swallowed. There is typically no overlap in food types (and hence competition) between the tadpole (in water) and the metamorphosed juveniles and adults (on land).

There is much variation in the abilities of amphibians to tolerate dry conditions but almost all return to water to breed. Amphibians (especially anurans) have entirely different juvenile and adult forms. The tadpole is essentially fish-like, and transforms into a tetrapod juvenile that is usually adapted for life on land. This process of metamorphosis is unique amongst vertebrates: the juvenile stage is redesigned and reconstructed out of the components that made up the larva.

Amphibians evolved from fish ancestors in the late Devonian period. The radiation that followed in the Carboniferous, Permian and Triassic led to an abundance of species and a worldwide distribution. However, all these lines became extinct and fossils of present-day amphibians, the Lissamphibia, appear first in the Triassic but then diversify in the Jurassic. Curiously, there is no overlap in the fossil record between the extinct groups that represent 'The Age of the Amphibians' and the ancestors of modern extant taxa. Timescales are impressive: the first amphibians evolved

380–360 million years ago (mya) and were abundant for around 120 million years. Subsequent to the extinction of these groups, the morphology of the oldest anuran fossils was already equivalent to that of modern representatives: thus, the pipids (the family to which *Xenopus* belongs) have fossils in the Cretaceous (125mya) very similar to present species. However, the major diversification of anurans is relatively recent with genera such as *Bufo* appearing in the Paleocene (60mya) and *Rana* in the Eocene (50mya). Remarkably, this evolution is roughly contemporaneous with that of the mammals.

There are three orders of Lissamphibians. Apoda (alternatively called Caecilia or Gymnophiona) comprise about 170 species. Urodela (alternatively called Caudata) – newts and salamanders – comprise about 540 species. Anura (or Salientia or Batrachia) – frogs and toads – have about 5200 species (Stuart *et al.* 2008). They are easily distinguished: apodans have no limbs or limb girdles and are worm-like, burrowing in tropical soils; urodeles have a long tail and their limbs are more or less of equal length; anurans have a very short vertebral column, no tail, and hindlimbs are typically longer than the forelimbs, adapted for jumping.

Over the past 20 years, there have been reports of declining amphibian populations. Comprehensive data have been compiled documenting both their diversity and threats to their survival (Stuart *et al.* 2008). At least 43% of all species are declining in population numbers and about one third (32%) of the world's species are classified as threatened. At least 34 species have become extinct since their recognition scientifically, nine since 1980, but over 100 others have uncertain status. Data on the causes of decline show that habitat loss represents the greatest threat, followed by pollution. Current concerns about disease focus on the chytrid fungus *Batrachochytrium dendrobatidis*, considered responsible for dramatic population declines in many regions worldwide. The survey also shows that many species are declining for unknown reasons and this increases concerns that amphibians may be sensitive indicators of wider fundamental changes affecting biodiversity.

### Uses in the laboratory

Biologists have long recognised that amphibians offer important advantages for laboratory investigation. Major advances in fundamental knowledge of physiology and biochemistry were first made with studies on amphibians, and subsequently these animals were used in research fields including embryology and endocrinology, genetics and immunology. For the past 30 years, one species – *Xenopus laevis* – has become one of the most intensively used of all 'laboratory animals' (alongside the mouse and chick) in developmental, cell and molecular biology (Gurdon 1996).

Reproduction is exceptional amongst tetrapod vertebrates in that mating of one male and female anuran may generate several thousand offspring that are siblings of one another. This is an advantage for laboratory studies that require replicate groups of animals with limited (brother/sister) genetic variability: such replication is impossible with the typically small clutch sizes of higher tetrapods including birds and mammals.

### Factors affecting the use of amphibians in the laboratory

In contrast to many 'lab animals', amphibians are often caught in the wild as adults before maintenance in the laboratory; these animals are accustomed to natural environmental conditions and have specific behaviours, especially predator avoidance, that influence their responses to laboratory regimens.

Amphibians are typically secretive animals, generally dispersed and more-or-less solitary in natural habitats and often encountered in large numbers only when breeding. Most species are nocturnal and their activity is strongly influenced by temperature and moisture availability. Not surprisingly, transfer to laboratory conditions may result in significant stress.

Many factors affecting the welfare of wild animals brought into the laboratory relate to their state and experience in the wild prior to capture. Season of the year is particularly important with respect to the physiology of amphibians beginning laboratory maintenance. In temperate regions, amphibians (especially frogs, species of *Rana*) caught during reproduction in spring may not have fed significantly for many months (since before hibernation). Typically, these animals have survived on stored fat reserves designed to meet reduced metabolic needs during hibernation at low temperatures. Following this, reserves may be near to exhaustion. In the wild, feeding may be relatively intensive post-breeding as temperatures rise in late spring/summer. Prey intake serves to restore physiological condition, including lipid reserves, and to prepare the gonads (in late summer/autumn) for the following year's reproduction. Laboratory maintenance that does not allow for this energy intake and increased metabolism may leave amphibians in a progressively weakening condition, ultimately so that they are unfit to be used in research. Thus, following collection in spring, frogs may be kept alive for several months at low temperatures with little or no food intake, but their stamina may be limited, especially if brought to higher temperatures for laboratory investigations.

Seasonal conditions in the natural habitat may strongly influence 'fitness for purpose' of wild-caught amphibians used for egg production (*Xenopus*, for instance). Thus, *X. laevis* at the Cape, South Africa (the origin of most laboratory supplies) breeds from early spring to mid/late summer, typically September to February. Females may spawn up to three times during this period, so a proportion of adults brought into laboratories worldwide for oocyte 'harvesting' may have gravid ovaries fully prepared for ovulation whilst others may have depleted ovaries following recent natural spawning. These animals may be accustomed to natural water temperatures close to those typically experienced in laboratories (ie, around 20°C). On the other hand, adult *X. laevis* collected during April–July (late autumn/winter at the Cape) may be taken from water at low temperatures (around 10°C), unprepared for immediate spawning, and transfer to laboratory temperatures may represent a shock. These natural seasonal cycles may explain part of the variation in physiological state of *X. laevis* when employed in laboratory research immediately after importation. This variation is avoided when *X. laevis* is maintained under appropriate

laboratory conditions (especially regarding temperature and food supply) for a period (at least 1 but preferably 2 months) after importation and before laboratory use. On the other hand, the use of lab-raised *X. laevis* in research eliminates these problems altogether.

Workers concerned with the maintenance of amphibians are familiar with instances where animals die suddenly or after a period of deterioration where it seems that 'nothing can be done' to alleviate ill-health. As a result, infectious diseases are much feared. The perception of vulnerability is enhanced by the fact that amphibians live naturally in damp, dark conditions favouring microbial growth and have a delicate, naked skin that seems to offer poor protection against pathogens. However, amphibians have occupied the equivalents of their present niches for over 100 million years, through periods of enormous environmental change – including the catastrophes linked with the extinction of the dinosaurs. Hence, we might anticipate profound and very successful specialisations. The delicate skin is equipped with glands that secrete over 50 different chemicals, many with protective functions including antibiotic action. Understanding the factors influencing the health of amphibians requires recognition of responses to unfavourable conditions, the effects of stress and the circumstances that can lead to infection and disease.

### Approaches to laboratory maintenance

One approach to the maintenance of amphibians in the laboratory is to provide environmental conditions closely matching those of natural habitats. With information on the ecology of a particular species, it is usually feasible to provide an aquarium or terrarium in which major habitat characteristics – including appropriate substrate, water supply, temperature, humidity, illumination, vegetation and cover – are reproduced at a scale sufficient to ensure well-being. Where there are specialist needs, for instance maintenance of rare species requiring critical environmental conditions, this approach may require the resources typically employed in zoos and conservation centres. For large-scale maintenance, simplified systems are often employed that are designed to achieve a cost-effective balance between numbers of animals maintained and the requirements for technician time, environmental control and feeding. For these, the aim is to provide essential needs in a 'minimalist' environment, without attempting to simulate natural habitat conditions. The major problem for amphibian maintenance is that, in most cases, there are no universally accepted methods for optimum husbandry. In particular, there have been few quantitative experimental studies producing data enabling laboratory 'users' to compare outcomes. Recommendations are often anecdotal and reflect the personal preferences of laboratory staff. Whilst experience often provides the best guide (in the absence of controlled experimental data) to high welfare standards, recent surveys of laboratory protocols reveal wide disparity in maintenance practices, including some that would be judged intuitively as inappropriate (Major & Wassersug 1998). There is a clear need for specific guidelines that will improve the care of laboratory-maintained amphibians

so that they can retain near-normal activity and physiological condition.

The approach of this chapter is, first, to use three examples to show how information on natural habitat conditions of an amphibian species can be linked to the design of maintenance procedures and, second, to discuss a range of techniques enabling the reader to make informed judgments according to his/her specific requirements. The successive editions of the UFAW Handbooks include detailed accounts of management approaches for amphibians, including comprehensive directions for urodeles. However, the anuran genus most widely used in laboratory research worldwide – *Xenopus* – has had relatively brief coverage so far in the UFAW Handbooks. So, this chapter ends with a special focus on this 'model organism'. The recommendations are based on the author's 40 years of experience of laboratory and field research involving *Xenopus* species and many of the suggestions reflect personal practice.

Alongside this, the author has also selected *Rana* species to illustrate the husbandry of anurans from a mesic environment (ie, damp terrestrial conditions) and, as an extreme contrast, the challenge of laboratory maintenance of a desert specialist, *Scaphiopus couchii*. The intention here is to show that, 'starting from scratch', it is possible to use knowledge of physiology and ecology 'in the wild' to design effective procedures for laboratory maintenance.

The best assurance of optimum care is to have laboratory personnel with a natural sympathy for living amphibians, able to recognise the behaviour patterns and other indicators that reflect good health and absence of stress. They should also possess a thorough knowledge of the 'natural history' of the species.

The following guidelines relate to anuran species that illustrate a range of needs for laboratory management. For urodeles that have general requirements related to those of mesic anurans, readers are referred to earlier editions of the UFAW Handbook (for instance, Verhoeff de Fremery *et al.* 1987; Halliday 1999).

### Husbandry of anurans from mesic environments, *Rana* spp.

#### Ecological and physiological considerations

Species of *Rana* are typically adapted for life in habitats where vegetation provides cover, relatively high humidity, protection from major temperature changes and concealment from predators. Populations are often established near water bodies and a common escape response by a frog on land is to jump into water. While feeding is generally terrestrial, frogs may rehydrate in water. Most activity is nocturnal, corresponding with greatest availability of invertebrate prey, decreased water loss by dehydration and reduced exposure to predators. Frogs are often observed to carry relatively large populations of parasites. For wild-caught animals maintained in the laboratory, these parasites may have implications for health (affecting use in research) and for disease transmission to other individuals.

## Laboratory maintenance

It is difficult to envisage effective and humane husbandry procedures other than the simulation, as far as possible, of semi-natural conditions. Most attempts at 'minimalist' accommodation are associated with significant stress and deterioration in condition. There should be no place in current laboratory practices for approaches intended simply to keep amphibians 'alive' until their intended use in research. Thus, it was formerly not unusual for frogs, caught after hibernation when stored reserves are low, to be kept at low temperature without feeding (or with little food intake). Where this approach was accompanied by continuous low-level mortality, it provided clear indication both of the inappropriateness of conditions and of the likelihood of poor performance of surviving animals in subsequent experimental procedures.

Some husbandry handbooks recommend a solid substrate (glass, plastic, metal, ceramic tiles) and a continuous flow of water, designed to wash away faecal material. These conditions are optimal for observation, but not for the well-being of the amphibian. Provision of live prey (crickets, mealworms etc) is difficult when these may become trapped in water and die. Light levels are often too high and frogs tend to huddle together creating a risk of skin damage from urination. Even when given refuges, frogs rarely show natural behaviour patterns. Laboratory aquarium design and size must avoid circumstances where the natural startle response – to jump – will result in collision with tank walls etc.

Appropriate maintenance conditions need to be relatively large scale, with a choice between areas with water and 'land' which has numerous refuges, vegetation, and a substrate of damp soil or seedling compost. Contamination of the soil with faeces (and hence microbial pathogens and parasite infective stages) may be addressed by removing the surface layer and replacing it with fresh sterilised soil, probably at weekly intervals. As with other amphibians that naturally seek concealment, provision of secluded refuges as part of optimum maintenance may conflict with the needs (and legal requirement) for daily inspection to check well-being.

Parasites requiring intermediate hosts such as snails and arthropods are not normally transmitted during laboratory maintenance, so burdens of trematodes (commonly in the lungs and alimentary tract) will not increase. However, the lung nematode *Rhabdias bufonis* has a direct life cycle with infective larvae passed in faeces and re-invading by skin penetration. This and other nematodes infecting the intestine and rectum may increase during laboratory maintenance. Smyth and Smyth (1980) provide a comprehensive account of parasites infecting frogs.

## Husbandry of an anuran from an arid environment, *Scaphiopus couchii*

### Ecological and physiological considerations

The example chosen for this section, the spadefoot toad *Scaphiopus couchii*, illustrates important principles regarding the laboratory maintenance of amphibians. First, successful

laboratory procedures can be devised even for species with highly specialised environmental requirements; but, a detailed knowledge of ecology and physiology is essential to understand these needs. Second, laboratory conditions may be required that diverge significantly from those experienced naturally: the design of procedures may require an innovative approach to achieve appropriate circumstances for feeding, growth and optimum welfare. While this case study represents a relatively extreme example of anuran lifestyle, the experience of laboratory management is equally useful for other anuran species.

*Scaphiopus couchii* is abundant in the deserts of the southwestern USA and northern Mexico. It might be expected that amphibians would be excluded from such areas of extreme aridity because of their limitations for terrestrial life including highly permeable skin, inability to concentrate excretory products, and the need for breeding and early development to occur in water. However, in most hot deserts, there are periodic weather patterns that, often very briefly, provide conditions favourable for life. The key for survival by many desert organisms includes a fast response to these favourable conditions and a life style geared to rapid growth, reproduction and accumulation of reserves enabling survival through the next period of hostile conditions (Tinsley 1999). *Scaphiopus couchii* escapes the most arid conditions for over 10 months each year by burrowing up to a metre below the desert surface. During this long period, the toads do not feed and rely on stored energy reserves for survival at low metabolic rate. Activity is prompted by heavy rainfall, which typically occurs in July and August in the Sonoran Desert. Spadefoot toads emerge immediately at the onset of torrential rain, triggered not by moisture but by the low frequency vibrations of rainfall on the soil surface. They breed on the first night when there is sufficient water to create temporary ponds. Typically, spawning is restricted to a single night each year (during darkness, 21.00h to 04.00h) but, if there are subsequent heavy rains, spawning may be repeated on two or three further nights. After this, activity is directed towards intensive feeding, but this occurs only on nights when the soil surface is reasonably moist, after rain. In southeast Arizona, *S. couchii* probably has a maximum of 20 nights each year when conditions are suitable for foraging. In between these, the toads bury themselves in shallow burrows to avoid the desert heat. In late August, conditions become dry again and, from late September onwards, relatively cold. Spadefoot toads excavate deep burrows for hibernation where they are buffered from the major temperature and moisture extremes at the surface. Digging is a backwards 'shuffle' using the thickened protuberances on the feet – the 'spades' of their common name. The process does not produce a tunnel; instead, the soil collapses in on the burrowing toad, which remains completely surrounded by soil during dormancy.

To meet spadefoot toads' needs in the laboratory, it is essential to understand the nature of their environmental constraints and specialisations. The skin of *S. couchii* is one of its major adaptations. This is delicate and permeable and might be thought to be the wrong covering for any desert animal. However, *S. couchii* is able to use its skin to take up moisture from the soil when buried beneath the surface. As moisture levels decline, the skin is able to absorb water

against an increasing concentration gradient, assisted by accumulation in the tissues of nitrogenous wastes as urea which increases osmotic potential. *Scaphiopus couchii* does not produce a cocoon to isolate itself from the environment as do some other arid-adapted anurans: the skin remains in intimate contact with the soil. Paradoxically, the toads cannot control water influx through the skin and if they are maintained in soil which is too wet they become waterlogged and die. The urinary bladder serves as a major water store: the weight of dilute urine in the bladder may amount to 50% of a toad's total body weight.

Although daytime temperatures on the desert surface exceed 50°C in summer, average temperature at a depth of 5 cm (the level of shallow burrows) is around 35°C, dropping to around 22°C at night. On damp nights when *S. couchii* emerges to feed, surface temperatures vary from 18 to 24°C. During the period of hibernation, surface temperatures fall below freezing and there may be snow; at the depth of the deep burrows, soil temperatures show reduced extremes but are still below 15°C for 6–7 months each year, and below 10°C for 3–5 months (Tocque & Tinsley 1991).

These desert conditions severely restrict the period each year during which *S. couchii* can obtain nutrients for growth, for storage of reserves to sustain hibernation and for production of gonadal products for breeding in the following year. Studies on feeding ecology show that *S. couchii* may be so efficient that it can, exceptionally, survive for 1 year on a single meal (albeit one equal to 55% of the toad's body weight and consisting of lipid-rich termites). Field data of Tocque *et al.* (1995) recorded that opportunities for such an energy-rich diet are limited to the start of the activity season; much of total prey intake comprises hard-bodied invertebrates (especially beetles, ants, crickets and spiders) that have lower calorific values but may provide other essential nutrients.

### Laboratory maintenance

With these ecological and physiological characteristics, *S. couchii* requires a carefully designed laboratory maintenance system. Animals can be kept successfully on a semi-natural temperature cycle: 25°C during the period of active feeding, growth and storage of reserves, followed by simulated dormancy during which temperatures reduce gradually to 15 and 10°C, and then rise again towards the next activity period. Soil composition is important: *S. couchii* remain in good condition in a loose friable soil consisting of sterilised loam, peat and sand in the ratio 7:3:2 (this may be obtained as a commercial potting compost in some countries). The soil should be kept moist when the animals are active; optimum water content is best achieved by mixing water a little at a time into the soil using the hands. The degree of wetness should not result in soil sticking to the hands. This mixing process provides aeration and prevents growth of moulds. Horticultural seedling composts with a high degree of organic material (including peat) may become too spongy and wet for the sensitive water uptake mechanism of the toad's skin.

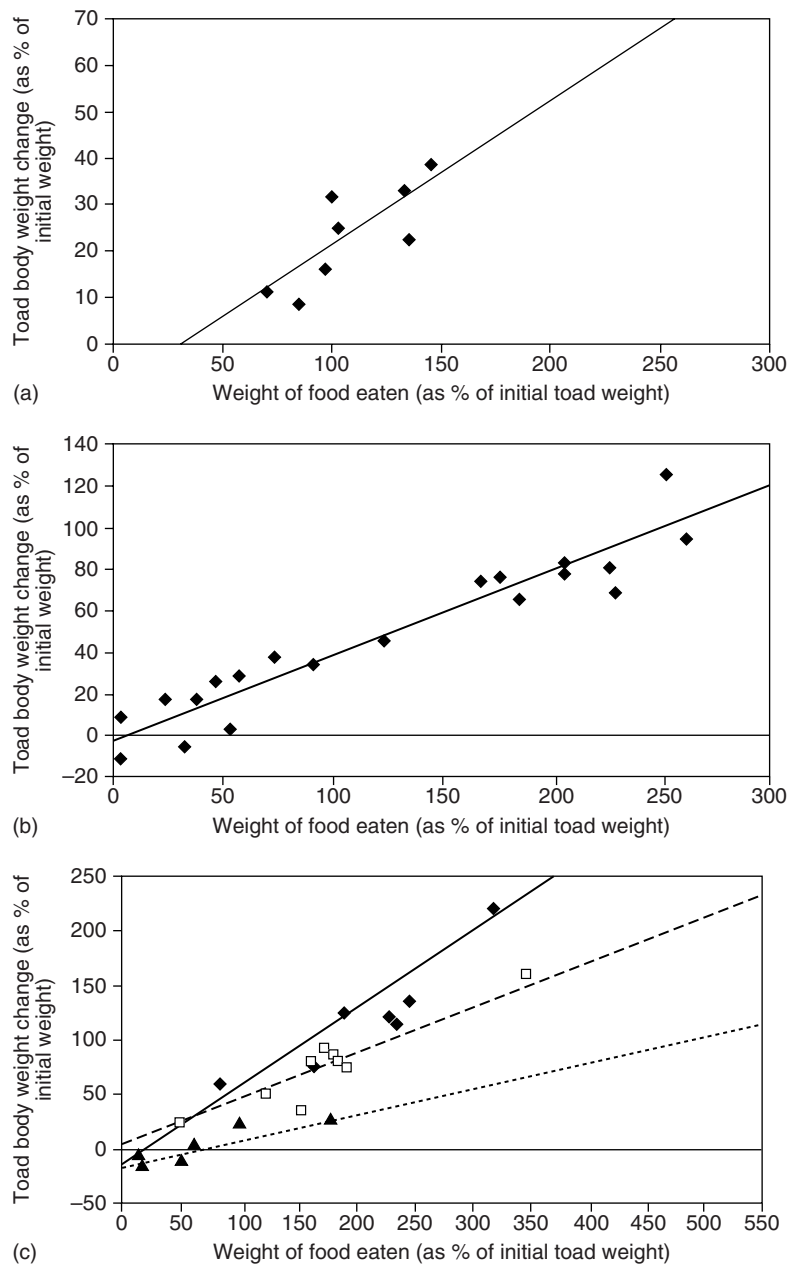

During the laboratory 'activity' period, *S. couchii* will burrow to a depth of 10–15 cm, but at the start of hibernation

(induced by reducing temperatures) toads burrow to greater depths. Hibernating toads can be maintained singly in plastic tubes (10 cm diameter sections of water pipe) containing soil 25–30 cm deep. The base can be sealed with a lid that is perforated to allow diffusion of moisture. If groups of tubes are stored vertically in a soil-filled tank, the surrounding soil provides insulation and can be watered at intervals so that moisture rises up inside the tubes. The tops of the tubes should be covered to prevent excessive moisture loss but finely perforated to allow air circulation.

Attempts to feed *S. couchii* during the 'activity' period by simulating semi-natural conditions are not successful. If groups of toads are maintained in tanks of soil on a 12h light: 12h dark photoperiod, and prey items (crickets, mealworms etc) are added during darkness, most toads remain buried and do not feed. Meanwhile, the prey animals seek refuge and become inaccessible. Entirely unnatural procedures work well in ensuring good food intake. Toads should be gently removed from the soil and transferred singly into plastic aquaria (approx 40 cm × 25 cm basal area) with secure lids, a pre-weighed quantity of prey organisms added, and left undisturbed in dim light. *Scaphiopus couchii* quickly adapts to this unnatural regime and begins prey capture immediately, feeding to satiation generally within an hour. After this, toads should be rinsed with clean water to remove urine that might burn the delicate skin and then returned to soil into which they promptly burrow until the next meal. The feeding periods provide the opportunity to check soil moisture and to re-mix it prior to return to the tube or tank. At the end of a 'feeding season' (perhaps 15–20 meals), the soil should be replaced with fresh sterile compost to exclude risks of infection from faecal material produced between meals.

Procedures involving individual maintenance and feeding allow detailed records of food intake (with prey items that remain after feeding weighed and subtracted from the weight initially offered), body weight increase, etc. Experiments reported by Tocque *et al.* (1995) showed that body weight increased in proportion to weight of food ingested over a 'feeding season' of 6–8 weeks (more than would occur in the wild). This relationship remained whether the toads were fed once or four times a week. Weight increase was greater at 20–24°C than at 31–33°C, presumably because a greater proportion of the energy intake was used in maintaining higher metabolic rate at higher temperatures. In these experiments, adult toads given 24 meals could eat a total weight of food equivalent to twice their own body weight and could increase in weight by around 100%. The nutritional quality of food significantly influences body weight gain and fat body accumulation: toads amassed very large fat reserves (up to 14% of their body weight) when fed with lipid-rich mealworms compared with those fed crickets (fat bodies up to 10% toad body weight). However, whilst ensuring energetic needs for hibernation, a lipid-rich diet does not enable good growth (in terms of protein deposition and bone formation). For this, crickets should be fed on a high-protein diet to boost nutrient value and dusted with mineral and vitamin supplements. In the wild, these nutrients would presumably be supplied by the wide diversity of prey organisms (and their gut contents) (Figure 48.1).

**Figure 48.1** Body growth (weight increase) of *Scaphiopus couchii* in alternative laboratory regimens, with varying food intake, frequency and quality. Toad weight change (shown in relation to original weight for each individual), (a) after 16 meals in 51 days at 20°C; (b) 6 or 24 meals in 42 days at 24°C (ie, toads fed once or 4 times per week: 6 meals were equivalent to <100% of toad weight); (c) 28 meals in 56 days at 25°C with crickets (solid diamonds), mealworms (open squares) or woodlice (solid triangles). Adapted from Tocque *et al.* (1995), which provides full details of relationships. Data from these procedures, modified for different amphibian species, are valuable for assessing the effectiveness of laboratory protocols for maintaining body condition and growth.

These findings confirm the exceptional capacity of *S. couchii* to convert energy intake into growth, and to accumulate reserves for hibernation. In laboratory maintenance, the ability to measure food intake and body weight increase provides assurance that animals will then survive a period of starvation, at low temperatures, matching the 9–10 month dormancy in the desert.

At the end of this long dormancy, *S. couchii* can be roused by simulating natural events: the drumming of heavy rainfall. If an electric motor (fan heater or hair dryer) is placed on the soil surface, the vibrations transmitted through the soil will prompt emergence. In one instance in the author's laboratory, animals that had been dormant for 9 months, buried in 30 cm of soil, reached the surface in 7 minutes after initiation of vibrations.

Maintenance regimens such as this require changes to the normal health inspection requirements. If *S. couchii* are disturbed regularly to confirm health during hibernation, they will die because of the repeated switching between low and high metabolic rate and associated consumption of reserves.

### Husbandry of an anuran from an aquatic environment, *Xenopus*

#### Ecological and physiological considerations

*Xenopus* species occur in most kinds of water bodies in sub-Saharan Africa, especially still waters of swamps, ponds and streams. They are strongly associated with man-made habi-

tats including dams, flooded pits, ditches and wells. They tend to be less common, or absent, from rivers or lakes especially those with well established fish communities. In general, *Xenopus* species prefer cloudy water and areas of vegetation where they are hidden from aerial predators once below the surface. Information on ecology, including habitat conditions and water chemistry, is reviewed by Tinsley *et al.* (1996).

There are currently 18 species of *Xenopus* (together with a series of other distinct forms not yet named) (see Evans *et al.* 2008). These are of major genetic and evolutionary interest because they form a polyploid series with two species groups: one with chromosome numbers of 20 and 40 (generally given a separate genus name, *Silurana*), and the other with 36, 72 and 108 chromosomes (*Xenopus*). *Xenopus* (or *Silurana*) *tropicalis* has increasing application in laboratory research as the only diploid species ( $2n = 20$ ); all others with higher ploidy levels evolved through allopolyploidisation – genome duplication associated with hybridisation between species (Evans 2008).

There are broad distinctions between the species on the basis of geographical distribution and habitat type, but it is difficult to determine niche separation at a fine scale: in some areas up to four different species can be found in the same ponds. However, the two species most commonly employed in laboratory research, *laevis* and *tropicalis*, are ecologically distinct. *Xenopus laevis* is a generalist savannah species occurring in a wide range of habitats from the Cape, South Africa, to Sudan, but typically occupying relatively cooler areas in each region. A succession of subspecies corresponds generally with latitudinal zones within this range. Most laboratory research has been based on *X. laevis laevis* from South Africa but even within this subspecies there is evidence of significant evolutionary divergence. The form occurring in the winter rainfall area of the western Cape is distinct from that in the summer rainfall area further north (Measey & Channing 2003). Fortunately, this should not cause confusion for existing research findings because worldwide export of *X. laevis* has been from populations around the Cape.<sup>1</sup>

*Xenopus* (or *Silurana*) *tropicalis* is strictly limited to lowland tropical forest in West Africa, from Nigeria to Senegal. It is not found outside the canopy of tropical forest (indeed, in areas when the forest margin is cut back, *X. tropicalis* also contracts its distribution). This suggests a strict requirement for shade, but perhaps also a requirement for relative uniformity of conditions including temperature (where ponds are not exposed to fluctuations in sunshine). Water temperature in natural habitats is typically around 25 °C (Tinsley *et al.* 1996). These species characteristics provide an important guide for laboratory welfare.

*X. laevis* has been released into the wild and has established self-maintaining populations outside Africa (Tinsley

& McCoid 1996). The current list of locations includes Europe (UK, France, Portugal, Italy), North America (many areas but most abundantly in California), South America (Chile), Ascension Island, Indonesia and Japan. Many of the localities have a Mediterranean climate equivalent to that at the Cape, but the diversity of habitat conditions confirms the adaptability of *X. laevis*. This adaptability has contributed to its success as a 'model organism' in laboratory research.

*Xenopus laevis* is normally very robust with the potential to survive more than 20 years in the laboratory. Animals in the laboratory are protected from many natural mortality factors, but successive recaptures of individually marked *X. laevis* in an introduced population in Wales show that they can also live 20 years in the wild (Tinsley *et al.* 1996 and subsequent unpublished records). Long-term laboratory experience has shown that *Xenopus* species can spawn successfully after 15 years of laboratory maintenance.

*Xenopus* is unusual in feeding underwater and, in contrast to most terrestrial-feeding amphibians, *Xenopus* may feed communally on larger prey items. Prey is located by sight, odour and by vibrations detected by the lateral line sense organs; this correlates with the preference for still water. The diet may include carrion and contrasts with the situation for most amphibians where, if there is no movement, a potential food item is not recognised. Both tadpoles and post-metamorphs of *Xenopus* feed in the same environment but there is no overlap in diet since the tadpoles are filter-feeders. However, post-metamorphic *Xenopus* may feed on tadpoles. This habit allows very efficient exploitation of energy sources, especially in newly formed habitats where food chains are not well established: the tadpoles feed on phytoplankton which gains energy directly from sunlight, and the adults trap this source of nutrients by cannibalism on the typically very large tadpole populations. *Xenopus* species communicate by specialised vocalisations, maintain territories underwater and have dominant/subordinate hierarchy; they are capable of complex learning and long-term memory (Elepfandt 1996a, 1996b). Above all, they are cryptic and nocturnal.

*X. laevis* exported from South Africa for laboratory research are caught as adults, after at least 3 years (probably up to 10 years) in natural habitats. The conditions to which they are transferred are often totally at variance with their previous experience. Nocturnal animals accustomed to the security of cloudy water are likely to experience stress in high-density populations in clear, shallow water, illuminated from all sides (and even below), with frequent disturbance and a lack of refuges.

## Laboratory maintenance

### Aquarium conditions

Laboratory environmental conditions reflecting the preferred habitats of *Xenopus* in the wild can be provided by a dark-sided aquarium with light coming primarily from above, water depth at least 50 cm, a partial surface covering, refuges and still water without appreciable circulation or disturbance.

This combination of features can be achieved with aquaria with thick glass walls and a substrate of rounded gravel ('pea gravel') in which sections of drain pipes or plant pots

<sup>1</sup>Note: *Xenopus* is variously described in the literature as a frog or a toad but these popular terms do not have strict scientific relevance and *Xenopus* is actually distant from both 'divisions'. Although the use of a genus name alone is not accepted scientifically, the name *Xenopus* will be used as an informal designation in this account for the species of *Xenopus* and *Silurana*.

are partially embedded as refuges. A 'three-dimensional' environment can be created with leafy plants (plastic foliage is easier to 'maintain' at low light levels and to wash/sterilise). An appropriate water surface covering can be provided by natural growth of duckweed (*Lemna* spp.) where there is good illumination, including daylight, or by floating synthetic material cut to resemble lily pads. 'Furnished' aquaria of this type can provide relatively stable environments if the bottom gravel supports a culture of bacteria that de-nitrify metabolic and digestive wastes. To maintain equilibrium in water quality, it is essential that the animals are not over-fed (avoiding breakdown of uneaten food in the gravel). This form of management works well with 'chunky' food items (ox-heart, meal worms etc) that are ingested intact, without creating debris during 'capture'. It is impractical with reconstituted, pellet-type food which disintegrates if not eaten quickly. Food input requires judgment (ideally direct observation to note the amount of food that will be eaten within 30–60 minutes). Animals fed to satiation with a single meal each week will maintain optimum physiological condition (with good gonad and fat body development). The complexity of setting up 'semi-natural' habitats such as this is off-set by ease of maintenance: the frequency of water changes can be judged visually by noting water clarity and the build-up of anoxic sediment in the gravel. With good management, water changes may be at 4–6-month intervals (shorter intervals if algal blooms occur in response to sunlight). Water changes require the removal of animals to temporary holding tanks whilst the aquarium is emptied completely and cleaned. The gravel should be thoroughly washed and re-introduced together with a small quantity of the original sediment from which the population of de-nitrifying bacteria can re-establish. Under these semi-natural conditions, animals appear not to be disturbed by movements adjacent to the tank and they can easily be checked for health and well-being. This approach works well for small populations of rare species, especially those sensitive to disturbance.

Whilst these aquarium conditions attempt to achieve optimum welfare by simulating natural habitat conditions, the systems found in some laboratories represent a marked contrast. In some cases, *X. laevis* are maintained in transparent aquaria that allow entry of light from all directions (including above and below), a featureless substrate without refuges, and water depth less than 10 cm. Under these conditions, *Xenopus* may locate themselves in a 'heap', resulting from their attempts to hide underneath each other. The rationale for such systems is that animals can be seen easily, aquaria can be kept clean, and feeding and water changing can be efficient. However, environmental design promoting optimum physiological condition of *Xenopus* requires careful evaluation.

#### Water depth

When undisturbed, *Xenopus* spend long periods at the water surface, with nostrils exposed to the air. This has been taken to suggest that maximum water depth should allow animals to stand on the tank bottom and reach the surface 'in comfort'; but the assumption is probably anthropocentric. Animals adjust their buoyancy in deep water with the air

capacity of their lungs so that they can 'hang' from the surface without effort. In the wild, *X. laevis* rarely occurs in shallow water: greater depths are preferred probably because of increased protection from predation. It has long been established (Alexander & Bellerby 1938; Bellerby & Hogben 1938) that shallow water and overcrowding lead to ovary regression. In the laboratory, deep water increases the three-dimensional structure of the aquarium habitat and, in conjunction with plants and other enrichment, allows greater subdivision of the space for groups of *Xenopus*. On this basis, water depth of at least 30 cm, preferably 50 cm, is recommended. (In the author's view, the recent European Recommendations (Council of Europe 2006, European Commission 2007) in which minimum water depth is approximately the same as snout-vent length is too low.)

#### Population density

For animals taken from the wild, it seems intuitive that the lowest practicable density (consistent with laboratory constraints) should be advisable. Recommendations in the literature based on volume of water per animal need to take account of associated parameters. If *X. laevis* is maintained at low density in a clear featureless tank, individuals will tend to huddle in a group, furthest from direct light or external movement, and may actually experience the effects of high density. Environmental enrichment creating subdivision of the habitat has an important influence on density. Water volume/animal must also take account of water quality, and hence frequency of water changes and type of diet.

Some guidelines in the literature omit consideration of body size (but presumably relate specifically to fully grown adults). Recommendations on the volume of water to be provided per animal vary (see Reed 2005a). As a general guide, 21 l/animal is too restrictive for adult *X. laevis*, while 121 l/animal (as recommended by the Council of Europe (2006) and European Commission (2007)) may be impractical for large-scale maintenance. Very fast growth rates of juvenile *X. laevis* (with sexual maturity in less than 10 months post-metamorphosis) can be achieved at relatively high density (1.5–21 l/animal at 40–50 mm snout-vent length) if feeding is intensive. This outcome may not necessarily indicate good conditions; instead, it may parallel the fast growth characteristics of intensively reared animals in agriculture and aquaculture.

#### Tank design

Tanks with darkened sides and a black base provide conditions resembling those in natural habitats but inspection of animals is difficult. *Xenopus* in thick glass-walled aquaria do not appear to react to minor movements lateral to the tank. Tank materials that are smooth and impervious include various plastics, glass and stainless steel, but moulded constructions with rounded junctions between the tank sides and base are easier to clean than the angular joins between glass sheets. 'Food grade' plastics avoid risks of leaching of toxic chemicals. Surfaces should never be cleaned with abrasive materials: the roughened surface may be more easily colonised by micro-organisms.

*Xenopus* are adept at exploiting any opportunity to escape. They can jump at least their own body length above the water surface, so tanks should have secure, well fitting lids. However, animals should not be able to reach the lid as this can cause nasal trauma; so tank design should allow for height of walls at least 20 cm above the water surface. Solid lids should have air holes. However, in large scale establishments, such tank design has major implications for space needs. Laboratories equipped with semi-automated systems typically find that adult animals maintain excellent condition with water depth 15 cm, density 31/animal, and lids only 5 cm above the surface. The key factor may relate to origin: *X. laevis* raised from metamorphosis in such systems adapt well and show no signs of stress; animals caught as adults from the wild are more likely to find such restrictions stressful.

### Environmental enrichment

Provision of refuges within the aquarium environment simulates habitat conditions in the natural environment. Various studies (eg, Brown & Nixon 2004) have shown that, when given a choice of secluded or exposed areas, laboratory-maintained *X. laevis* prefer cover. This may be provided by sections of plastic pipe (including water pipes around 100 mm diameter), plastic aquarium foliage etc. It might be expected that this should reduce stress. However, in tanks with appropriate refuges, *X. laevis* remain much more sensitive to disturbance and are startled more easily than animals maintained without cover. Hilken *et al.* (1995) recorded poorer growth in *X. laevis* given shelter compared with those without; this was attributed to greater shyness. There are potential problems where provision of refuges conflicts with the need for periodic inspection to ensure well-being. There is also the possibility of increased stress created by competition within groups of *X. laevis* over utilisation of refuges. The provision of refuges requires further research and evaluation.

### Temperature

Information on the ecology of *X. laevis* is necessary to appreciate the thermal limits of this 'laboratory amphibian'. At the Cape, South Africa, *X. laevis* experiences a Mediterranean climate with temperatures below 10 °C in winter and above 25 °C in summer. Records from the various introduced populations in the northern hemisphere show a tolerance of wider extremes. In the eastern USA, animals overwinter beneath the ice of frozen ponds; in Arizona, *X. laevis* occurs in ponds whose summer temperatures reach 30 °C (close to the thermal maximum). In addition to longer-term seasonal variations in temperature, *Xenopus* naturally experience short-term fluctuations determined by habitat conditions including thermal differences between pond areas exposed to sun and in deep shade. Temperature records in ponds inhabited by introduced *X. laevis* in the UK show an annual cycle between 4 and 24 °C, and short-term changes (especially in spring and autumn) of up to 8 °C over 5 days. In these UK populations, *X. laevis* typically experience temperatures below 10 °C for over 6 months (October to March), but they still show fast growth rates, excellent condition and

successful breeding. Experience from the author's laboratory shows that *X. laevis* can adapt to long-term maintenance (up to 2 years) at 10 and 15 °C and can be maintained for more limited periods at 5 °C. Although spawning appears to be optimal at around 20 °C, *X. laevis* can spawn in water at 15 °C and the tadpoles can develop to metamorphosis at this temperature that is low relative to conditions in South Africa.

It is clear that *X. laevis* can adapt to a wide range of temperatures, but this is not reflected simply in increased or decreased activity and metabolic rate. There is evidence of behavioural, physiological and immunological changes that represent acclimation to extremes of temperature. Thus, locomotor performance of *X. laevis* acclimated to low temperature is significantly greater at low temperatures than that of animals acclimated to high temperature (Wilson *et al.* 2000). Haematological profiles change in relation both to oxygen-carrying capacity of the blood and to the mechanisms of immune defence. All aspects of laboratory maintenance must take account of profoundly altered physiological characteristics at different temperatures. The functioning of the immune response of *Xenopus* (as in other ectotherm vertebrates) is temperature dependent (Robert & Ohta 2009). At temperatures below about 18 °C, *X. laevis* are progressively immunosuppressed, so special care is necessary to prevent infection. At low temperatures (including 10 °C), *X. laevis* are relatively quiescent and will not tolerate the frequent disturbance typically associated with water changes. (Thus, long-term maintenance is best achieved with stable aquarium systems including a gravel substrate where water changes are necessary only at several month intervals.) Food supply should be proportional to temperature, corresponding with respective metabolic needs. *Xenopus laevis* may remain in good condition in long-term maintenance at 25 °C but they require increased food supply to fuel higher metabolic rate and more frequent water changes to remove waste products.

Laboratory maintenance at different temperatures must also take account of rate of change. Thermal acclimation requires time for physiological changes to occur. Green *et al.* (2003) attributed deaths of *X. laevis* in a laboratory colony to thermal shock following direct transfer from 16 to 23 °C. However, there are no established data for rates of change that are tolerated. Changes of about 5 °C over 2–5 days would accord with conditions experienced naturally; but, for greater changes, animals should be allowed time to acclimate at intermediate temperatures. Animals should not be transferred directly from a tank of water at one temperature to another at higher or lower temperature: they should be moved in water at their original temperature to new conditions where this water then warms or cools gradually. Alternatively, with thermostatically controlled heater/chiller units, settings should be changed by only about 2 °C per day. Jackson and Tinsley (1998) transferred *X. laevis* through a thermocline from 20 °C to 6 °C, leaving animals for about 2 weeks between each 2 °C change.<sup>2</sup>

<sup>2</sup>Note: Reed (2005a) was in error in stating that a 2–5 °C temperature change could cause thermal shock and mortality. The reference mis-cited (actually Green *et al.* 2003) gave this finding for other amphibian species, not for *X. laevis*.

As with other aspects of *Xenopus* biology, approaches to management of laboratory temperatures should take account of other stressors related to maintenance. Thus, transfer between temperatures may have no ill-effects for animals in good physiological condition in a stress-free environment, but may precipitate illness in animals maintained in suboptimal conditions.

It is generally accepted that optimum temperature conditions for *X. laevis* fall within 18–22°C. Hilken *et al.* (1995) found no significant differences in growth of *X. laevis* maintained at 19, 22 or 24°C. The immune system is most effective above 20°C. Recommendations in the literature for maintenance at lower temperatures than these (including 15 or 16°C) may lead to risks of pathogenic infection. Researchers primarily interested in egg production should note that spawning in the Cape, S. Africa is triggered by temperatures at or over 20°C (although oocytes may have developed at lower temperatures in the period preceding spawning). The field and laboratory evidence reported here confirms that *X. laevis* will adapt to temperatures throughout the range 15–25°C, but on either side of the central band of about 19–22°C animals will be more vulnerable to co-occurring stress.

### Diet and feeding frequency

While there is much debate in publications about optimal environmental conditions for maintaining *Xenopus* species, there is relatively little discussion about diets. Although some laboratories advocate specific preferences, a range of alternative diets appears to satisfy nutritional requirements. A 'scientific' approach suggests the advantages of commercially formulated composite diets (including regulated quantities of proteins, fats, carbohydrates, minerals, trace elements, etc). Certainly, *X. laevis* will grow rapidly on high-protein diets and reach sexual maturity in only about 8 months post-hatching. Although it is counterintuitive, the author has maintained *X. laevis* for over 15 years exclusively on bovine muscle (ox heart), without vitamin or other supplements. In vertebrate taxa, such diets often lead to bone disease due to lack of calcium but no nutritional deficiencies were evident in the *X. laevis*, and females spawned prolifically when aged 12–15 years. Other diets are reviewed by Reed (2005a). Live food such as *Tubifex* carries risks of infection while the gut contents of prey such as earthworms produce significant water contamination.

Some accounts of *X. laevis* maintenance protocols put emphasis on the presumed benefits of a so-called 'feeding frenzy'. Certainly, animals that are stimulated to feed simultaneously avoid the outcome where some that are slow to react may miss a meal. This seems to accord with circumstances in nature where one or a few individuals finding food may trigger searching behaviour by others in the vicinity. A 'frenzy' can be advantageous in the wild when *Xenopus* encounter a food source, including carrion, that is too big for an individual to ingest alone. A group of *Xenopus* can quickly shred a large food item by repeated scratching with the sharp hindfoot claws. However, the author is not convinced that this behaviour is an advantage in the laboratory. When two or more individuals attempt to ingest the same

food item, the violent struggles and kicking with the claws are potentially damaging. Pieces of food (eg, cubes of meat) should be small enough to be swallowed quickly, avoiding simultaneous 'capture' by other individuals. In practice, *X. laevis* become conditioned to a regular feeding routine and all individuals respond together when food is given, so a 'frenzy' does not improve intake.

Different authorities advocate feeding *X. laevis* at a variety of frequencies. Young post-metamorphs certainly require frequent feeding: their gut size may limit food intake per meal and significant gaps between meals may affect growth. Fast-growing juveniles benefit from two to three feeds per week and fastest development to maturity can be achieved with daily feeding. However, fully grown adults can maintain excellent condition and develop ripe ovaries with a single meal per week. The key to this regimen is that all animals in a tank should be fed to satiation avoiding competitive effects that might induce differences in growth rate and size. Satiation can be achieved by providing a sufficient quantity of food so that some always remains uneaten at the end of a session. Otherwise there can be no assurance that some individuals are not under-fed (or unfed). In relatively large-scale maintenance, a meal appropriate to each population can be added to the aquarium, which is then inspected about an hour later; if all food has been eaten, more can be added until just a few items remain. This slight excess can be removed (with a net) at the end of the day, avoiding fouling of the water. This process of matching food supply to need is more difficult with a pellet-type diet where uneaten food disintegrates relatively quickly and an excess leads to greater water fouling.

### Water changes

Mains tap water intended as drinking water should meet the maintenance needs of *X. laevis*, but supply pipes must not contaminate the water with metals such as copper and lead: heavy metal contamination can have serious effects on oocyte quality. Water must be dechlorinated (most simply by allowing it to stand for 12–24 h) but where water supplies are treated with chloramines these can be removed with commercial aquarium agents containing sodium thiosulphate.

For *X. laevis* maintained in 'fill-and dump' systems, there are two alternative approaches to the feeding/water change sequence. Where animals are fed once weekly and the water is also changed once per week, some lab regimens advocate feeding on the day before the water change. Alternatively, the water change may be carried out first and the animals are then fed (usually immediately afterwards). In the first case, maximum water pollution in the weekly cycle occurs on the day after feeding: a combination of accumulated waste from the previous week (including faeces) and debris from the recent feeding process, including fragments of uneaten food. All this is removed and the animals begin the next week with clean water, which becomes progressively more contaminated until the next feed/water change. In the second case, maximum pollution (lowest water quality) occurs in the period preceding feeding but ingestion of food takes place in clean water. The start of the inter-change week

may then have debris resulting from feeding but faecal material does not begin to accumulate for several days. The advantage of this latter sequence is that food intake avoids re-ingestion of faeces, shed skin and other debris with the meal. Both approaches appear to work well and good-quality oocytes may be obtained from females. One disadvantage of the first 'feed-then-change' sequence is that animals experience the major disturbance of the water change on the day after feeding and this may provoke regurgitation. If the change is delayed by a further day or two, the animals remain in poor-quality water for longer. In practice, *X. laevis* readily become conditioned to the change-then-feed sequence: with repetition, they begin to search for food as soon as they are transferred to clean water. This means that the meal is eaten more efficiently and there is less debris. It has the further advantage that animals are undisturbed (for a week) after food intake and digestion does not experience the disruption inherent in water changes.

Feeding with commercial formulations (pellets) leads to more rapid deterioration in water quality (especially from disintegration of uneaten pellets), so more frequent water changes may be necessary.

Water change procedures must ensure that animals are transferred to water at the same temperature. The smoothest changes are achieved by direct transfer of animals from one tank to a duplicate, limiting disturbance to the moment of transfer. For a series of tank changes, the just-vacated tank can then be cleaned out, refilled and used to receive the animals from the next tank to be changed, and so on. This minimises disturbance but incurs the risk that any infection established in one tank is transferred between groups. An alternative approach is to transfer animals from their aquarium to a temporary 'holding' tank; the original container is washed, re-filled and the same animals are returned to it. Animals and tanks always remain together, but this method increases the disturbance to the animals during temporary holding and successive transfers.

At no point in the transfer process should animals be left in very shallow water or, even worse, be left in their original tank whilst the old water is drained out and new water poured in. Rapid decrease in water depth (equivalent to disappearance of the natural habitat), and temporary exposure of animals out of water is highly stressful.

Transfer of animals may be by net but this should have a mesh size sufficient to prevent carrying over debris from dirty to clean water. Animals should not be transferred in groups in a net such that they fall on top of each other. For experienced laboratory workers, it is often most efficient and least disruptive to transfer animals gently by hand. Using naked hands (without plastic gloves) provides a check on the condition of each animal: roughening of *Xenopus* skin and decrease in slipperiness (reduced mucus secretion) give early warning of poor health (see later in this chapter).

To reduce risks of infection, tanks should be washed between water changes and the sides and bottom wiped; this also removes growths of algae. Rinsing with clean water before refilling will wash away parasite eggs (if natural infections are present). Basic maintenance protocols associated with water changes etc should incorporate rigorous commonsense hygiene measures. Nets, cleaning cloths etc should be washed thoroughly (ideally with hot water)

between uses. Most pathogens affecting *X. laevis* do not survive complete drying: there are no resistant stages (but the capillarid skin nematode is an exception). So, tanks, aquaria, holding containers, nets, cloths, etc should be dried thoroughly between uses (with aquaria propped upside-down to drain completely). Containers (including plastic aquaria) must not be stacked with moisture trapped inside.

Increasingly, laboratories that keep *Xenopus* are adopting automated or semi-automated systems in which racks of aquaria are maintained with recirculating water, controlled for water chemistry, temperature and other parameters. Purpose-built systems provide a standardised design that removes many of the uncertainties considered in the previous sections and achieves greater uniformity in conditions without the cyclical changes in water quality inherent in static, 'fill-and-dump' regimens (Figure 48.2). With these systems, some laboratories employ every-day feeding with pellet-type diets and achieve fast growth rates (equivalent to those in 'intensive rearing' in agricultural production).

Recirculation and continuous flow systems that are little modified from those designed for tropical fish may have racks of relatively small translucent tanks in which animals

**Figure 48.2** Example of purpose-designed, automated aquarium housing for laboratory-maintained *Xenopus* species, providing comprehensive environmental control including temperature, pH, conductivity, and regulating water quality with continuous circulation and filtration. In this design, each tank contains 27 l of water (depth 12 cm) and is intended for up to nine adult *X. laevis*; 10% of the water is replaced each day and passed through biological, mechanical and charcoal filters before UV sterilisation. Racks of tanks may be self-contained (upper image) or joined together in series with a central water treatment and environmental control unit (lower image). Photographs courtesy of Techniplast, Italy.

are exposed to all-round light. Such conditions are likely to be stressful. Improvements include 'smoked' plastic tanks with opaque bases. The choice between manual or automated husbandry systems has more to do with costs (including installation and servicing), technician workload, space and other resources, than the condition of the animals.

### Reproduction, rearing of tadpoles

One of the major advantages of *Xenopus* for laboratory research derives from the ease with which these amphibians can be bred in captivity at any time of year. In the wild, age at sexual maturity is generally 2 years for males and 3 years for females; but, with intensive growth in the laboratory, *X. laevis* can reach maturity at about 6 months post-metamorphosis (Tinsley & Kobel 1996). Males in mating condition develop black nuptial gloves on the inner surface of the arms to help grip the female; in receptive females, the cloacal labia become pink. Acoustic communication is well developed in the *Xenopus* species and males and females have a repertoire of vocalisations based on clicks. The male advertisement call is a continuous trilling made by the larynx without any visible movement. Amplexus is inguinal (around the waist). Egg production in the laboratory under hormonal stimulation typically results in deposition of eggs *en masse* on the bottom of an aquarium tank. Under natural conditions, eggs are released singly or in small groups during slow swimming by the mating pair, and the eggs are stuck to vegetation and vertical surfaces: eggs are not deposited on the pond bottom where they would encounter anoxic conditions.

Under optimum conditions, spawning can occur spontaneously in the laboratory at around 20–22 °C, but it is usually induced by injection of human chorionic gonadotrophin (hCG). Females should have been well fed for several weeks and should be plump and pear shaped, reflecting an enlarged ovary. Males should have nuptial gloves (these can be induced by isolating the male for a week before spawning). Typically, two injections are given 48 h apart: a primer to bring animals into mating condition and a final dose to stimulate spawning. Male and female are kept separate after the primer and put together after the final injection. Doses are related to body size but, for adult *X. laevis*, the primer may be 50 IU for males and 100 IU for females, and final doses 100 IU and 300 IU respectively. The aquarium tank in which spawning occurs should be fitted with a false platform of plastic (not wire) netting through which eggs can settle avoiding risk of being eaten by the parents.

To avoid damage to spawn, the adults should be removed from the tank and eggs left *in situ* until they hatch. Larvae break free after about 48 h (at 22 °C) and attach to a vertical surface until remaining yolk is absorbed. The tadpoles are filter-feeders, sieving microscopic particles from the water whilst hovering head-down at an angle of 45° with the tip of the tail flicking continuously. In the wild, tadpoles of *X. laevis* form large schools, all orientated in the same direction and swimming in unison. Under these natural conditions, body length (head to tail tip) typically exceeds 90 mm, but in the laboratory maximum body size is considerably less.

Tadpoles may be fed a range of diets including finely powdered plant material (nettle powder, algae), commercial fish food, finely ground pellets intended for post-metamorphic *X. laevis*, and milk (which produces a droplet suspension of appropriate size for filtration). Feeding frequency should allow the suspension to be cleared between meals. The amount of food required increases with development; material that settles to the tank bottom can support an infusorial culture that adds to the food supply. Large aquaria may become relatively stable with water changes needed at intervals of a few weeks but, with intensive feeding, once-weekly changes may be required. Water quality can be maintained with gentle aeration but *X. laevis* tadpoles also breathe air, visiting the surface about every 30 minutes in normoxic water. A study of factors affecting growth and developmental rates of *X. laevis* tadpoles (Warren 2008) found no significant differences in growth rates in populations maintained in a range of different laboratory conditions. Parameters measured included feeding frequency, aquarium design and materials, water surface cover and even population densities (within the range cited by many laboratories). These findings emphasise that the adaptability of *X. laevis*, well known for the adults, also includes the tadpoles.

### Laboratory procedures

#### Handling

The slippery skin of *X. laevis* makes capture by predators – and handling by laboratory workers – difficult. The powerful hindlimbs and sharp claws may deter inexperienced handlers. Practice is required so that attempts to pick up animals are neither too tentative nor too rough. The hand should be positioned palm down above the animal so that its head is facing the handler's wrist. The index finger should be moved between the animal's hindlimbs and flexed forward beneath its abdomen. Then the thumb and remaining fingers can be closed around the animal's flanks. The animal can then be lifted above the water surface with its body held gently but firmly against the palm of the hand and its legs hanging between thumb and forefinger on one side and forefinger and middle finger on the other. In this position, the animal is unable to bring its hindlimbs forward to push itself away or scratch the handler. In routine maintenance, *X. laevis* becomes accustomed to this procedure (and so do the handlers), so that animals can be transferred between adjacent containers in a few seconds, without struggling.

Small individuals may be more agile and it is often better to catch these with two hands enclosing the animal in the cupped palms and avoiding gaps between the fingers through which it may squeeze. *Xenopus* should not be held in a position where, if they do escape from the hands, they may fall to the floor. For further manipulation, animals should be held immediately above an uncluttered bench surface where escape would not cause injury. Temporary immobilisation is best achieved by holding the animal in soft paper towelling; the dampness of the animal after removal from water prevents skin abrasion and the soft paper

towelling facilitates appropriate grip. Instructions in some laboratory manuals to handle *X. laevis* with a rough cloth are best avoided: restraint relying on a rough surface may risk skin damage, and a cloth used for a succession of animals becomes slime-covered and could transfer infection. Paper towelling can be discarded after a single use.

### Administration of substances

For injection (for instance, with hormones to stimulate spawning), *X. laevis* can be held securely by the extended hindlimbs if these are gripped together in soft paper towelling just posterior to the pelvis. There must be no possibility that one or both legs can be brought forward, allowing the animal to push itself out of the restraint. The abdomen and anterior of the animal can then be rested on the bench surface (on damp paper towel) with the hindlimbs immobilised within a 'wrapping' of paper towelling. In this position, an injection can be given without risk of movement that could lead to injury. Gonadotrophic and other hormones are typically introduced into the dorsal lymph sac; fluid in this large subdermal space is quickly transported into the general circulation and hence around the body. Injection directly through the skin of the back can lead to leakage so it is more efficient to introduce the hypodermic needle very superficially (almost horizontally) through the skin of the dorsal thigh and then forwards through the septum that separates the lymph spaces of upper leg and back. Injected fluid can then be expelled into the dorsal lymph sac with reduced risks both of loss through the perforation and of entry of potential infections. The needle should meet only very fine superficial capillaries so the procedure should not produce bleeding or bruising.

### Monitoring

For measurement of weight and length (to record growth rates and other indices of condition), it is least stressful to weigh animals in a container of water on a top pan balance. Measurement of body length (typically the distance from the tip of the nose to the cloaca: snout-vent length) in *X. laevis* is prone to errors created by the sliding pelvis. The forward-directed iliac processes of the pelvic girdle articulate with the sacral vertebrae by means of a sliding joint (resembling the sliding seat of some rowing boats). This adaptation, enabling the animal to shorten or lengthen its spine by up to 15%, is effective in rapid escape movements and also burrowing in mud. Accurate snout-vent length data require *Xenopus* to be measured in a relaxed 'standard' position (without the legs being contracted up to the body, reducing length, nor extended too fully, increasing length). With practice, this can be done in a few seconds with animals transferred quickly from water to damp paper towel on a flat surface. A flexible transparent ruler is most efficient; callipers should be avoided because of the risk of injury if the animal moves suddenly. It is difficult to reduce variation between successive measurements of the same individual to <2mm but, even with this error, valuable data on growth and condition can be compiled.

### Identification and marking techniques

Individual identification of amphibians may be valuable in laboratory maintenance to follow growth rates, breeding history etc under specific husbandry regimens. Older established techniques that include removal of combinations of digits are no longer acceptable and, in *Xenopus*, cut toes re-grow.

In laboratory populations, with limited numbers of individuals, photographs of skin patterns provide an effective, although sometimes laborious, means of individual recognition. However, with large populations in the wild, the unknown extent of pattern variation may make this impractical. Use of other methods, including applications of dyes and other distinguishing marks (summarised by Halliday (1999)), depends on the skin of the species. In many amphibians, the skin is too delicate to tolerate dye injection.

*Xenopus laevis* is unusual in having a relatively tough skin and marks applied to the white ventral belly skin are easy to see. The author's field studies based on populations of several thousand individuals have confirmed the effectiveness of several methods and the lack of ill-effects when employed carefully. Introduction of dye (typically alcian blue) with a pressure injector (a 'panjet') produces discrete spots that have remained visible for over 20 years (in very long-lived *X. laevis*). Freeze-branding using metal numbers and digits produces dark, easily-read figures on the white belly skin that are permanent (over 15 years in marked natural populations) and have never been found to cause skin damage or infection. In the UK, this procedure requires a Home Office licence. Currently, introduction of PIT tags (passive integrated transponders) beneath the skin does not require a licence. The cylindrical tags (approximately 5mm long, 1mm diameter) produce a unique signal that can be read with a portable scanner. However, the process of insertion seems questionable on welfare grounds. The needle injectors work effectively on the thick skin and subcutaneous muscle of mammalian species where the point of insertion in elastic tissues closes as the needle is withdrawn. However, in amphibians, including *X. laevis* that has relatively inelastic skin, the perforation can remain open producing a risk of infection and sometimes loss of the tag.

A recent development that exploits the natural distinction between dorsal pigment patterns and avoids the labour-intensive comparison of photographs involves digital imaging and machine vision techniques (Figure 48.3).

### Safety considerations

There are no records of transfer of infection from *Xenopus* species to humans (although extra caution is needed in cases of antibiotic-resistant bacteria). Commonsense hygiene measures should be adopted when handling *Xenopus* and aquarium water. Hand creams that might irritate amphibian skin should not be used. Some workers use gloves but these reduce sensitivity in handling: information on the animal's condition from its skin texture is missed. Latex and nitrile gloves cause high mortality in amphibian tadpoles includ-

## Anaesthesia

MS222 (tricaine methane sulphonate) is the most effective anaesthetic, administered by immersion of the animal in a 0.05–0.10% solution. MS222 forms an acidic solution in water and should be buffered to pH7 with sodium bicarbonate. Adult *X. laevis* left in MS222 for about 10 minutes after loss of reflexes will take 20–30 minutes to recover when transferred to clean, preferably flowing, water (but times vary with factors including body size and temperature). During anaesthesia and recovery, animals should be propped with nostrils above the water surface and, if out of water, should be kept wet with damp tissue.

## Euthanasia

Amongst several alternative methods (Reed 2005a, 2005b), an overdose of MS222 (generally 2–3 g/litre of water, buffered to pH7) is most effective and humane. After unconsciousness, time to death is variable (commonly more than 1 h); *X. laevis* anaesthetised for less than this time should be double-pithed to ensure destruction of brain and spinal cord tissue. Where perfusion might wash out MS222, barbiturate overdose (injected into the dorsal lymph sac) may be recommended.

## Transport

Problems that may affect *Xenopus* during transport include exposure to unfavourable environmental conditions (especially heat, poor water quality, restricted access to air); stress from overcrowding; and physical damage from movement within containers. It is essential that containers are not exposed to sun during transport. Animals should not be fed for 3–4 days prior to travelling to reduce fouling of the water.

*Xenopus laevis* are sometimes transported over long and short distances with minimal water in insulated boxes packed with damp moss or sponge. The lightness of the packaging reduces cost but the method increases the risk of stress or injury. Although *X. laevis* will tolerate emersion from water in a damp environment, they continue to excrete ammonia that can cause severe skin burns. Without water, the animals are also more vulnerable to temperature fluctuations and to injury from erratic movements of the container.

It is better to transport *Xenopus* in clean water deep enough to cover all individuals. Addition of sterile sponge reduces waves and provides a more stable covering for submerged animals. Polystyrene boxes that are waterproof (sometimes lined with polythene sheeting) provide insulation; it is essential that air holes cannot become blocked. In relatively shallow boxes, *Xenopus* may jump and hit their heads, incurring injuries ('red nose' symptoms) and subsequent bacterial infection.

For transport over shorter distances between laboratories, typically by road where there may be reduced constraints on weight and volume, it is best to house animals in relatively deep water (around 30 cm) in a tall container (where the lid is above jumping height): securely covered bins are

ideal. Travel should be at a time of day avoiding high temperatures (including exposure to sunshine through vehicle windows); air conditioning may be advisable.

Some suppliers expect mortalities during transport; however, there should be no deaths if animals are in good condition and appropriately packed and transported.

## Quarantine

Reports of outbreaks of severe disease (including that caused by the nematode *Pseudocapillarioides xenopodis*, see Parasites section) in animals maintained in laboratories for over a year without symptoms, indicate the need for extended quarantine periods. In practice, maintenance of *X. laevis* in separate tanks provides some restriction on spread of infection. Nevertheless, animals newly imported from the wild should be kept in separate accommodation (with separate nets, cleaning equipment etc) for at least several months.

## Welfare issues

### Health and disease

In response to unfavourable conditions or poor health, *X. laevis* may adopt a 'hunched' posture with fore- and hindlimbs held close to the body and the head depressed. Skin texture is an important indicator of well-being: it should have a glossy appearance and slippery feel (reflecting effective mucus production), but in ill-health may feel relatively rough and 'dry'. In healthy animals, the process of moulting involves separation of large sheets of outer keratinised skin which are typically pushed into the mouth with the forelimbs and eaten. When animals are unhealthy or stressed, the outer skin is shed into the water in small fragments. In chronic ill-health, there may be pinpoint haemorrhages visible on the white skin of the belly and legs.

The older literature provides detailed accounts of a range of pathological conditions affecting *Xenopus* including degenerative diseases, neoplasms and microbial infections (described from a medical perspective by Dr Edward Elkan and others). These conditions are rare and tend to illustrate three related principles (Tinsley 1995). First, *X. laevis* may carry a range of pathogens without the development of disease until there is a physiological check, caused by malnutrition, temperature change or other environmental stress; until this point, the condition may apparently be controlled and it becomes overtly pathogenic only following the additional precipitating factor. Second, once disease has become established, pathogenesis may develop to an extreme degree before *X. laevis* exhibits obvious ill-effects. Commonly, in tuberculosis of the lungs, liver or gut, a considerable part of the organ may become non-functional before illness and death occur. Reichenbach-Klinke and Elkan (1965) observed that such 'crippling injuries and disease would have killed warm-blooded animals at a much earlier stage'. Third, in the overcrowded conditions of laboratory maintenance, one animal may develop severe disease (tuberculosis, for instance) and die, whilst others in the same aquarium remain unaffected. These observations suggest that immune defences are normally highly effective in the control of microbial disease.

In contrast to these chronic conditions, a variety of microbial pathogens may cause acute disease leading rapidly to high mortality, including severe generalised sepsis attributable to haemolytic bacteria, particularly *Aeromonas hydrophila*. Little is known of the influence of these infections in wild *Xenopus* populations: virtually all experience derives from lethal outbreaks under the unnatural conditions of laboratory maintenance.

The concerns of export authorities about spread of disease, and of receiving laboratories about introduction of infections, now result in routine treatment for infection in wild-caught *X. laevis*. Whilst the principle is commendable, the effectiveness is currently uncertain. For parasitic worms, the optimum drugs and dosages are generally not known and imported *X. laevis* may still arrive at their destinations with parasitic infections. For bacterial infections, there is the major concern that uncontrolled antibiotic use may select for resistance leading to the export of pathogenic infections that cannot be controlled in the receiving laboratory. Personal experience of this includes a consignment of over 400 *X. laevis* from the Cape that showed symptoms on arrival in the UK of pathogenic *Aeromonas hydrophila* infection. The bacterial strain had resistance to some of the most important antibiotic groups – the beta lactams (penicillins), quinolones (oxolinic acid, ciprofloxacin and enrofloxacin), potentiated sulphonamides (co-trimoxazole) and the tetracyclines. Despite control and treatment efforts over a period of 6 months, all animals died or were culled. The unsuccessful control of this infection suggests that outbreaks of such severity are best managed by early culling, not least to prevent spread to established populations within laboratories. Many laboratories have experience of other devastating epidemics (including the skin nematode *Pseudocapillaroides xenopodis*), indicating the need for careful attention to the disease risks of laboratory maintenance of *Xenopus*. Wider implications include the potential for international spread of antibiotic resistant bacteria and establishment of exotic infections in waterways in distant countries.

For relatively minor skin infections and abrasions, the strong immune defences of *Xenopus* are often the best means of recovery. Affected animals should be transferred to clean water at frequent intervals (preferably daily), so that skin healing is not hampered by elevated ammonia or bacterial populations, and animals should be maintained in isolation, free of disturbance. Feeding may be minimal and should be restricted to food taken immediately by the animal, with uneaten food removed to prevent chemical and bacterial contamination of the water. In cases where this natural recovery is effective, the improvement is visible over a few days to 1 week, with progressive reduction in areas of damaged skin. If there is deterioration, antibiotic treatment may be required (under direction from a vet). If there is severe pathology and visible distress, recovery is often unlikely and euthanasia may be necessary to reduce suffering. Strict hygiene is essential to prevent pathogen spread to other groups of *Xenopus* (especially with nets, tanks and tank-cleaning materials): sterilisation of containers in bleach should be followed by repeated rinsing in clean water which is left to stand for at least 24 h.

*Xenopus laevis* is naturally infected by a chytrid fungus, *Batrachochytrium dendrobatidis*. Infection leads to epidermal

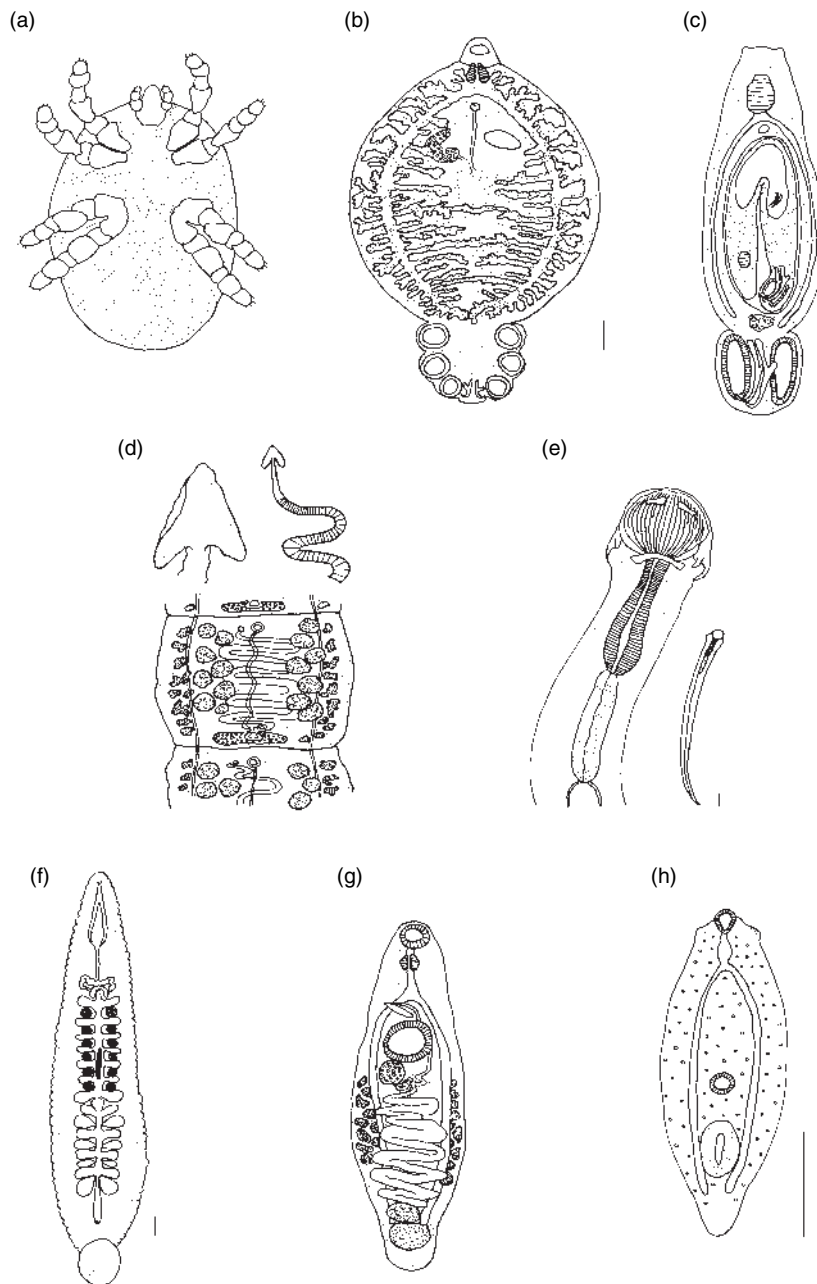

damage but in *X. laevis* this appears normally to be relatively minor. Current evidence is that, both in the wild and in laboratory populations, a few percent of *X. laevis* show detectable infection and this may be related to immune status (influenced by factors such as temperature and stress). Major concerns are not for the health of *X. laevis* but for the risk of spread to other susceptible amphibian species, including the possibility of environmental contamination via drainage water.

### Parasites

*Xenopus* species carry a richer assemblage of parasites than most other anurans – over 25 genera from seven invertebrate groups infecting almost every organ of the body. This spectrum appears to reflect a dual origin: some of the parasites are characteristic of those found in anurans, reflecting a common evolutionary origin, and some are related to those typical of fish, reflecting an ecological origin through shared diet, habitats etc. Almost all are strictly host-specific to *Xenopus* so they do not normally represent a hazard to other amphibians. References to studies on these parasites are listed in Tinsley (1995, 1996) (for earlier work) and Jackson & Tinsley (2001) (for later accounts) (Figure 48.4).

Workers in *Xenopus* laboratories may encounter worms passed into the water from recently imported wild-caught *X. laevis*, but their significance requires evaluation. For parasites with indirect life cycles that require specific intermediate hosts, there are generally no risks of transmission in the laboratory. These parasites, present at the time of capture, gradually decline and are not replaced. Thus, although potentially worrying to non-specialists, occasional expulsion of gut parasites, including tapeworms (*Cephalochlamys namaquensis*), nematodes (*Camallanus* and *Batrachocamallanus* species) and several species of digenean flukes, has little importance for health and welfare. Parasites with indirect life cycles employing *Xenopus* species as an intermediate host may occur in large numbers, including *Tylodelphylus xenopodis* in the pericardium and echinostome metacercariae in the eyelids. Pathological effects are rare (reviewed by Tinsley 1996). However, all these worms may represent a confounding factor if present in *Xenopus* used in controlled experiments (for instance, on growth rates or physiological characteristics).

Those parasites that have direct life cycles (with only a single host species in the life cycle) have the potential to increase in laboratory conditions and need precautions. One helminth parasite of *X. laevis*, the nematode *Pseudocapillaroides xenopodis*, is notorious for lethal pathogenic effects in laboratory populations. Affected animals develop roughened skin, become anorexic, emaciated and die. The worms burrow throughout the epidermis causing severe damage. Parasite reproduction involves deposition of embryonated eggs within the epidermal tunnels, so infective larvae hatch already in their final habitat leading to a progressive increase in worm burdens. Host-to-host transfer is assumed to occur by skin penetration, through existing abrasions or intact skin. However, the circumstances leading to epidemics in laboratory populations are not clear-cut. Reports in the literature describe outbreaks in *X. laevis* that had been imported from South Africa more than a year before the appearance

**Figure 48.4** Selected parasites of *Xenopus laevis*. (a) *Xenopacarus africanus* (acarine mite; nasal and eustachian passages). Reproduction occurs within the host and heavy infections may accumulate in laboratory *Xenopus* populations. Larval stages are white; digestion of host blood produces black pigmentation as the mites develop. (b) *Protopolystoma xenopodis* (monogenean platyhelminth; urinary bladder and kidneys): blood-feeding flukes with a direct life cycle; eggs are released with urine, a swimming larva hatches and invades the host via the cloaca. Infections can transmit in laboratory maintenance if sediment is allowed to accumulate in aquaria (see text). (c) *Gyrdicotylus gallieni* (monogenean platyhelminth; membranes of the oral cavity). An offspring develops to maturity within the uterus of the parent worm and may, in turn, contain a further developing embryo *in utero* before its birth. This method of reproduction, with progeny emerging directly at the site of infection, produces rapid increase in parasite numbers; host-to-host transfer of worms occurs by contact. (d) *Cephalochlamys namaquensis* (tapeworm, intestine): infections can be detected when mature segments are passed in the water; arrowhead-shaped scolices may also be expelled as a result of host stress or hormone treatment. Worms present in wild-caught *Xenopus* are gradually lost in laboratory maintenance and are not replaced. (e) Several species of camallanid nematodes attach by a chitinized buccal capsule to the wall of the oesophagus, stomach and intestine. As in the tapeworm (d), the life cycle requires a copepod intermediate host and transmission does not normally occur in laboratory maintenance. (f) *Marsupiobdella africana* (leech; external skin): this species is unique amongst leeches in brooding up to 50 offspring in a ventral pouch; when developed, the young emerge through a mid-ventral pore and attach to *Xenopus*, feeding on blood from epidermal capillaries. (g) *Oligolecithus elianae* (digenean platyhelminth; intestine). This and three other species of digeneans occurring in the gut (stomach, intestine, gall bladder and rectum respectively) all have complex life cycles with a snail intermediate host; they do not transmit in laboratory populations of *Xenopus*. (h) *Tylodelphylus xenopodis* (digenean platyhelminth; pericardial cavity): larvae may be detected only at host dissection; worms released from the pericardial membranes sometimes occur on the surface of the ovaries. Infections result from skin penetration by larvae from snail intermediate hosts in natural habitats, so there is no laboratory transmission. Related trematodes, all requiring transfer to a predator of *Xenopus* to complete their life cycles, occur in the body cavity, lateral line system and eyelids. The pathogenic nematode, *Pseudocapillaroides xenopodis*, is not shown. Fine thread-like worms may be found in teased fragments of skin examined as fresh, wet preparations under the microscope. Eggs hatch within epidermal tunnels created by adult worms; parasite burdens accumulate within individual hosts and transmit by contamination. Anthelmintic treatment and strict hygiene are necessary for control (see text). For references to parasite infections, see text. All scale bars = 250  $\mu\text{m}$ .

of symptoms. So, wild-caught laboratory populations may harbour individuals carrying pre-existing low-level, asymptomatic infection. There is evidence for the role of a thymus-dependent immune response in protecting against development of disease; overt symptoms may follow factors that cause immunosuppression, such as reduction in water temperature (Tinsley 1995). Once infection becomes apparent, no spontaneous cures occur. However, the infection can be treated with anthelmintic drugs, including thiabendazole and ivermectins (either by injection or addition to aquarium water). The infective eggs are highly resistant and can be transferred between aquaria on nets and, possibly, the hands of laboratory workers. In parallel with control of infection in the host, it is essential to eliminate all potential sources of re-infection by disinfection of equipment, aquaria and associated surfaces with bleach (followed by thorough rinsing to eliminate traces of chemicals).

Occasionally, *X. laevis* are imported with infections of the leech, *Marsupiobdella africana*. Wounds produced by blood-feeding may become a site for bacterial infection, but the leeches are easily removed with a dilute salt bath. There are also two monogeneans (*Protopolystoma xenopodis* and *Gyrdicotylus gallieni*) and an acarine mite (*Xenopacarus africanus*) that have direct life cycles with the potential for multiplication during laboratory maintenance. However, for all three there is direct or indirect evidence that primary infection leads to an immune response that eliminates the parasites (Tinsley 1996). In laboratory colonies where different populations of *X. laevis* are maintained separately from one another, infection would eventually die out after a period reflecting the lifespan of the original infection: around 4 months for *G. gallieni* but over 2 years for *P. xenopodis*. However, if new imports of *X. laevis* or successive generations of laboratory-produced animals are mixed with previously established populations in the laboratory, the naïve individuals will provide susceptible reservoirs for infection that could persist for long periods.

Transmission by *G. gallieni* and *X. africanus* involves transfer of established parasites from host to host – by reattachment of parasites dislodged into the water or by direct contact between hosts. However, *Protopolystoma xenopodis*, in the urinary bladder, produces eggs that pass out with the urine, develop for about 3 weeks in the sediment, and hatch to release a swimming ciliated larva that invades the next host via the cloaca. Juvenile worms develop in the kidneys for 2–3 months before migrating to the bladder, maturing, and beginning egg production. This life cycle is easily controlled in the laboratory when parasite eggs are removed during routine water changes or by continuous inflow/outflow of water. Detailed studies on *P. xenopodis* show that burdens in the urinary bladder and kidneys are very strictly regulated (reviewed by Tinsley 2005). Despite continuous transmission in the wild, the numbers of worms present at sexual maturity is low (mean <2 adult parasites per host). So, although these parasites feed on blood, there is strict limitation on the extent of blood loss. However, juvenile infections in the host kidneys are potentially more serious. A major part of the host response occurs in the kidneys (a highly immunogenic site in amphibians), but repeated invasion by infective stages may produce a continuous ‘rolling’ population of parasites. Even though these may be killed within about 1 month post-infection, they are nevertheless

responsible for continual low-level pathology including disruption of kidney tissue, blood-feeding and stimulation of inflammatory and other anti-parasitic responses. As with the other parasites, the presence of *P. xenopodis* could represent a confounding factor in controlled experiments.

The risk of pathogenic disease is increased by the husbandry procedure of partial water changes. Where routine maintenance involves removal of half or even three quarters of the old water in an aquarium tank and replacement with clean water, the layer of sediment may allow parasite eggs to complete development, hatch and reinfect the occupants of the tank. It is essential, with ‘fill and dump’ maintenance, that the aquarium tanks are emptied, rinsed and refilled with a complete change of clean water. At around 20°C, weekly water changes prevent transmission of *Protopolystoma xenopodis* but infrequent water changes risk auto-infection. Therefore, wild-caught *X. laevis* potentially still carrying their natural parasite infection, should not be maintained in tanks with a gravel or sand substrate where parasite eggs may accumulate.

Thus, there is direct and indirect evidence for low-level infections of all the important pathogens of *X. laevis*, including *Aeromonas* and other bacterial infections, chytrid fungus, the skin-infecting nematode and the monogeneans, in most groups of wild-caught imported animals but that infections are kept in check by highly effective immune responses. The potential exists for severe disease but only when immunity is compromised by stress and other factors. Overt pathology is rare but sporadic infections may be important in laboratory research as a confounding factor in controlled experiments. This highlights two general principles: first, the importance of ensuring optimum conditions that eliminate stress; and second, the desirability of employing purpose-bred, laboratory-reared animals for most research use, rather than *Xenopus* caught in the wild.

### Behavioural considerations

Semi-natural conditions are recommended for small-scale maintenance of *Xenopus* species caught in the wild and required for breeding, especially rare species. However, this approach is impractical for large-scale laboratory maintenance of *Xenopus*. Semi-natural conditions require careful management (to regulate food input, monitor water quality etc). They are also less suitable for achieving fast growth rates by juveniles for which it is better to provide an excess of food with more frequent feeding and, hence, water changes.

There have been many attempts to produce a ‘compromise’ between simulation of natural habitat conditions and sterile ‘battery farm’ systems. In general, these have been guided by a commonsense, intuitive approach that recognises the need for adequate space, water depth, refuges etc for reduction in stress, whilst achieving ease of feeding and water changes together with reduction in labour (time and cost). The literature includes a range of experimental approaches that attempt to quantify the benefits of specific maintenance regimens assessed by growth rates, ovary condition, etc. However, it is still difficult to find a consensus supported by experimental data. Frustratingly, attempts to compare different environmental parameters have often not found significant differences in the animals. Three aspects

may be important. First, there is typically very marked variation in growth and condition of animals in experimental trials (eg, Hilken *et al.* 1995). Recent studies (Tinsley in prep) have shown large differences in growth rates, maturation time, etc between different sibships of *X. laevis* maintained under the same conditions. So, it is possible that genetic effects may have confounded some published trials. Second, *X. laevis* is highly adaptable, even to regimens that are apparently inferior. In these situations, general health (including growth rate) may be indistinguishable from that of animals in more favourable conditions but ill-effects may be subtle, perhaps affecting the quality of oocytes. Third, animals provided with conditions that exclude all (or almost all) stressors may suffer extreme stress when they are disturbed for routine maintenance. As a result, these animals may show suboptimal attributes determined by brief but significant stress even though the investigator designed their maintenance to be 'optimal'.

As an illustration of potential confounding effects of husbandry, *X. laevis* in open tanks seem not to adapt to overhead movements (including shadows). This response corresponds with the direction of major risk in the wild from aerial predators. Indeed, when housed in tanks with lids the animals typically show great alarm when a tank lid is lifted for visual inspection and this is made worse if there are vibrations when the lid is lowered. The stress created by periodic overhead disturbance may outweigh the benefits of intended 'optimum' conditions operating for the majority of each day.

Hence efforts to provide conditions intended to reduce stress by simulating natural conditions may actually result in greater overall effects of stress. This dilemma is illustrated when we consider the alternative sources of laboratory populations of *Xenopus*. In the case of wild-caught adults, attempts to provide aquarium conditions resembling those in natural habitats reflect a recognition that these animals will have spent at least 3 years 'in nature' with behavioural patterns adapted to stresses including predator avoidance. Features such as refuges may inhibit adaptation to laboratory conditions. Where laboratory-maintained *X. laevis* have been raised in captivity throughout life, their experience relates to these artificial conditions. For these animals, refuges that increase sensitivity to periodic disturbance may be unnecessary as long as other aspects of aquarium design (for instance, freedom from overhead movements) remove overall stress.

This discussion points to the conclusion that, for the most demanding research needs, especially in molecular, cell and developmental biology, the use of wild-caught animals generates behavioural and welfare problems for laboratory maintenance that are best avoided by the use of purpose-bred populations.

### Concluding remarks

The use of amphibians as a major 'laboratory animal', in research and teaching, was formerly motivated by the belief that amphibians (especially frog populations) are an abundant, easily caught, relatively inexpensive source of live vertebrate material for practical exercises. However, in most cases now, large-scale capture of frogs is not sustainable

(especially where populations are threatened by human activities), physiological condition is often poor (especially because of inappropriate maintenance or holding facilities) and large-scale use can no longer be justified. This conclusion is inescapable on the grounds of conservation, ethics, welfare and cost, but use of amphibians may be additionally unjustified on scientific grounds where the reliability of results may be compromised by poor condition or stamina.

However, laboratory use of *Xenopus laevis* differs in important respects. Populations in the areas of supply are abundant; animals occur in huge numbers in man-made habitats. There are no major conservation concerns. It is ironic that this species which is exploited for scientific needs is, at the same time, favoured by human activities especially the creation of water supplies for agricultural and domestic use. The export of *X. laevis* from South Africa, principally the Cape, has been very successful in meeting a major research need. Research based on the *Xenopus* species continues to contribute to major advances in biomedical and fundamental science.

However, there are growing concerns about wider aspects of laboratory use based on wild-caught animals. In the case of *X. laevis*, it is anomalous that very demanding research should be based on animals that have spent their lives in the natural environment, prior to being caught and transported to the artificial conditions of a laboratory. These animals exhibit unavoidable variation reflecting their experience of seasonal changes in environmental conditions, food supply and stress over several years. They will have been exposed to natural parasite and microbial infections and, despite attempted treatment, often reach laboratories still carrying transmissible infections. There is now a greater concern that *X. laevis* established in introduced populations outside Africa are becoming part of the international trade. Currently, this is the case for populations that were introduced in Chile in the 1970s and are now exported to laboratories elsewhere in the world. Transport of these creates a risk of worldwide transfer of additional pathogenic infection from a continent where *X. laevis* is not native. All these considerations suggest that it is an anachronism that wild-caught animals should be employed in modern laboratory research.

It is likely that a series of separate pressures – relating to cost, welfare, legal regulations and disease risks – will combine to replace wild-caught *Xenopus* species. However, *Xenopus* will continue to be a very important model system for advancing understanding in molecular, cell and developmental biology and use is almost certain to expand in the future. It is appropriate that this should increasingly be based on laboratory-raised animals. This shift in practice will also reduce concerns about stress, especially the inevitable problems associated with transfer of animals adapted to natural conditions to the artificial restrictions of laboratory maintenance.

### Acknowledgements

Research on *Xenopus* has been supported by grants from the Natural Environment Research Council and the Biotechnology and Biological Sciences Research Council, most recently BB/C506272/1 and BB/D523051/1 from BBSRC, which I gratefully acknowledge.

# Fish

# 49 Fish

James F. Turnbull and Iain Berrill

## Introduction

The central theme of this chapter is the diversity of fish. An understanding of the nature of this diversity, and its implications for the needs of different species in captivity, will help care staff and researchers to be better equipped to care for and conduct experiments with fish. In a single chapter it is not possible to provide detailed advice on the husbandry of all species that might be used in research. Instead, we will provide detailed information for some of the more common species including, rainbow trout (*Oncorhynchus mykiss*), Atlantic salmon (*Salmo salar*) and zebrafish (*Danio rerio*). Other examples will be used, including Atlantic cod (*Gadus morhua*) and the guppy (*Poecilia reticulata*) where these species illustrate diversity.

## What is a fish?

Fish inhabit a vast range of habitats and ecological niches. From the smallest vertebrate *Paedocypris progenetica* which matures at less than 8 mm (Kottelat *et al.* 2006) to one of the largest, the whale shark (*Rhincodon typus*), reaching lengths of over 12 m (Colman 1997). It has been estimated that almost half of all known vertebrates are fish. There are around 28 000 extant species of fish; the majority (>96%) are the bony fishes (Osteichthyes), with the cartilaginous sharks and rays (Chondrichthyes) representing less than 4% and the jawless lampreys and hagfish (Agnatha) less than 1% (Potts 1999a; Nelson 2006). The term teleost is frequently used when referring to bony fish, this is a common form of the infraclass Teleostei within the class Actinopterygii (ray finned fishes) subclass Neopterygii. Cyclostome is another term used, which, although not a formal classification, is commonly used to refer to the lampreys and hagfish. The class Pisces is no longer used since any clade containing fish also contains tetrapods. A reasonable definition of fish would be aquatic vertebrates that rely, at least in part, on gills for respiration in the adult form.

In addition to species diversity fish can also be highly adaptable, even within sibling groups. They have the capacity to exhibit various behavioural, anatomical and physiological adaptations to environmental cues. Many of the fixed characteristics of mammals and birds are more flexible in fish; not even gender is genetically determined in some species of fish, with individuals changing from functional

males to females sequentially or in response to their social or physical environment.

## Fish welfare

The study of fish welfare is still in its infancy. Experiments that have allowed us to understand the basic coping mechanisms or explore preferences in terrestrial animals have not yet been replicated in fish. This would seem to pose an insurmountable challenge when attempting to provide guidance on the care and welfare of fish. However, the thriving aquaculture industry, which relies on healthy and productive fish and the wealth of high-quality science conducted using live fish, testifies to the ability of fish keepers to take care of fish despite this lack of scientific information. This chapter will attempt to provide a basic understanding of the care of fish kept for experimental purposes but can in no way replace familiarity with the fish under your care. Provision of training for personnel taking care of fish is essential as are appropriate resources, health and contingency plans. More detailed descriptions can be found in other texts such as the previous edition of this handbook (Potts *et al.* 1999).

Although there is an ongoing scientific debate regarding the ability of fish to suffer pain (eg, Rose 2002, 2007; Sneddon *et al.* 2003; Chandroo *et al.* 2004a, 2004b; Braithwaite & Boulcott 2007), various national legislation, regulation and guidelines (Canadian Council on Animal Care 2005; Home Office 2006; Council of Europe 2006) provide protection for fish used for experimental or other scientific purposes. In Europe, for example, fish are protected from the time that they are capable of independent feeding on the assumption that they are capable of experiencing pain, suffering and distress (European Directive 86/609 implemented within the UK by The Animals (Scientific Procedures) Act 1986). Therefore the capacity of fish to suffer will not be discussed further here.

The subject of fish welfare is discussed by Huntingford *et al.* (2006), in a book on the subject edited by the late Edward Branson (2008) and in a dedicated special edition of Diseases of Aquatic Organisms which is open access<sup>1</sup>.

## Biological overview

### General biology

The ecological niches occupied by fish include most of the water on the planet from small freshwater puddles or pools to oceans, from the sea bed (benthic) to open waters (pelagic). The fish occupying these niches range from those with limited capacity to adapt to those that are highly adaptable. Some (eg, Atlantic cod) have limited capacity to adapt to changing salinity (stenohaline) whereas others, eg, Asian sea bass (*Lates calcarifer*), are highly adaptable (euryhaline).

Fish can be predatory carnivores, omnivorous or herbivorous. The vast majority of fish are ectothermic with their internal temperature close to that of the surrounding environment. Consequently, all biological processes are temperature dependent. This means that growth, inflammation, healing, reproduction, metabolism, excretion of chemicals and many other physiological processes are not just a function of time but a function of time and temperature. Ectothermy requires much less energy than homeothermy for an equivalent sized animal. Unlike birds and mammals, ectotherms do not have to constantly feed a demanding metabolism and can survive on relatively little feed and use available feed to grow very efficiently. Many salmonids in commercial culture facilities will achieve a food conversion ratio (weight of feed consumed to wet weight of fish produced) of less than one. Fish can also be naturally anorexic for periods of time.

Many fish demonstrate plasticity where a single group of siblings will adopt a variety of behavioural and physiological strategies. For example, young freshwater Atlantic salmon may undergo smoltification (pre-adaptation to the marine environment) in the first year of life or only after 2 or more years, dependent on available food resources.

### Life cycles and reproduction

There is considerable diversity in the life history strategies of different species. However, it is possible to simplify most life history strategies as follows. After external fertilisation, embryos develop within the egg. They hatch and rely on the yolk sac until they are able to ingest and digest external sources of food. The exception may be some of the live-bearing species, where nutrients are passed between the mother and embryo. Following first feeding, fish develop into juveniles, in some species, such as flatfish, undergoing dramatic metamorphosis; and then become reproductively mature adults. Some species may include a habitat switch during their life, often as part of their reproductive cycle. For example adult eels (*Anguilla anguilla*) reside in fresh water, but migrate to the sea to reproduce (catadromous) whereas Atlantic salmon mostly grow in the sea but reproduce in fresh water (anadromous). As with so many aspects of their biology, there is considerable species diversity in fish reproduction.

One method of categorising reproduction is through the level of protection provided by adults for their embryos before and after fertilisation (eg, Balon 1990). Reproductive styles range from fish that are non-guarding pelagic spawn-

ers, producing a large number of small ova requiring a long larval period (eg, Atlantic cod), through to live-bearing fish, in which a relatively small number of eggs are fertilised and develop within the female and are released as fry capable of independent feeding (eg, guppies).

Reproduction in fish might occur during specific spawning seasons (eg, rainbow trout), or throughout the year (eg, captive-reared zebrafish). Environmental signals play an important role in cueing both the seasonal and daily timing of reproduction. Photoperiod is one of the most important environmental signals influencing reproduction (Bromage *et al.* 1991) but other variables may also be of importance, eg, temperature (Gillet & Dubois 2007).

Under some culture conditions, maturation and reproduction may be considered beneficial, for example to maintain a specific strain of fish. However, maturation can lead to traits that may be considered undesirable in laboratory systems. In many species, maturation leads to changes in behaviour and, most notably, increased aggression. Male Siamese fighting fish (*Betta splendens*) will fight to the death when reproductively mature, and so should be housed singly. Maturation may also be considered detrimental as it may be linked to a decrease in immunocompetence and an increase in susceptibility to pathogens (Suzuki *et al.* 1997; Skarstein *et al.* 2001). Maturation often also results in a reduction in growth as energy is diverted into gonadal development (eg, Lester *et al.* 2004).

Where maturation is detrimental it may be appropriate to use sterile fish. The production of triploid fish, which have three sets of chromosomes instead of two, is one of the most practical ways of producing sterile fish (reviewed by Piferrer *et al.* 2009). Triploids are typically produced using a thermal, pressure or chemical shock applied to embryos during a specific stage in early development. While the use of sterile triploid fish might protect against the negative effects of sexual reproduction, there is currently a lack of information regarding the physiology of triploids. Therefore, it may not always be appropriate to extrapolate from results obtained with triploids to diploid populations.

To illustrate the diversity, we now describe the fish life history strategies of four species reared in captivity. Of these, three lay eggs: a tropical freshwater species (ie, zebrafish), a temperate freshwater species (ie, rainbow trout) and a temperate marine species (ie, Atlantic cod); the fourth is a tropical fresh- to brackish water live bearer (ie, the guppy).

#### Zebrafish (*Danio rerio*)

The zebrafish is one of the most widely used models of vertebrate development (Spence *et al.* 2008) and it is commonly used in genetic and toxicological studies (Home Office 2006). It is a small, omnivorous cyprinid (rarely exceeding 40mm in length). In the wild, it inhabits slow-moving water bodies in the south-eastern Himalayan region. Breeding in captivity can occur all year round, although in the wild it is more seasonal, possibly linked to changes in food availability (Spence *et al.* 2006). Zebrafish mature at between 3 and 4 months of age and they are then able to reproduce every 2–3 days. They produce between 100 and 200 relatively large eggs (0.7 mm diameter), which are

fertilised externally and afforded no further parental care. Indeed, in captivity, zebrafish can be voracious predators of their own eggs (Andrews 2000). Following fertilisation, development is rapid and at a standard rearing temperature of 28.5°C embryos hatch after 48–72 h. Three to four days later the embryos inflate their swim bladder and begin feeding on fine particulate food. Gonads initially develop as ovaries, with testes differentiating after 5–7 weeks. Zebrafish live for 3.5 years on average, with the oldest individuals reaching 5.5 years (Gerhard *et al.* 2002).

For more detailed descriptions of zebrafish development, ecology and culture see Kimmel *et al.* (1995), Westerfield (2000), Lawrence (2007) and Spence *et al.* (2008).

#### Rainbow trout (*Oncorhynchus mykiss*)

The rainbow trout is a carnivorous salmonid, which inhabits oxygen-rich waters. Its native distribution covers the Pacific coast of North America, but humans have distributed it widely and it is now farmed throughout the world (Hershberger 1992). They are also used in experimental and toxicological studies (Home Office 2006). Previously it was commonly classified as *Salmo gairdneri* but has been confirmed as *Oncorhynchus mykiss*.

In the wild, maturation in rainbow trout (like all salmonids) is stimulated by a decreasing photoperiod, but spawning times can vary greatly between strains (Bromage & Cumaranatunga 1988). Under natural photoperiod in temperate regions, hatchery strains spawn in late autumn and winter, with a broodstock population producing eggs over a 6–8-week period (Bromage *et al.* 1992); individual salmonids produce a single batch of eggs in a season. However, eggs and milt are available throughout the year due to the use of photoperiod manipulation. When spawning occurs in the wild, eggs (3–6 mm diameter) are deposited and fertilised in gravel nests called redds, covered with gravel and left to incubate. Outside their native range they do not normally spawn naturally. For example in the UK there are only one or two naturally spawning populations, despite the wide distribution of potentially fertile rainbow trout throughout the country. In captivity, eggs and milt are manually stripped from the adults, and artificially fertilised.

Following fertilisation embryos take approximately 300 degree days (ie, the average daily temperature in degrees Celsius multiplied by time in days) to hatch and a further 200 degree days to reach first feeding (Bromage 1995). After hatching, growth can be rapid, depending on the temperature, with males typically maturing in their 2nd year and females in their 3rd year. Rainbow trout live for between 5 and 6 years and can reach weights of over 10 kg.

#### Atlantic cod (*Gadus morhua*)

The Atlantic cod is an omnivorous, demersal (living on or near the sea bed) soft-finned fish belonging to the family Gadidae, that is found throughout the North Atlantic Ocean and the European coast, through to the Barents sea (Cohen *et al.* 1990). The commercial culture of this species is still in a relatively early stage of development and predominantly occurs in Norway.

The Atlantic cod is a batch spawner with each female producing several batches of eggs within the spawning season, which occurs between November and September, varying between sub-populations and location (Cohen *et al.* 1990). In captivity, photoperiod manipulation allows fish to be spawned throughout the year (Norberg *et al.* 2004). In the wild, Atlantic cod spawn pelagically and in captivity they spawn and fertilise their eggs naturally. Atlantic cod are highly fecund, producing many small eggs (1.0–1.5 mm), up to  $4.30 \times 10^5$  eggs/kg of fish (Hansen *et al.* 2001). Following fertilisation, hatching takes approximately 250 h, after which first feeding takes a further 3 days at 7°C (Hall *et al.* 2004), although these times vary depending on strain and temperature. At hatch, the embryos are poorly developed, requiring a 2.5 month pelagic larval period (Cohen *et al.* 1990) after which they become demersal. Cod then grow and reach sexual maturity after 2 years at the earliest (Karlsen *et al.* 1995; Olsen *et al.* 2004). Atlantic cod can live for 20 years and reach lengths of up to 2 m (Cohen *et al.* 1990).

#### Guppy (*Poecilia reticulata*)

The guppy is an omnivorous fish belonging to the viviparous family Poeciliidae. It is a popular aquarium fish but it is also used in a range of scientific studies (Home Office 2006). In the wild guppies are found in a range of brackish and freshwater habitats in South America (notably Trinidad, Venezuela and Barbados). It is a live-bearing fish, with internal fertilisation and development of embryos. Males have a modified anal fin, the 'gonopodium', which transfers sperm into the female. Females are able to store sperm and use it to fertilise several batches of eggs. Once fertilised embryos take 3–5 weeks to develop before being released by the female. In that time they will rely solely on yolk as a nutrient source: they do not receive any additional nutrients from their mother. Females are able to produce batches of juveniles at approximately 4 week intervals throughout the year with no specific spawning season. In captivity 20–200 juveniles are produced in each batch, although in the wild this number is lower. Following release by the female, juveniles are capable of independent feeding and are afforded no further parental care. Cannibalism by parents is common. Males reach sexual maturity after 2 months, at approximately 19 mm, and females after 3 months, at approximately 25 mm. Adult male guppies reach a maximum size of 35 mm and females 60 mm.

Detailed information on the biology, ecology and culture of guppies can be found in Axelrod and Schultz (1990), Magurran *et al.* (1995) and Andrews (2000).

#### Biological data

To monitor a culture system, feeding, behaviour, water quality and health should all be recorded. Fortunately only a relatively small number of species are kept in the laboratory (see Ostrand 2000), however, even these species exemplify the complexity and plasticity of fish. Inter-individual variability in fish is generally greater than in terrestrial animals and the inherent plasticity of fish is demonstrated by the variability of normal values for the majority

of haematological parameters (see Wedemeyer 1996). For this reason haematology and clinical biochemistry is much less useful in fish.

Growth rates are determined not only by rate of feeding, but also by social cues, environmental conditions, genetic factors and physiological states such as reproductive condition. Growth charts are available for commercial production, mostly supplied by feed companies and combined with suggested feeding rates. In some cases these are more complex than simple tables and may be based on multiple regression models. The determinants of fish growth can be complex. In Atlantic salmon, growth in the sea is determined by the size of the fish (bigger fish have higher daily weight gain) but also by daylight, with temperature having a relatively minor role. Salmon grow faster during periods of decreasing day length and during longer days, therefore the period of most rapid growth is usually June to September in the northern hemisphere (Metcalf 1994).

Since most growth and feeding charts are developed for commercial systems they can be used as a starting point but must be adapted for use in experimental systems, since the aim in most cases is not necessarily to achieve rapid cost-effective growth. Accurate and accessible records are necessary to ensure you can develop a prediction of normal growth and feeding in your systems. This can be developed into predictive models to allow early detection of deviations from expected performance.

## Normal behaviour

Fish are capable of creating complex social and internal environmental models (reviewed in Braithwaite 2006). Male Siamese fighting fish are able to judge the performance of other fish from observing fights. This is not simply recognition of the winner and loser but a true evaluation of the relative fighting abilities. In some cases the observer will act aggressively to both winner and loser, in others respond aggressively to only the loser or respond submissively to both (Oliveira *et al.* 1998). This is thought to represent a process of comparing his own abilities with those of the observed combatants. Some fish are also able to develop complex spatial maps, a goby (*Bathygobius soporator*) can create a model of the topography of the shore line at high tide which allows it to escape from a rock pool to other pools and eventually back to the sea at low tide, when it is impossible for it to see its destination (Aronson 1971).

Commonly observed behaviours in captivity include feeding, predator avoidance, exploration, social interactions and reproduction. In experimental systems it is preferable to avoid any form of behaviour that can be damaging to the fish. For example, reproduction and territoriality, which are often associated with increased aggression.

Many species of fish, such as salmonids and tilapia, establish territories if provided with the opportunity. However, such behaviour can result in unequal access to food and injury through fighting. Potentially territorial species can often be encouraged to adopt a less damaging shoaling strategy through manipulation of the water flow and number of individuals in the tanks (Christiansen *et al.* 1992). Since aggression is often a feature of competition for resources,

avoiding defensible food resources and visual cues, which identify territories, can also reduce aggression. This may result in a conflict of priorities when attempting to provide environmental enrichment. Aggression can also be influenced by the size distribution in the tank. This is not simply a matter of maintaining uniform size, since the presence of larger obviously dominant individuals can suppress overall aggression (Adams *et al.* 2000). There is also evidence in salmonids that the removal of dominant individuals from small populations can result in increased levels of aggression (Adams *et al.* 1998).

Predator avoidance is most obviously seen in tanks of salmonids with bright overhead light and no access to cover. In these conditions, fish will crowd together swimming rapidly from group to group or crowd into any shade. Such behaviour may be indicative of poor welfare, however this area requires further study.

In experimental or commercial facilities, the behaviours that will be observed are dependent on the nature of the tank or husbandry unit, the number and density of fish and the clarity of the water. Frequently, observation is limited to the times when the tank lid is lifted to feed the fish or clean the tank. The behaviour of fish at this time can in no way be considered to be resting or normal behaviour. They may either show an escape response or rise to the surface in anticipation of feeding, depending on the nature of the disturbance and their previous experience. Although over time there may be a reduced response to disturbance we do not fully understand the consequence of such adaptation. The degree of habituation to any form of human interference is species dependent. Sea bass (*Dicentrarchus labrax*), if frequently disturbed, may become very difficult to stress since they appear to interpret any form of human presence as a prelude to feeding (M. Pavlidis, personal communication). Under commercial conditions underwater video equipment is used to monitor fish behaviour, especially in large production units, allowing observation of their undisturbed behaviour.

Often the best conditions for observing fish are not the most suitable for the fish under observation. Clear water in glass tanks can be stressful for some species, particularly those more suited to living in dimly lit or turbid water.

## Sources, supply and conservation status

Many of the commonly used laboratory species are available from captive-bred stocks. However, some species, particularly marine fish, must be collected from the wild. The capture of wild fish for experimental purposes is covered in the previous edition of this handbook (Andrews 1999; Potts 1999b). For ethical reasons, no fish that is collected using unsustainable methods or from endangered species or populations should be used in experiments, except where those experiments are directly related to their conservation. At the time of writing only 86 out of the 5000 species of animals protected against over-exploitation through international trade by CITES were fish. Protected species include the whale shark and the common or European eel (*Anguilla anguilla*). None of the protected species are commonly used for experimental purposes.

The sources and previous history of the fish are extremely important for experimental populations. Uncontrolled genetic variability can lead to unacceptable levels of error. However, the plasticity of many fish species means that even in relatively genetically homogeneous populations there is considerable variability. This is compounded by the influence of previous experience. For example, a study examined two populations of rainbow trout selected for either a low level of cortisol response (proactive and socially dominant) or a high cortisol response to a standardised confinement stressor. When they were deprived of food during a long transportation the fish switched roles, the low responders becoming subordinate (Ruiz-Gomez *et al.* 2008). Other work has shown that other relatively small changes in the early rearing environment can result in substantial difference in the behaviour of fish in later life (Braithwaite & Salvanes 2005). Therefore, it is important that wherever possible fish with known genetic make-up and rearing history should be used. In many cases this is most easily achieved by breeding on site. Where this is not possible unknown variability in the population should be controlled for in experimental designs.

Individual fish, in common with many animals, demonstrate an inherent tendency to be proactive or reactive. Even in well studied species, separating individuals into these two categories is still problematic and it is generally only possible to identify those individuals exhibiting extremes of pro- or reactive nature. Recent work has demonstrated that the causes or effects of these strategies influence all processes down to the level of gene transcriptions (MacKenzie *et al.* 2009). Assuming that individuals from a genetically homogeneous population of fish with similar previous experience are uniform in their responses may lead to increased error and significant effects being masked.

There are clonal lines of fish available and these provide potential experimental populations with no genetic variability, eg, tilapia (Sarder *et al.* 1999).

## Transportation

Any procedure that involves handling or disturbance of fish should usually be preceded by a period of starvation. This period is necessary for several reasons. Immediately following feeding, fish have an increased oxygen demand associated with digestion; this specific oxygen demand necessitates increased oxygen supply. Similarly, the excretion of ammonia via the gills increases after feeding and by using a period of starvation the level of ammonia excreted into the relatively small volume of transport water can be reduced. In addition, if the digestive tract is empty there is less chance the fish will regurgitate or defecate in the water. The length of time that they should be starved is dependent on the digestive transit time, which in turn is related to body size and the temperature. Generally small fish, <400 g, would be starved for 24h and larger fish for 48h.

Wherever possible, fish should be transported in water even for very short period of time (<1 minute). Many commercial farms now use fish pumps rather than nets to move fish. During transportation, oxygen levels must be maintained and stocking densities kept to a level that will avoid

excess deterioration of the water quality over the duration of the transport. Typical densities used for commercial transportation of trout range from 40–150 kg/m<sup>3</sup> (unpublished data). Commercial fish transporters recommend that the fish should not be disturbed during transportation unless absolutely necessary. Therefore, there should be a remote method of monitoring dissolved oxygen, and water should not be exchanged during transportation under normal circumstances.

On a small scale, fish can be transported in sealed plastic bags. Usually two bags, one within the other, would be used to reduce the risk of breaking, especially with fish with spiny fin rays such as tilapia or many species of catfish. The inner bag should be one third filled with water from the tank the fish are kept in (provided that is of high quality) and the remainder of the bag filled with oxygen. The neck of the bag can be twisted and bent over before being tied with cable ties or castration rings (Figure 49.1). If small fish are being transported the corners of the bag may be tied off to provide a rounded rather than pointed corner to avoid fish becoming trapped and suffering from hypoxia.

During any transportation, temperature fluctuations should be kept to a minimum. In order to maintain steady temperature, bags may be packed in polystyrene boxes (Figure 49.2) and should not be transported during periods of high temperatures. For larger groups of fish, transportation tanks are used which have an opening in the top and a drain for releasing fish and water at the bottom, and are usually insulated.

On arrival at the destination the fish should be acclimatised to the new environment. Acclimatisation is not only for temperature but also water quality including pH. Even adaptable species have a limited capacity to adapt rapidly and therefore every effort should be made to ensure that the transportation water conditions are similar to the receiving conditions. In some cases this may require the originating water to be adjusted slowly over a period of several days to reduce any rapid changes following transportation, for example pH or salinity. Under normal circumstances the bags should be floated on the new water until temperature has equilibrated (30–60 minutes). Either during this time or

**Figure 49.1** Elastic castration rings and applicator, an easy way of sealing fish transport bags.

**Figure 49.2** Fish transportation bags about to be sealed in a polystyrene box.

subsequently some of the recipient water should be mixed with that in the bag to avoid any rapid changes in water chemistry. Acclimatising fish on arrival is always a compromise. Fish should not be confined in the bag for longer than necessary and if they have already had a long transportation it may be necessary to aerate the bag during the acclimatisation period. In some circumstances if the water quality has deteriorated to a dangerous level, as may happen if some fish have died during transportation, then the need for acclimatisation may be secondary to the urgent need for clean water. Under such circumstances the surviving fish should be separated from the dead fish and placed in clean water of similar temperature as soon as possible.

Fish should be closely monitored after transportation for signs of ill-health or damage since moving fish can result in disruption of the social structure and result in social stress, aggression and damage (Adams *et al.* 1998).

The International Air Transport Association's Live Animals Regulations (LAR) Manual 2008/2009, contains details of transporting fish and is available from the IATA website<sup>2</sup>.

## Use in research

Estimates of the number of fish used for research worldwide are difficult to obtain. However, in Europe in 2005, 12.1 million animals were used for research, of which 15% were cold-blooded animals, including fish (European Commission 2007). Taking the UK as a specific example, in 2008, the last year for which statistics are available, 0.605 million live fish were used for scientific procedures. This equated to 17% of all the animals used for experiments in the UK and an 85% increase from the previous year, continuing an increasing trend since 2001 (Home Office 2009). Previous statistics from the UK (Home Office 2006) suggest that more than 13 different species of fish were used for research, safety and efficacy testing in 2005.

The need to provide protection for all animals, including fish, used in scientific experiments has led to the develop-

ment of guidelines on appropriate rearing conditions and animal care (eg, Canadian Council on Animal Care 2005; Council of Europe 2006).

## General husbandry

### Enclosures

Fish are cultured commercially in a wide range of systems and environments, from temperate to tropical and fresh to salt water, in tanks, ponds and cages using semi-natural waters. Although the majority of experimental work is conducted in purpose-built facilities, some also occur on a range of commercial scale sites.

Various systems employ different degrees of water exchange and treatment. Systems can rely entirely on water exchange to maintain the environment or rely entirely on water treatment. The extent of water exchange and treatment has been used to define static, flow-through and recirculation systems. Many experimental systems would employ some form of water filtration or treatment combined with replacement of a proportion of the water. Systems with relatively small amounts of filtration and only occasional replacement of water, such as many simple ornamental fish tanks, are often described as static systems. Semi-closed systems, where water is circulated from each tank through a filter are often referred to as recirculation systems. Filtration systems typically include a mechanical filter, to remove particulate matter, and a biological filter to remove harmful ammonia and nitrite, converting them into less toxic nitrate. Some recirculation systems may also include chemical filters (eg, activated carbon) to improve water quality and also protein skimmers, which remove excess protein from the water. Recirculation systems typically require a low rate of water replenishment. Other systems referred to as flow-through rely primarily on exchange of water to maintain the environmental conditions. The rate of exchange can vary from total replacement in less than an hour to very slow partial replacement over days or weeks.

All systems used to rear fish have several common key functions, they must provide appropriate water, allow feeding, cleaning, waste disposal and necessary access to the fish. In many cases these functions conflict (eg, feeding systems may restrict access to the fish, or interfere with cleaning) and the range of enclosures or systems used is not just determined by the various species or the purpose for which the fish are kept but also an attempt to produce a manageable system.

### Environmental provisions

It may seem facetious to say that water is important for fish but it is easy to forget the range of functions water serves for fish. Obviously it is the medium in which they live and which supports their weight. It also supplies oxygen to them, dilutes and removes toxic waste, carbon dioxide and all other excretory products. Fish can also absorb soluble minerals such as calcium directly from the water. Water also has many other physical properties including velocity,

<sup>2</sup><http://www.iata.org/index.htm>

turbulence, opacity, colour and many chemical properties resulting from substances carried or dissolved in it. Maintaining adequate water supply is the central and essential aspect of caring for fish. In recirculation systems the water filtration and treatment systems may require as much effort to maintain as the fish. Many recirculation systems rely on biological filtration consisting of a large biomass of organisms exposed to a constant flow of water through a physical substrate. Treatment with chemicals damaging to the biological filter or failure of the water flow can result in collapse of the filter and catastrophic deterioration in the water quality.

The requirements of the species and life stage of the fish can vary dramatically, depending upon their natural habitat. Salmonids require very clean water and high levels of dissolved oxygen while some catfish (eg, *Clarius* spp.) appear to prefer turbid water and as air breathers are largely independent of dissolved oxygen.

In any aquatic system the loading (ratio of fish to water for dilution/removal of toxic waste metabolites) of the system is related to its vulnerability or susceptibility to failure. Typically problems deteriorate more rapidly in systems with higher biomass of fish to water volume. Often, but not in every case, an increase in loading of the system is associated with increasing complexity or sophistication of the system. Again the more complex the system the more likely there will be system failures. Vulnerable systems require more regular and detailed monitoring, higher levels of staff competence, more effective contingency planning and resources to deal with problems. For all these reasons it is not possible to recommend a single water quality monitoring protocol.

Many fish in simple tank or pond systems at ambient temperature, with regular water changes, and adequate aeration, require very little monitoring above regular observation of the fish. The most common form of monitoring is that of temperature with many tropical fish kept in temperate regions supplied with combined heater thermostats. Complex recirculation systems with high loading rates or sensitive species may require additional automated monitoring and in some cases automated manipulation of oxygen and other parameters.

Regular monitoring of the rearing system is required for any fish used in controlled experiments. Ideally, such parameters as water level, temperature, pH and dissolved oxygen should be monitored twice daily. In large systems with many units on a common filtration or water supply it may only be possible to monitor a limited number of positions in the system. How such monitoring is conducted depends on the scale of the system, for systems holding large numbers of salmonids or any marine species there would normally be automated temperature, dissolved oxygen and water level monitoring, linked to at least an alarm system and perhaps to an automated oxygenation system.

For small systems with either heavy loading rates or sensitive species it is possible to monitor a large number of parameters with inexpensive test kit technologies. These would usually be supplemented with an electronic dissolved oxygen meter and perhaps an electronic pH meter. With all electronic systems regular calibration is essential,

although more recent technologies greatly reduce the necessity for calibration (eg, LED-based oxygen probes).

The ability to alter the nature of the incoming water is dependent on the supply and the volume used. The most common manipulation is that of temperature. This may be expensive if the deviation from ambient is substantial, and cooling water may be more costly than heating. The cost of changing water temperature is so great that the main function of some recirculation systems is to conserve heat. Another common and essential manipulation is the removal of chlorine from domestic water supplies. Chlorinated water can be very harmful to the gills of fish and vigorous aeration or filtration through activated charcoal is essential.

No single set of criteria is suitable for all species of fish and much of the available information relates to salmonids. Many species are capable of adapting to a wide range of environmental parameters; however, there is very little understanding of either the welfare implications or the consequences of such adaptation other than acute toxic effects. Adaptive capacity is dependent on species and the animals' past experience, but can be remarkable; for example, freshwater phases of salmon are easily able to adapt to temperatures from close to 0°C up to 20°C. Different species have different pH requirements, with salmonids performing best around pH 7, while the Japanese *Tribolodon hakonensis* lives in water from pH 3.4–3.8 (Hirata *et al.* 2003) and the African lake Magadi tilapia (*Oreochromis alcalicus grahami*) survives in a lake at pH 10 (Randall *et al.* 1989).

Any attempt to define appropriate water quality levels for fish is constrained by lack of data and the complex interaction of water quality parameters. There is very little evidence for the effect of water quality on functional or feeling-based aspects of fish welfare of even the most commonly studied species, most of the information relates to effects of water quality on survival or growth. The stability of the fish's natural environment affects its capacity to adapt to changes. Fish from the deep ocean such as Atlantic halibut (*Hippoglossus hippoglossus*), especially in the larval stages, require very constant conditions, whereas fish adapted to rock pools may be capable of withstanding sudden and extreme fluctuations in salinity and temperature. The ability to adapt may be function specific so that while fish may survive a wide range of conditions they may not be able to reproduce outside a limited environmental range. Some life stages and very young or old fish may be less able to cope with fluctuations in environmental conditions and the rate at which conditions change often has a significant effect on the ability of fish to cope with new environmental conditions.

Water quality parameters can be grouped into those largely determined by the water supply (acidity, alkalinity, hardness, temperature, conductivity and heavy metal concentration), those largely determined by the practices in the fish-keeping facility (oxygen, ammonia, carbon dioxide and nitrite) and those that are a product of the source water and the management (nitrate, suspended solids and supersaturation).

Table 49.1 is a guide to the levels of various parameters that have been found to be safe for fish health and productivity. A recent review of water quality and welfare of farmed trout deals with this topic in considerably more

**Table 49.1** Suggested water quality parameters for commonly used species of fish.

Species	O <sub>2</sub> (mg/l)	Temp (°C)	pH	Ammonia (NH <sub>3</sub> )	Source(s)

detail (MacIntyre *et al.* 2008). Table 49.1 contains an indication of appropriate water quality levels for common species.

Photoperiod is the most regularly periodic of variables and conveys a lot of information to fish, it is therefore very important to consider in long-term experiments. The length of daylight and the change in day length experienced by fish control many processes in temperate species including reproduction, smoltification (pre-adaptation to salt water in young salmon) and, in marine Atlantic salmon, can have a greater influence on growth than temperature (Metcalf 1994).

Bright illumination can also be stressful for fish and should be avoided, with many species seeking shade or cover when exposed to bright lights. Although fish have no eyelids to protect the sensitive photoreceptors they do have other protective mechanisms and, unlike mammals, the photoreceptors of fish can regenerate. However, continuous high-intensity light can result in damage to the eyes of fish (Vihtelic *et al.* 2006).

Many species of fish may show a fright response to rapid changes in illumination (for example when aquarium lights are switched on). This can be stressful to the fish and may result in injury, for example if the fish strikes the tank walls or another fish as a result of the fright response. Dimmer switches used on any lighting system that illuminates rearing systems can minimise this problem. Currently, there is little information regarding the effects of the spectral composition of light on fish, although this area is the focus of current research.

Fish are very sensitive to vibrations, through their lateral line system and in some cases inner ears. Any vibration transmitted through the water can have an effect on fish and where possible should be kept to a minimum. However, some disturbance through observation and routine husbandry is unavoidable. Although inevitable, vibrations and other forms of disturbance are rarely uniform throughout

the experimental facilities and should be controlled for in experiments (Adams *et al.* 2007). Predictable disturbance appears to be less stressful for fish and therefore routine care and feeding should be conducted on a regular and consistent timetable.

The practical procedures for establishing a fish-keeping facility are very diverse depending on the nature of the system (tanks, ponds, cages), the type of fish (species and life stage) and the purpose for which they are kept. More detailed practical descriptions can be found in other texts such as the previous edition of this handbook (Potts *et al.* 1999), and for example, cage aquaculture (Beveridge 2004), aquaria (Scott 1997), intensive aquaculture (Shepherd and Bromage 1992) and many other species specific texts.

## Environmental enrichment

We know that even relatively simple environmental enrichment can have a significant effect on the behaviour and development of Atlantic cod (Braithwaite & Salvanes 2005). However, the effects of environmental enrichment are species specific (Williams *et al.* 2009) and for many species there is a lack of robust information on the benefits of various environmental enrichments (Kihlslinger & Nevitt 2006; Brydges & Braithwaite 2009). It is also possible that some forms of enrichment may be detrimental through providing cues for territorial behaviour or by causing physical harm. Objects in the tank may also make it harder to clean without disturbing the fish and can also provide areas for parasites such as *Ichthyophthirius multifiliis* to reproduce (Shinn *et al.* 2003). Water flow could be considered as a form of environmental enrichment over static conditions.

Some fish such as wrasse (eg, *Ctenolabrus rupestris*) seek out shelter and have to be provided with pipes or similar structures to hide in (Sayer *et al.* 1996). Some form of

substrate is also essential for larval salmonids or alevins to prevent them crowding and/or becoming overactive, prematurely exhausting the energy supplies in yolk.

## Feeding

Fish, as ectotherms, require significantly less food to survive and grow than homeotherms of equivalent size. Fish are adapted to periods of shortage rather than excess and can be naturally anorexic. While there is little evidence to suggest that short periods of food deprivation have any significant adverse effect on the welfare of fish it is known that over-feeding has many adverse effects, both physiological and environmental.

Fresh feeds may be required by some adult wild-captured fish but the quality and disease risk make such feeds unsuitable under most conditions. Under no circumstance should closely related fish species or fish from similar ecosystems be fed to each other since this is associated with a higher disease risk. Other animals such as snails or zooplankton can also be intermediate hosts for parasitic infections.

It is essential that the specific requirements of the species and life stage are catered for (see Conklin 2000). The majority of hatching embryos initially rely on a yolk sac. This supplies the developing larvae with energy until they are capable of independent feeding. The size of the yolk sac and the rate it is depleted depend on the species and on the incubation temperature. Atlantic cod larvae, for example, reach first feeding 3 days after hatching at 7°C (Hall *et al.* 2004), whereas rainbow trout may take 20 days at 10°C (Bromage 1995). Access to sufficient food (in terms of quantity and nutritional content) when larvae are ready to feed is critical to development and survival. Food should be made available some time before the complete absorption of yolk. For Atlantic cod, food is made available immediately after hatching to avoid significant mortality (A. Davie, personal communication). The type of food given to first-feeding fry also varies between species. Larvae that are small and poorly developed are often given a suitably sized live food source (eg, *Artemia* or rotifers). Some larger, well developed larvae may be fed directly on a commercially available formulated diet. Even in species such as salmonids, which have no particular need for live food, first feeding is still a critical time when food must be made available in an appropriate manner or the fish will not successfully achieve independent feeding and will eventually die. Species that require live feed at the start of their life usually require to be weaned onto more easily managed feed (eg, commercial pellets). First feeding of demanding species and especially provision of specialist live feeds such as algae cultures or rotifers requires considerable technical expertise, since the production of live feed is the culture of an additional organism equally or more challenging than the fish themselves (see Conklin 2000).

There is often a tendency to use what is easily available and that is often trout pellets, goldfish or tropical ornamental fish food. Although this can be a reasonable solution, in some cases it is inappropriate: feeding trout feed to tilapia or carp can result in nutritional pathologies including liver damage due to the very high lipid content. In general fish

have a requirement for high-quality unsaturated lipids in their diets in order to retain membrane integrity especially at lower temperatures. Many species are also highly susceptible to oxidised or rancid fats in the diet. Therefore, it is important not only to source the correct type of feed, but also to store it correctly to avoid oxidation of the high proportion of polyunsaturated lipids. Storage should be for a minimum of time and in cool dry conditions. Incorrectly stored food not only runs the risk of rancidity but will probably have dangerously low levels of the more labile micro-nutrients eg, vitamin C. If stored under damp conditions, feed with high lipid content is also prone to contamination with the fungus *Aspergillus fluviatus*. This fungus produces aflatoxins, which in high concentrations can result in liver failure and at lower doses can result in liver tumours.

## Provision of social housing

Some species of fish are so aggressive that they cannot be kept in groups, eg, snakeheads (*Channa* spp.). Such territoriality can often be overcome in large groups where the fish revert to shoaling behaviour. Other fish have tightly fixed social structures. Clown fish (eg, *Amphiprion ocellaris*) are hermaphrodite: the largest individual in the population is female and if she is removed a smaller immature male will become female. However, if two mature females are mixed in a small tank where they are unable to establish separate territories they will fight, often resulting in the death of one individual. Reproduction in many species requires particular types of housing. In both Siamese fighting fish and three-spined sticklebacks males and females must be separated following spawning to avoid harm to the female and fry. This is a strategy also used in other species. In species such as tilapia, fish can be brought into spawning condition if they can see a suitable member of the opposite sex. However, keeping them together as a pair can result in injuries due to their aggressive courting behaviour. A simple solution is to keep them in aquaria with a dividing transparent partition.

Fish are often housed in mixed species groups for display purposes and under these circumstances it is essential that the fish have compatible environmental and social habits. Housing a piscivorous snakehead (eg, *Channa striata*) with any other fish of similar or smaller size will generally result in one large snakehead and few if any other survivors. One type of mixed species group is the use of 'dither fish'. When keeping some shy species, for example discus (*Symphysodon* spp.), shoals of small fish that spend time in the open can result in bolder behaviour from the larger discus. Similar cross-species behaviour is seen in birds and mammals (Barlow 1968).

Many people have claimed that limiting the stocking density or biomass of fish per unit volume is a means to protect the welfare of fish. However, the relationship between stocking density and fish welfare is complex (Turnbull *et al.* 2008). Stocking density is only indirectly related to fish welfare, and is mediated through and confounded by water quality, social interactions, feed availability and other factors. Both good and bad welfare can be observed over a range of stocking densities and low stocking

densities can result in territorial behaviour and increased aggression. Therefore suggesting or dictating specific stocking density guidelines can be misleading. Any recommendation for stocking density to protect welfare would have to take account of many other parameters and could not be a simple table of density for given species at specific sizes.

## Identification

A variety of methods have been used for identifying fish, and the choice is largely dependent on the purpose for which they will be used. However, as a general principle the least invasive method that is practical should be used. The methods can be grouped into body mutilations, or implanting visual or electronic tags. The first type of identification includes fin clipping and freeze branding. Fin clipping is the removal of part or all of a fin, usually to identify a population. This technique has been used for identifying hatchery-reared fish after restocking. The removal of even a small amount of fin can have an adverse effect on the swimming ability of the fish (Horak 1969; Deitrich & Cunjak 2006). For this reason the adipose fin was often removed from salmonids. Although this fin was thought to have little mechanical function its size and coloration, especially in mature male brown trout (*Salmo trutta*), would suggest that it may have some signalling or display function (I Semple, personal communication). The other method of body mutilation is freeze branding, which damages the pigment cells providing some form of identification.

There are a large number of methods for either injection or inserting a simple coloured compound or small tags for identification (Figure 49.3). The coloured compounds can either be injected or forced into the skin as a high pressure jet, as with the panjet system (Deitrich & Cunjak 2006). Several brightly coloured elastomers (Hartman & Janney 2006) are also available for identifying fish (Olsen & Vøllestad 2001). A combination of colours and location can be used to provide a range of identifications.

**Figure 49.3** Fish tag inserted by needle with an identification number.

It is usually necessary to handle fish to check for the identification mark and confirm identity when using fin clipping and coloured spots as marking techniques. There are also passive integrated transponder (PIT) tags, which contain and transmit a unique identification code in response to a radio signal from a reader. Although these readers do not penetrate water for any great distance they can be used for identifying fish passing through an area of shallow or narrow water without touching them. There are also various other tags from coded wire tags to those containing monitoring and data-logging functions.

When applying any form of tag it is essential to anaesthetise the fish and hold them on a soft wet surface; the time out of water should be kept to a minimum. Any operative should practise the techniques under supervision and initially on dead fish until competent.

## Health management

The health status of fish used in research is crucially important since in many cases the health of the experimental animals can have a more significant effect on the outcome of the experiment than the treatment under study. In addition to outbreaks of introduced infections, some pathogens are endemic in cultured and wild populations of fish such as *Mycobacterium* spp. infections in zebrafish and *Flavobacterium psychrophilum* in trout. Therefore, health management is much more than just keeping infections out of a system. It concerns all aspects of the construction and management of the system and should be a central consideration when establishing any fish-holding facility. Strategies to avoid introducing infections and to control them if they do occur are essential. Health management also has financial implications: if a disease occurs, resources must be available to deal with it. In the event of a disease problem it may be necessary to seek advice from, and send samples to, experts in the field and the necessary contingency funds must be available.

Every population of fish for experimental purposes should have a veterinary health plan, developed with the named veterinary surgeon. This should be a comprehensive plan including data recording, staff training, health and safety and any other statutory data requirements. The nature of the plan will be dependent on the business of the unit (eg, experimental research, environmental monitoring, toxicological studies, breeding of animals for other purposes etc). The plan must essentially be a part of a process that ensures effective implementation. In the UK, the Fish Veterinary Society<sup>3</sup> can be contacted to identify veterinary surgeons with expertise in fish health management.

In general terms, health management can be divided into three main areas: (1) general prevention; (2) monitoring; and (3) response to problems. In some cases, fish will be kept with the purpose of exposing them to adverse conditions, disease-causing agents or introducing harmful genetic traits. This section, however, concentrates on maintaining optimal health and productivity in stock fish. All aspects of disease prevention and control should be discussed with the

<sup>3</sup><http://www.fishvetsociety.org.uk/>

named veterinary surgeon and included in the veterinary health plan. In this section the subject is discussed in enough detail to allow a non-specialist to obtain an overview of the subject.

### General prevention of disease

All management and husbandry systems should be designed to maintain the health of the fish. Key points include:

- only handling when necessary and in the least stressful and harmful way;
- maintaining as near optimal physical and social environment as possible;
- not only supplying the necessary feed but also delivering it in a way appropriate to the fish;
- ensuring a sound breeding strategy.

Biosecurity (or keeping infections out) should always be a central concern. In terms of introducing infections, introductions of new fish are the largest risk. Any introduction of stock into the system has an associated risk, since even the most stringent testing cannot be perfect due to the limitations of the tests, subclinical or carrier states of diseases and occasionally the large sizes of the populations involved. Sampling aquatic populations and issues of test limitations are discussed in detail elsewhere (Cameron 2002). The capacity to quarantine introduced fish should be planned into every system. There is no rational general recommendation for length of quarantine, although a figure of 3 weeks is often quoted. In reality the length of the quarantine period is related to the risk of introducing a serious pathogen. Where there has been a substantial investment in the existing stock, introductions should be avoided altogether or at very least be limited to disinfected eggs or second-generation of quarantined fish. Where this is not possible a trial introduction should be attempted to identify any potential problems.

Other sources of infections include the water, especially if it is from a natural water body, contains fish or potential intermediate hosts. Incoming water may be treated or filtered but only in low throughput systems. In systems open to the environment, intermediate hosts for multihost pathogens, eg, snails and piscivorous birds, may introduce infections. Control of intermediate hosts and predators can be difficult and may require the welfare of fish under your care to be balanced against the welfare of wild and perhaps endangered species.

Processed feed has not been the source of many infections in animals but the spread of bovine spongiform encephalopathy ('mad cow disease') in mammals demonstrates that there may be unexpected risks. Equipment should not be shared between establishments where possible, but if sharing cannot be avoided good disinfection practices are essential (ie, clean, disinfect and dry). People should also be discouraged from moving between establishments in quick succession or at least discouraged from using the same clothing and footwear. Footbaths are frequently cited as a means to remind people of the need for biosecurity. It is debatable whether a poorly maintained footbath has any such effect and many are not well maintained. Again, if the

population at risk is valuable it is better to keep people out where possible.

Biosecurity overlaps with hygiene (or preventing infections spreading within establishments). As with biosecurity the largest risk is movement of fish. Where possible populations of fish should not be mixed and certainly different age groups should be kept separate. Water can also present a risk within establishments and can spread infections through systems reusing the same water. In the case of flow-through systems, which reuse water in a cascade, it is preferable to have younger fish in the first use water and older fish in the subsequent use water. Water can also spread infections through aerosol or splashes. Bacterial and viral infection can easily spread by this route (Wooster & Bowse 1996). There are also pathogenic fungal spores that can spread through the air, eg, *Phoma herbarum* (Ross *et al.* 1975). Individual units (systems with separate water supplies) should be supplied with separate nets and cleaning equipment. The cost of separate equipment is minimal and the alternative of cleaning and disinfecting between each use is so time consuming that eventually a busy person will not do it effectively or at all. Personnel should be discouraged from moving between separate units when possible, especially when they contain different age groups, for example hatchery and on-growing units.

A key aspect of controlling the spread of infections is using a compartmentalised system. Although some textbooks suggest that systems for zebrafish should run on a central reservoir and filtration system, keeping a large number of valuable animals (eg, genetically modified fish) on a single recirculating system is a very high-risk strategy. A common health problem in zebrafish is *Mycobacterium* spp. infections; these are easily spread through water and once established are difficult to eradicate. Compartmentalisation of the system reduces the risk of the infection spreading and also provides the opportunity to eradicate the infection through identification and removal of infected stocks, followed by thorough disinfection and fallowing. Even in the absence of a specific infectious threat, a compartmentalised system allows parts of the system to be occasionally emptied and thoroughly disinfected. The risk of infectious disease is greatly reduced by using an all-in all-out stocking policy rather than continually adding and removing stock without the option to fallow the system.

The spread of some infectious diseases can also be limited through the use of vaccination. In temperate commercial aquaculture facilities the majority of fish are vaccinated against at least one infectious disease. Currently there are vaccines available against several of the major bacterial pathogens and in some parts of the world against viral infections. The majority of vaccines are administered by intraperitoneal injection; further details can be found in Sommerset *et al.* (2005).

### Health monitoring

Monitoring health comprises the detection of problems (surveillance) and the identification of those problems (diagnosis). Wherever possible, protocols for monitoring health and welfare should be species-specific; it is often not appropriate

to provide generic guidelines covering all species of fish (Johansen *et al.* 2006). Detecting a problem in the earliest stages requires familiarity with the normal behaviour, feeding and appearance. For example being aware of normal feed response, fish coloration, ventilation rates, position in the tank, swimming activity, body condition and responsiveness to for example human presence or nets. In small animals such as guppies or zebrafish, fin clamping or holding the fins close to the body is often an early sign of stress or poor health. Clinical signs or evidence of disease detectable to the unaided senses may be useful to detect problems. Unfortunately they are seldom adequate to identify the specific cause of the problem. The reasons are that fish have a far more limited capacity to express clinical signs than mammals and birds, secondly individual pathogens can result in dramatically different clinical syndromes, thirdly different pathogens can produce similar clinical presentations and finally even within a single disease outbreak there will be variability in the presentation between individuals.

A further challenge is the difficulty of conducting clinical examinations: you cannot easily palpate a fish, its temperature is not informative and there is no movement of gasses within the body to create any sounds worth listening to. Neither is it easy to observe the normal behaviour of fish in many systems. Given all these limitations what can a fish keeper do to monitor the health of the fish and obtain a diagnosis in the face of a disease outbreak?

As has been frequently mentioned throughout this chapter, familiarity with the normal appearance and behaviour of the fish under your care is crucial in order to detect the earliest signs of deviation from normality. Some time spent observing the fish should be a normal part of a keeper's job description. Records are also important and these should be based on sound data, stored in a manner enabling them to be easily accessed, analysed and regularly checked for deviations from expected values. Records can be valuable for the daily management of the system but also to retrospectively investigate problems. Those responsible for measuring and recording data should appreciate the importance and the task should be proportionate to the benefit. Recording excessive amounts of apparently useless data is very demotivating and can result in poor data or failure to record any data at all.

Records should include environmental data, feeding records, details of stock number and movements allowing the origin of fish to be tracked through the system. Although batches may have to be mixed it should be easy to identify the originating populations. Records should also record fish growth and reproduction information. Finally, all health data should be recorded including evidence of ill-health, samples taken, diagnoses or evidence of pathogens and any treatments. There will also be a statutory requirement to record and display data relating to experiments, health and safety.

Diagnosis is a complex term that has been variously defined but may be considered as identifying the nature or cause of some phenomenon (disease) or distinguishing one disease from another. In the discipline of aquatic veterinary studies, diagnosis is constrained by the lack of informative clinical signs, and the limited capacity to conduct clinical

examination. There is also a lack of true diagnostic tests, although there are several pathogen identification tests (falsely called diagnostic tests by some). While these tests may have a role in the control of notifiable pathogens and when eradicating pathogens from a husbandry system, they are of little value in the control of endemic diseases. Many of the common aquatic pathogens are endemic. For example, on some trout farms there may be four or five endemic pathogens. The task when controlling diseases is usually to determine the cause of the disease problem; identifying the presence of a pathogen is at best only part of this process. Most of our truly diagnostic techniques are related to histopathology or the examination of fresh tissue preparations. Histopathology is one of the only disciplines available for fish that can identify the nature of the disease process and provide strong evidence for the nature of any associated pathogen. Despite the power of histopathology, it has to be combined with all other clinical and laboratory evidence to reach a diagnosis. Achieving a diagnosis requires specialist and lengthy training; however, the person in charge of fish should have a sufficient understanding to provide the necessary information when seeking advice and should be able to take samples for diagnosis and pathogen identification (see below).

### Response to a problem

When a health problem occurs there can be rapid deterioration and, therefore, advice should be sought at the earliest possible stage. Once a diagnosis is achieved a course of action has to be decided. This requires an understanding of the nature of the husbandry system, the purpose of the system (what are the fish used for), the disease and available treatments. Again, identifying the appropriate course of action is a specialist task but it is important to know that treatment with therapeutic substances is not always the most appropriate course of action. For severe diseases that are difficult or impossible to treat, eradication may be the best option. In some cases an understanding of the natural history of the disease may provide an opportunity to avoid transmission of the infectious agent. In other cases it may not be possible or necessary to do anything at all.

Following a disease outbreak there should be a detailed discussion with the veterinary surgeon and the veterinary health plan should be amended where necessary.

### Breeding

Given the diversity of reproductive styles (eg, Huet 1994; Andrews 2000; Westerfield 2000) it is not possible to provide details of breeding for all commonly cultured species. Here we provide an overview of the general principles of breeding fish, which apply to a wide range of species.

Reproduction is energetically demanding (Jonsson *et al.* 1991; Okuda, 2001), due to the investment in gametes and associated behaviour. The condition of the parents can influence fertilisation, hatching and survival of offspring (eg, Laine & Rajasilta 1999; Saillant *et al.* 2001; Donelson *et al.* 2008). In some species reproduction leads to fatal exhaustion

and in others survival depends on their condition at spawning (Hutchings 1994; Okuda 2001). Therefore, under laboratory conditions it is important to ensure that fish are in good condition prior to spawning and that following spawning they are given sufficient time to recover fully before they reproduce again.

Environmental cues, including photoperiod, temperature and pressure, have been shown to influence reproduction. For many seasonally spawning fish it is now possible to manipulate the timing of reproduction by artificially controlling the photoperiod, and to a lesser extent temperature. However, we have very little understanding of the welfare implications of such manipulations.

Most fish held in captivity exhibit some degree of reproductive dysfunction (reviewed by Zohar & Mylonas 2001). In the most extreme cases, this might involve a complete absence of reproduction in captivity, eg, European eel (*Anguilla anguilla*). However, two common dysfunctions occur in females and are relatively easy to address. Firstly, in some species, although females are able to produce and ovulate eggs normally they are unable to release them into the water (eg, rainbow trout). To alleviate this problem, mature females can be manually 'stripped' of eggs. Pressure is applied to the abdominal region of the fish in order to gently force the eggs out. Eggs will then be fertilised by the fish keeper using sperm gathered by stripping males. Secondly, in some species eggs may develop normally in the female but final oocyte maturation, ovulation and release into the water do not occur. This problem is often addressed using hormone treatment. Currently agonists of gonadotropin-releasing hormone (GnRH<sub>a</sub>) are the preferred substances for inducing final maturation in fish (Zohar & Mylonas 2001). GnRH<sub>a</sub> has been found to be effective in inducing final maturation over a range of concentrations (eg, Arabaci *et al.* 2004; Vermeirssen *et al.* 2004; Corriero *et al.* 2007), although levels are typically <100 µg/kg of fish. Commercial hormone induction products (ie, injections and sustained-release pellets) are now available to rapidly stimulate maturation 60–238 h post treatment (Marino *et al.* 2003); such treatments are only effective in relatively mature fish, however, not in immature fish. As well as inducing final maturation, GnRH<sub>a</sub> may be used to synchronise maturation in males and females and to increase milt (sperm) output in males, which is often necessary in captive-reared fish.

Following the fertilisation of eggs, the fish keeper must provide suitable care for the developing embryos and fry. These life stages are sensitive and it is important to ensure that optimal, species-specific rearing conditions are provided. The environmental requirements of fish change throughout their life and those of embryonic and juvenile stages may be different from those of their parents (Ishimatsu *et al.* 2004; Imsland *et al.* 2005), from subtle differences to the change from fresh to salt water seen in some salmonids.

Cannibalism can occur when fish are bred in captivity. This can take the form of adults eating eggs and juveniles (eg, zebrafish; Andrews 2000) or sibling fry cannibalising one another (eg, Atlantic cod; Puvenandran *et al.* 2008). The tendency for cannibalism varies between species as do the methods to control it, which include separating adults and eggs/fry, maintaining high feeding rates, adjusting stocking

densities and introducing refuges (Andrews 2000; Kestemont *et al.* 2003; Al-Hafedh & Ali 2004).

## Laboratory procedures

### Handling

Fish vary in their ability to withstand handling, but capture and handling are undoubtedly stressful (Mazeaud *et al.* 1977; Billard *et al.* 1981; Pickering *et al.* 1982; Barton & Iwama 1991; Pickering 1992; Wendelaar Bonga 1997). Handling fish appropriately is not only important for their health and welfare but can also improve the outcome of experiments by reducing another source of variability (Pottinger & Calder 1995).

Fish skin is very different from that of terrestrial animals. The epithelium is relatively thin, unstratified and consists of live cells with no keratinisation. The surface layer has a complex pattern, which is species specific (Figure 49.4). This pattern increases surface area and may have the effect of retaining the superficial layer of mucus. The mucus is continually produced from the mucous cells in the epidermis and is continually sloughed off. The scales are contained within pockets of dermis extending up into the epidermis and therefore removal of a scale creates a wound extending into the vascular tissue. The loss of a scale is **not** equivalent to losing hair or the ends of claws. Although some species have relatively tough skin, many including salmonids have very delicate skin. Physical handling must be kept to a minimum and any abrasive or dry surfaces must be avoided, they should only come in contact with soft, non-abrasive wet surfaces. This means that nets should be soft, knot-less and placed in the water prior to handling. The mesh size of the nets should also be small enough to avoid parts of the fish protruding through the net and being damaged. Fish should be handled with wet hands or wet gloved hands and kept moist even during brief periods of air exposure since this is highly stressful in most species (eg, Sloman *et al.* 2001; Lankford *et al.* 2006). In warm conditions, with rapid airflow, fish skin can desiccate very rapidly and, when the temperature is below freezing, can freeze very rapidly.

**Figure 49.4** Scanning electron microscope photograph of the superficial epidermis on the ventral flank of a rainbow trout. (A single cell is outlined.)

As previously mentioned, fish should be starved prior to any form of handling and any air exposure should be kept to a minimum. Where possible fish should be encouraged into a container and then removed from the tank in water (Brydges *et al.* 2009). Capturing a specific individual can be difficult; this is especially true when capturing larger fish in larger tanks or any fish in tanks containing objects or structures. Capturing larger fish is often easier using two nets with which to corral the fish. Capturing is a skill that requires practice and inexperienced people can spend a lot of time chasing a fish, which can be very stressful and potentially damaging for it.

Fish can generally be weighed in water by first measuring the weight of the container and water. There are numerous references to blotting fish dry prior to weighing, it is doubtful whether this is a justifiable process. It is damaging and the small amount of water removed probably represents less error than the content of the gut and water in the mouth and opercular cavity. If individual or groups of fish are weighed in a net then the total weight in the net should not be too heavy or fish at the bottom can suffer injury from crushing.

Occasionally fish may have to be held in temporary containers, such as when administering anaesthetic. While adequate aeration in such vessels is essential, excessive aeration can disturb the fish and even damage them. The need for anaesthesia when handling fish is dependent on the species of fish and its previous experiences. Some may be easily handled with little or no signs of distress or attempts to escape, for example some flatfish may be handled quite easily, even out of water, providing their eyes are covered. Others, for example salmonids, may be severely stressed by even the gentlest handling. Once again the necessity for anaesthesia requires an assessment based on familiarity with the fish.

### Training/habituation for procedures

There is evidence for poorer functional welfare resulting from disturbance but also complex interaction between other aspects of the environment such as stocking density and disturbance. It would appear that in some circumstances occasional disturbance can have greater detrimental effects than more regular exposure to mild disturbance (Adams *et al.* 2007). Fish can also be rapidly trained to use self-feeding systems (Alanara 1996) and will anticipate any form of feeding through visual cues (Stien *et al.* 2007).

### Monitoring methods

Fish present the keeper with many challenges since they are difficult to observe in all but glass display aquaria. The position of fish can be tracked through video analysis software (Kane *et al.* 2004), or PIT tags (see section on identification) can be used to identify individuals and also determine their location in larger tanks or flumes but these techniques have limited application. Tanks that are suitable for easy observation may subject the fish to visual disturbance and affect their behaviour. There is no doubt that the effects of distur-

bance are complex and we have a very poor understanding of the consequences of adaptation to disturbance. Therefore in many experimental systems monitoring is confined to observation of feeding response, obvious aspects of group behaviour and gross signs of disease, occasionally combined with destructive sampling.

Monitoring the condition of fish in larger populations and in systems where they cannot be easily observed is more problematic. Growth and food conversion ratio are very useful indicators of the health of the population but monitoring these obviously involves disturbance and handling which may not be appropriate under some circumstances. Other important signs of good health include, 'normal' swimming, feeding, response to disturbance and appearance for that population. It may not seem to be very useful to say 'normal', however, it is not possible to identify generic appearance across species, husbandry systems or even between apparently similar populations. Variability is probably the result of inherent population dynamics, genetic and epigenetic variability.

It has been suggested that evaluation of reflex responses as described by Davis and Ottmar (2006) might be used to monitor the health and welfare of fish. However, the stimuli used to evaluate reflexes were in themselves stressors, including lifting the lid of the tank or striking the side. Non-invasive methods for monitoring fish are not well developed and this is an area requiring urgent attention.

Although clinical biochemistry and haematology have relatively little value for monitoring the health of fish, blood samples are taken for a variety of reasons. Blood samples can be obtained from fish in a variety of ways. In most cases with fish over 10 cm in length, blood is collected from the caudal vessels, which lie under the spine. In some cases the fish may be killed prior to blood sampling. With a typical fusiform fish such as the trout, it should be placed on its side with the ventral surface facing towards the operator. The needle should be inserted on or close to the mid-line behind the anal fin angled slightly forward towards the ventral aspect of the spine. Once the needle touches the spine, negative pressure should be applied to withdraw blood, the needle may need to be repositioned in order to puncture one of the blood vessels (Figure 49.5). Other techniques may be used for fish with other shapes such as flat fish or laterally compressed fish. With these, it is easier to obtain a sample by inserting the needle in the flank below the level of the spine and then directing the needle up towards the ventral spine. Provided it complies with national or local regulatory guidelines fish may be blood sampled under anaesthesia and then allowed to recover; however, the volume of blood removed should not exceed 1% of the weight of the fish. Blood samples may also be obtained through cardiac puncture and from other vessels, however, such techniques require specialist training and often require euthanasia. Obtaining blood samples from very small fish can be difficult via venepuncture and therefore they may be killed and the tail cut off at the caudal peduncle. Blood can then be collected from the severed vessels, with a capillary tube or small syringe and needle. This technique has the disadvantage that extravascular fluids contaminate the blood.

Since the health of fish is a major aspect of their welfare, destructive sampling for health checks is a normal part of

**Figure 49.5** Insertion point for needle when blood sampling a typical fusiform fish.

the husbandry of many fish populations. Although the necessity and exact nature of the sampling would be part of the veterinary health plan, some basic principles are an important part of training for fish keepers since samples may have to be taken at very short notice.

Fish, unlike warm blooded animals, will often increase in temperature after death and, due to enzyme systems designed to function over wide temperature ranges, autolysis occurs very rapidly even in fish that are cooled after death. Therefore, the most important principal of sampling is to use very recently killed fish, even a 5 minute delay can result in changes in the gills rendering diagnosis more complex (Ferguson 2006). In the majority of cases fish suffering from clinical disease or those to be sampled for other purposes should be killed and then immediately sampled. Fish that are already dead can only be used for a limited number of specific purposes.

One has to be practised in order to take a full set of samples from a single fish before autolytic changes set in and the number and range of samples that can be collected are dependent upon the size of the fish. Once the fish is killed it should be kept moist in the water from which it was removed since many parasites are most easily detected by their movement and either desiccation or chlorinated water will kill them.

Prior to collecting samples, a brief examination of the external appearance should be conducted paying attention to the eyes, gills and vent and ensuring both sides are examined. Fresh preparations can then be made from the skin or gills, although interpretation requires some training. To examine the mucus on the body surface a scalpel blade should be gently scraped over the surface of the fish especially behind fins. The areas behind fins are protected and are therefore a site preferred by parasites (Figure 49.6). The resulting material should primarily consist of mucus with epithelial cells. If there are scales in the material then the scraping was too vigorous and deep. The accumulated material should be transferred to a glass slide, a drop of the water in which the fish was kept added and a cover slip placed on top. This can be examined under the microscope once the other samples have been collected. It may be easier to observe the cells and any parasites by lowering the con-

denser on the microscope. A sample of gill should be taken for examination. Part or all of one of the gill arches should be removed and placed on a wet Petri dish or a glass slide. A group of the primary lamellae should be removed above the level of the bifurcation (Figure 49.7). The freed primary lamellae should then be placed on a glass slide with a drop of water (as before). When the cover slip is placed over the tissue it may be necessary to move it in order to observe the secondary lamellae. Again the preparation can be examined under the microscope at the end of sampling, ensuring that the preparation does not dry out in the mean time.

Once external examination or sampling has been carried out, in fish over 5–7 cm in length the body surface is opened to expose the internal organs and take samples for bacteriology and histopathology.

**Figure 49.6** Diagram of process to collect superficial scraping from a fish avoiding deeper tissues and scales.

### Bacteriology

Petri dishes containing solid medium (agar) are used to provide a large surface of media for the cultivation of bacteria and fungi. The agar used for most common fish pathogens is tryptone soya agar (TSA) and incubation temperatures are usually as close as possible to the temperature of the water from which the fish were sampled (Frerichs & Miller 1993; Inglis *et al.* 1993). Inoculation of an agar plate is often carried out using the streak plate technique. This involves

**Figure 49.7** Diagram of process to collect superficial fresh preparation from the gills.

diluting the sample, eg, kidney material, by smearing it across the surface of the agar. Organisms present in the samples will be separated and after suitable incubation each organism (or at least attached group) present will give rise to a colony. Although this colony contains many millions of organisms they will have all originated from one, and therefore all organisms in one colony should be identical.

For typical fusiform fish >5–7cm long:

1. Using a scalpel blade, carefully make an incision through the body wall in the mid-ventral line at the base of the pelvic fins.
2. Using scissors or scalpel blade extend the incision anteriorly and posteriorly to expose the internal organs. Take care not to puncture any part of the intestinal tract.
3. Hold or pin back or remove the side of the body wall.
4. Carefully move the alimentary tract to one side to expose the swim bladder.
5. Carefully peel back the swim bladder to reveal the kidney.
6. Note any abnormalities.
7. Sterilise a bacteriological loop by heating and allow to cool (touch edge of an uninoculated area of medium to ensure coolness) or use a disposable loop.
8. (Sterilise a scalpel blade and use this to make a small incision in the kidney.) – Optional
9. Insert a sterile loop into the kidney and remove a small portion of kidney using the loop, taking care not to touch the loop on any other part of the fish.
10. Inoculate the sample on a segment of the surface of the culture medium. This is known as the 'well'.
11. Sterilise the loop, allow it to cool.
12. Spread part of the sample over about one quarter of the plate by making three to four parallel streaks with the loop.
13. Repeat streaking procedure as shown (Figure 49.8), sterilising and cooling the loop or using a new disposable loop between each step. By using this method organisms can be cultured in the laboratory and individual colonies selected. This process is essential since it is impossible to carry out bacterial identification on

**Figure 49.8** Diagram of plate streaked for bacterial recovery.

mixed cultures. Care should be taken to ensure that plates used for this purpose are not contaminated by water droplets from condensation. Avoid unnecessary exposure of the agar surface to potential contamination from the environment throughout the procedure.

14. Label underside (not lid) of the plate using a waterproof marker, writing only round the edge, and incubate at a suitable temperature.
15. Material from other organs, eg, liver, spleen, heart, can be taken if any abnormality is evident.

For smaller fish it may be possible to open the abdomen and insert a very small loop or straight wire avoiding the gut. Whole fish homogenates can be used but are difficult to interpret since the bacteria from the gut, skin and gills are mixed with the tissues.

#### Samples for histopathology

Samples for histology must be taken as soon as possible after death and fixed immediately, preferably in neutral buffered formalin, which may be cooled for improved preservation if the ambient temperature is high. Neutral buffered formalin consists of:

- 40% formaldehyde 100 ml
- $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$  4 g
- $\text{NaHPO}_4$  6 g
- Tap water 900 ml

The organs sampled depend on the nature of the problem but in most cases most of the major organs are sampled (eg, gill, skin including muscle around lateral line, heart, liver, pancreas/gut, spleen and kidney). The samples should be sufficiently small to allow the fixative to penetrate rapidly through the tissue. Therefore one of the dimensions of the tissue removed should be less than 7.5mm. The tissues should be placed in at least one part tissue to ten parts fixative. Small fish may be killed and placed directly into fixative or preferably the abdomen opened and then placed in fixative. The tissue can be kept in formalin for prolonged periods but they should be stored in such a way as to avoid any portion of the tissues remaining out of the fixative.

## Administration of substances

Substances, whether for experimental or therapeutic purposes, can be administered in food, by injection or by immersion. Anyone treating fish should be trained before undertaking any treatments and the nature of the treatment should be agreed with the veterinary surgeon. There are, however, some general precautions and considerations that anyone taking care of fish should be aware of.

### In-feed administration

When administering a substance in food there are several major considerations. The substance has to be evenly mixed with the feed, fixed to the surface to avoid leaching prior to consumption and any unpalatable tastes masked. The medicated feed then has to be fed to the fish in sufficient quantities and sufficiently regularly to maintain levels in all the fish in the population. If the substance is being administered for therapeutic purposes it is important to realise that any fish suffering from clinical disease are probably inappetent and therefore the treatment will only be taken by those that are not yet ill. The use of veterinary medicines and the mixing of medicated feed may be covered by national legislation and advice should be sought from the veterinary surgeon responsible.

### Immersion

There are various forms of immersion administration (dip, bath or flush) which can be used depending on the system and the purpose of the treatment. As with any form of handling fish should be starved for 24–48h prior to treatment and the general health of the fish should be checked. Fish are commonly treated with formalin to remove skin parasites. Formalin is a reducing agent and will reduce the available oxygen in the water. If the fish have concurrent gill pathology the formalin treatment without very careful monitoring of the oxygen levels could result in the fish dying from hypoxia.

Calculating the dose of chemical for administration is simple arithmetic but it is still easy to misplace a decimal point or make some other simple error and therefore two people should calculate the dose independently. It is also worth having a system to quickly and easily make a rough estimate. For example, one cubic metre is 1 tonne of water or 1000 litres or 1 million ml. Therefore a dose of 150 parts per million (ppm) will be 150ml of the chemical in 1 cubic metre.

There are many things that can change unpredictably and therefore if a large number or expensive fish are being treated then it is wise to conduct a trial therapy on a small number of fish in the water and chemical that will be used. Trial therapies are particularly important for inexperienced staff but can avoid mistakes by even the most experienced staff.

Normally, the volume of the system to be treated would be reduced to minimise the amount of chemical that has to be used and therefore the amount that has to be disposed of. Disposal must be in accordance with all relevant legislation and compliant with the discharge consents for the

premises. In flow-through systems the water inflow would be turned off to avoid dilution of the chemical. In recirculation systems the effect of the chemical on any biofiltration must be considered before any treatment. Even in systems without specifically designed biofilters there will be a large biomass of microorganisms on all wet surfaces. If the chemical treatment kills these organisms they will decompose leading to the release of nutrients and a decline in water quality. The ability to treat the fish for minor parasitic infections while protecting the biofilter should be designed into the system. This may necessitate removal of the fish from the system. However, in some cases the pathogens may be able to survive in the filter and in these cases the only option is to sterilise the system and re-start the filter system.

Some of the chemicals that might be used, including anaesthetics, may be held in a pre-prepared stock solution. Storage conditions are important since evaporation or deterioration in the chemical can result in an over- or under-dose. The chemical would normally be premixed in a container with some of the water from the system so that it can be rapidly and evenly dispersed through the tank. Some of the substances that may be administered will also be irritants, which may necessitate an alternative route of administration or diluent.

At all times adequate dissolved oxygen levels should be maintained, through aeration, oxygenation or agitation of the water. The combination of confinement and the effects of the treatments may stress the fish increasing their oxygen demand.

At the end of the treatment the water in flow-through systems should be turned back on and the discharge water run to waste in accordance with legislation. Following a treatment all the details should be recorded and the efficacy of the treatment confirmed by the collection of further samples.

If a treatment causes the fish excessive stress or injury they may become lethargic, hyperactive or gasp at the surface of the water. The priorities are to reduce the concentration of the chemical and ensure adequate oxygen supply. In circular tanks it is necessary to ensure that diluting the chemical does not also result in increased directional flow, which may be fatal for already stressed fish. In most tanks the inlet would be arranged to create a directional flow by angling the pipe round the circumference of the tank. If the treatment has to be terminated then the pipe should be directed vertically down into the tank to increase the water exchange without increasing the water velocity (Figure 49.9).

## Anaesthesia/analgesia

Anaesthesia is defined as the blocking of all sensation, whereas analgesia is the blocking of the conscious sensation of pain. It has been shown that fish respond to noxious stimuli and it is believed that they are able to experience pain although this is still the subject of debate (see section on fish welfare). However, it is necessary to use anaesthetics or analgesics whenever any laboratory procedure might result in significant pain or distress. Here the discussion is focused on anaesthetics, which are more widely used in fish. There is a range of methods for anaesthetising fish, but here

**Figure 49.9** In the case of a treatment causing the fish distress the chemical should be diluted as rapidly as possible but avoiding increasing the directional flow in the tank.

an overview of only on the most widely used approaches is provided. For more detailed information see Burka *et al.* (1997) and Ross and Ross (2008).

In fish, anaesthetics may be used for two purposes: to alleviate pain during procedures and to restrain fish, often for routine tasks such as weighing. Anaesthetics can be applied to fish by injection or via ventilation through the gills. Injections are only occasionally used for surgical or lengthy procedures. Their use requires considerable expertise and specialised training. This section will focus on the more widely used methods, the most common of which involves immersing fish in water containing anaesthetic, which is taken into the body via the gills.

Various anaesthetic compounds are available for use with fish, the most common being tricaine methane sulphonate (MS 222). MS 222 is the only anaesthetic licensed for use on fish in the UK and approved by the US Food and Drug Administration. It is highly soluble and can be used in either fresh or salt water. However, when MS 222 is dissolved in the water it reduces the pH, which can be harmful to fish. Therefore working solutions should be buffered to a pH of between 7.0 and 7.5 using sodium bicarbonate or Tris-buffer. Benzocaine is another widely used anaesthetic, which is often considered a less expensive alternative to MS 222. However, it is relatively insoluble in water and must be prepared in acetone or ethanol prior to use. Other anaesthetics include clove oil, 2-phenoxyethanol, metomidate, quinaldine and quinaldine sulphate. Doses necessary to induce anaesthesia vary between compounds and also between different species and due to biotic and abiotic factors such as temperature, life stage and fish size (Hoskonen & Pirhonen 2004).

While it is necessary to consider the aversive properties of an anaesthetic there is a lack of research in this area<sup>4</sup>.

The main issues associated with anaesthetising fish using immersion methods are discussed here. Other more specialised and less commonly used techniques are described by Ross and Ross (2008).

Prior to anaesthetising fish, it is recommended that they are starved for 24–48 h. The tanks, air supply, nets etc used

to anaesthetise fish should be set up in advance of handling any fish. They should be located in a convenient position close to the tanks where the fish are held and where any procedures will be conducted. The system should include a static water tank (not flow-through) for anaesthetising the fish and a separate tank with very low or no directional flow in which fish will recover before to being returned to their normal tank. Fish should not be allowed to recover in their normal tank as other fish might be aggressive towards them and any directional water flow may disorientate them resulting in superficial damage. Each tank should be appropriately sized for the species concerned. Tanks should be filled with water from the normal rearing tanks and gently aerated, since vigorous aeration can be stressful or disorientating. It must be possible to see the fish in the tanks but bright lights should be avoided. Water in the anaesthetic and recovery baths must be replaced if there is any evidence of deterioration in water quality. The keeper should give due consideration to hygiene and biosecurity before anaesthetising any fish.

Due to the variability in the responses of different fish to anaesthetics, published doses should be used only as a guide. Initially, the water should be dosed with a concentration of anaesthetic at the lower end of the calculated range. Then one fish should be placed into the anaesthetic bath and monitored until it is anaesthetised. More anaesthetic can be added if necessary or the concentration diluted if anaesthesia occurs too rapidly. Once a suitable concentration of anaesthetic is achieved, more fish may be anaesthetised at a time. However, the anaesthesia bath (and the recovery tank) must not become over-stocked as this may lead to deterioration in water quality or it may become difficult to monitor the fish adequately.

Different levels of anaesthesia are classified in four stages ranging from light sedation (stage 1) to medullary collapse (stage 4). The level of anaesthesia achieved can be assessed by monitoring the behaviour of the fish. Behavioural changes might range from reduced swimming activity in stage 1 anaesthesia (light sedation), to a loss of equilibrium and altered ventilation rate during stage 2 (light to deeper anaesthesia), through to a total loss of reactivity and a very low respiratory rate in stage 3 (surgical anaesthesia) (Burka *et al.* 1997; Ross & Ross 2008).

Following anaesthesia, recovered fish should display normal ventilation and swimming behaviour, and be responsive to stimuli. However, some effects of anaesthesia (eg, changes in physiology or blood chemistry) can persist for a significant time after recovery, in some cases for several hours. Fish should therefore be monitored regularly in the hours and days following anaesthesia. Personnel should also be aware that anaesthesia can result in side effects which might influence their experimental results.

Finally, prior to undertaking anaesthesia users must consider all personal and environmental health and safety implications. Anaesthetic compounds can have broad, sometimes unknown, effects on animals and man (including possible effects through the food chain). The physical process of anaesthetising fish presents further risks to health and safety. Therefore anaesthesia of fish must be conducted in compliance with institutional, regional and national guidelines and legislation.

## Euthanasia

Euthanasia requires an appropriate humane killing method and any handling or restraint should have as little adverse effect on the animals as possible (see Chapter 17 for general principles of euthanasia). Most of the information relating to the humane killing of fish is in the context of slaughter of farmed fish (Robb & Kestin 2002; van de Vis & Kestin 2003; Lines & Kestin 2005) and there is relatively little evidence for the most humane method in the wide range of circumstances where experimental fish have to be euthanased.

The two techniques recommended in the UK for humane killing of research fish are concussion and destruction of the brain prior to the regaining of consciousness, and overdose of a suitable anaesthetic. However, whilst an overdose of anaesthetic is considered a humane method for killing fish, it also requires that death is confirmed or assured. This can be through confirmation of permanent cessation of the circulation, destruction of the brain, dislocation of the neck, exsanguination (ie, fatal blood loss), the onset of rigor mortis or instantaneous destruction of the body in a macerator. The choice of method to confirm or assure death will depend on any subsequent sample collection, for example if brain tissue is required it is not appropriate to destroy the brain to assure death.

Problems that can occur whilst killing fish include those associated with dealing with fish which have heavily armoured heads making them difficult to effectively concuss and differing susceptibility to anaesthesia, eg, air breathers. An attempt should be made to maximise the dose of the anaesthetic to reduce the time to loss of sensibility but avoiding irritant or aversive nature of the anaesthetic. Large numbers of fish or very small fish can also be a problem since concussion may not be feasible and following anaesthetic overdose it may be difficult to confirm death in a short period of time. Large fish can also pose a problem since capture and restraint prior to killing may be difficult and stressful for the fish. While adding anaesthetic to the water where the fish are kept may avoid the stress of handling it may not be possible where only some individuals need to be killed or in recirculation systems.

Other methods that have been proposed are maceration, chilling (which raises welfare concerns) and electrical stunning<sup>5</sup>. Although electrical stunning is now widely used in trout farming (Lines & Kestin 2005) at this point there is insufficient data to support the use of the other techniques in fish for experimental purposes.

## Common welfare problems

Any discussion of fish welfare is constrained by a lack of information regarding the preferences expressed by fish. The majority of relevant work to date has focused on functional aspects of welfare. The welfare of fish was discussed by Huntingford *et al.* (2006), Branson (2008) and a special edition of *Disease of Aquatic Organisms*<sup>6</sup>.

When evaluating the welfare of fish it is often not appropriate to extrapolate from terrestrial animals since fish are a diverse group of cold-blooded animals, do not have the same constant need for food and can be naturally inappetent for protracted periods; most live in a three-dimensional environment, may exhibit shoaling behaviour and many aspects are inherently adaptable.

We have little information with which to assess the welfare implications of the various behaviours observed in fish, unless they result in damage such as escape behaviour, hyperactivity or aggression. The majority of welfare issues could be summarised as injury through handling, predators, conspecifics or self-inflicted through contact with solid objects. Infections are common and fish suffer from the same range of pathogens as humans or animals (viruses, rickettsia, bacteria, fungi, protozoa and a wide range of metazoan parasites). Fish suffer from pathology as a result of inappropriate water quality or feed. They may also suffer from genetic manipulation intentionally introducing harmful traits or from careless breeding strategies. Detailed descriptions of the pathologies and disease can be found in Ferguson (2006) and Roberts (2001).

Despite the lack of information, practical experience and adherence to basic principles of health management can avoid many of the most obvious welfare problems observed in captive fish; we hope this chapter provides at least a useful starting point and have attempted to include reference to useful review texts or those containing useful specific information.

# Cephalopoda

# 50 Cephalopoda

Bernd U. Budelmann

*Note: This short chapter has not been written to stand on its own. It is an update of Peter Boyle's Chapter 7 in the 7th edition of the UFAW Handbook, which was published in 1999 and is reprinted after this update. Consequently, for details and earlier references the reader should consult that chapter as the authoritative text. In addition, some key literature on cephalopods published earlier (but not mentioned in that chapter) has been added. For an easy follow-up and comparison, the updates given below use (sub)headings similar to those of the earlier chapter. This chapter update is dedicated to the memory of Peter Boyle.*

## Introduction

Cephalopods are the only invertebrate animal group included in this edition of the Handbook, however information on decapod crustaceans is available in the 7th edition of the Handbook. Invertebrates are not generally protected in animal welfare legislation, although certain species are included in some national legislation (eg, UK, New Zealand & Australian Capital Territories, and some Scandinavian countries). The UK, at the time of writing, includes one species, *Octopus vulgaris*, in its legislation on the use of animals in research. However, there is debate within Europe (unresolved at the time of writing) as to whether some, all or no cephalopods (as well as decapod crustacea) should be included in a new European Directive on research using animals (see also Chapter 8 on legislation).

Cephalopods belong to the phylum Mollusca and thus are close relatives to gastropods and bivalves. Although the cephalopod body design conserved some typical molluscan features, it developed a level of complexity, and especially a sophisticated nervous system and sense organs, that in several aspects reach vertebrate standards (Budelmann 1995). The cephalopod nervous system is certainly the most advanced of any invertebrate nervous system and this complexity correlates well with the animals' (in general) very active, fast moving predatory life styles and sophisticated behaviours (Bullock and Horridge 1965; Budelmann 1995; Hanlon & Messenger 1996). Not surprisingly then, beginning in the 1930s with J.Z. Young's rediscovery of the giant axon and the subsequent early understanding of the processes involved in nerve impulse conduction and transmission (Adelman & Gilbert 1990), cephalopods have become fascinating and valuable invertebrate model systems for comparative vertebrate research. However, in such comparisons a number of limitations apply (see below, nervous

system). It is important that these limitations should be understood because of the recent increased interest in this animal group from media and laymen that is sometimes combined with a tendency for 'over-interpretation' of the fascinating behaviours that cephalopods show.

The class Cephalopoda comprises two sub-classes: Nautiloidea (*Nautilus*) and Coleoidea (octopuses, cuttlefish and squids). The latter two are often referred to as 'decapods' but care should be taken as this term is also commonly used for the order of crustaceans that includes crabs, lobsters, prawns, etc). Nautiloids and coleoids show significant differences with regard to their anatomy, physiology and behaviour (for example, nautiluses have a much less sophisticated nervous system and sensory outfit; they show no colour change and have a much simpler behavioural repertoire; and they are scavengers and thus seem to have a well developed chemosensory system for food detection). These differences between nautiloids and coleoids, however, unfortunately are often not considered in the literature when the term 'cephalopod(s)' is applied. The term as used often refers to the coleoid cephalopods only (that is, to the octopuses, cuttlefish and squids) and, therefore, great care must be taken in the use, interpretation and generalisation of the 'cephalopod' data described.

## Cephalopod biology

A number of comprehensive monographs has become available that cover almost all aspects of cephalopod biology, from palaeobiology (Landman *et al.* 1996, 2007), evolution, systematics, identification, and biogeography (Clarke 1986; Guerra 1992; Sweeney *et al.* 1992; Payne *et al.* 1998; Voss *et al.* 1998; Norman 2000; Capua 2004; Jereb & Roper 2005), to gross and microscopic anatomy (Mangold 1989; Budelmann *et al.* 1997; Nixon & Young 2003), physiology (Abbott *et al.* 1995), ecology, fisheries and culture (Boucaud-Camou 1991; Boyle & Rodhouse 2005; Chotiyaputta *et al.* 2005), age determination (Jereb *et al.* 1991), behaviour (Hanlon & Messenger 1996; Nixon & Young 2003; Borelli & Fiorito 2008) and diseases (Hanlon & Forsythe 1990; Hochberg 1990). Some more recent data are summarised below.

## Habitat and distribution

An excellent monograph is now available on many aspects of cephalopod ecology and fisheries, including: cephalopod

biodiversity and zoogeography; life cycle, growth and reproduction; population ecology; cephalopods as prey and predators; fishing methods and scientific sampling; fishery resources; fisheries oceanography; and assessment and management (Boyle & Rodhouse 2005).

### Locomotion

The cephalopod musculature lacks a skeletal support system and, instead, operates on the principle of a muscular hydrostat, similar to the 'mechanism' of an elephant trunk or the human tongue (Kier & Smith 1985; Smith & Kier 1989). This allows cephalopod (specifically octopod) arms a great range of movement. Over the past more than 10 years, significant progress has been made in understanding the nervous control of cephalopod arm movements; this ultimately could inspire completely new strategies for the control of highly flexible robotic arms (Gutfreund *et al.* 1996, 1998; Matzner *et al.* 2000; Sumbre *et al.* 2001, 2005; Walker *et al.* 2005; Yekutieli *et al.* 2005a, 2005b, 2007).

### Shell and buoyancy

The neutral buoyancy of many squids is achieved by storing ammonia in body tissue. The various mechanisms for storage (in coelomic cavities, vacuoles, or gelatinous outer layers) have been reviewed in support for the argument that ammoniacal squids have evolved as a polyphyletic animal group (Voight *et al.* 1994).

### Respiration and circulation

Water temperature, pH and oxygen supply are critical factors in cephalopod culture and breeding. Recently, the cuttlefish (*Sepia officinalis*) has served as a valuable model system for understanding the mechanisms of thermal tolerance in ectothermic animals (Melzner *et al.* 2006, 2007).

### Nervous system

The cephalopod nervous system is the most highly evolved of all invertebrate nervous systems. On the other hand and despite that level of complexity, the overall organisation of its central part (the brain) is fundamentally different from that of the vertebrate nervous system and, therefore, any direct comparison between the two has serious limitations. This, however, neither excludes careful comparison of basic brain functions, nor weakens the great value of the cephalopod nervous system in comparative research. Details of the anatomy of the cephalopod central nervous system are available for *Nautilus* (Young 1965), *Octopus* (Young 1971; Budelmann & Young 1985; Plän 1987) and *Loligo* (Young 1974, 1976, 1977, 1979; Messenger 1979; Budelmann & Young 1987); recent overviews are given in Budelmann (1995), Budelmann *et al.* (1997), Nixon and Young (2003) and Williamson and Chrachri (2004).

In addition to their highest level of complexity, cephalopod brains are also the largest of all the invertebrate brains; their brain:body weight ratio exceeds that of many fishes and reptiles (Packard 1972). This is not too surprising, however, since cephalopods lack an internal skeleton and lack joints, and thus lack a 'simple' antagonistic muscle control of movements. Consequently, about half of the volume of the brain of coleoid cephalopods consists of the relatively large motoneurons that form the sub-oesophageal mass of the brain; this area includes the motoneurons that expand all the chromatophore organs in the skin (for a summary of the numbers of nerve cells in the various parts of the *Octopus* brain, see Budelmann 1995). On the other hand, the comparatively large size and complexity of the brains of octopuses, cuttlefish and squids are the basis for the animals' large repertoire of fascinating behaviours, including various forms of learning and short- and long-term memory (Hanlon & Messenger 1996; Hochner *et al.* 2003; Borelli & Fiorito 2008). Ultimately, these make coleoid cephalopods, especially shallow-water octopods, cuttlefish and squids, the only invertebrate species with which humans can directly interact ('communicate') in a back and forth manner and beyond a simple reflex-like (re)action on the animals' side.

Octopuses, cuttlefish and squids are often considered the most 'intelligent' invertebrate species (whichever way intelligence is defined). The web-based Wikipedia summarises this issue quite well:

*Cephalopod intelligence has an important comparative aspect in our understanding of intelligence, because it relies on a nervous system fundamentally different from that of vertebrates. ... The scope of cephalopod intelligence is controversial ... Classical conditioning of cephalopods has been reported, and one study (Fiorito and Scotto 1992) even concluded that octopuses practice observational learning. However, the latter idea is strongly disputed, and doubt has been shed on some other reported capabilities as well. In any case, impressive spatial learning capacity, navigational abilities, and predatory techniques remain beyond question.*

Other impressive behaviours that can be added to this list are cephalopod mating and social behaviours, including social recognition (Hanlon & Messenger 1996; Boal *et al.* 2000; Dickel *et al.* 2000; Karson *et al.* 2003; Boal 2006; Alves *et al.* 2008; Borelli & Fiorito 2008).

Powerful techniques have now successfully been applied to cephalopod brains to the study of their anatomy and function (Budelmann *et al.* 1995): three-dimensional magnetic resonance imaging of brain pathways (Quast *et al.* 2001) and individual neurons (Gozansky *et al.* 2003); brain slice recordings (Williamson & Budelmann 1991); recordings from intact animals with implanted electrodes (Bullock & Budelmann 1991); and mapping of metabolic brain activity (Novicki *et al.* 1992). With these modern neurophysiological techniques cephalopods have become an increasingly valuable invertebrate model system for comparative vertebrate research, such as the evolution of learning and memory and other higher brain functions (Hochner *et al.* 2006). Recently, laterality in the brain (Byrne *et al.* 2002, 2004, 2006), play behaviour (Kuba *et al.* 2006), personality (Sinn & Moltschanivskyj 2005), sleep (Brown *et al.* 2006) and

complex phenomena, such as consciousness and suffering in cephalopods, have been discussed (Mather 2001, 2008).

### Sense organs

Cephalopods have a sophisticated sensory outfit that includes all major sense organs, such as photoreceptors (including extra-ocular photoreceptors), distance and contact chemoreceptors, and various mechanoreceptors (including equilibrium receptor organs, a lateral line analogue system and a neck proprioceptive organ) (Budelmann 1996). Knowledge about touch, pressure and muscle proprioceptors is limited, and it still remains to be seen whether cephalopods have electroreceptors and are sensitive to pain. For a comprehensive summary on cephalopod sense organs, see Budelmann *et al.* (1997).

### Eyes and vision

The cephalopod and vertebrate lens eyes are a textbook example of analogy (convergent evolution) between an invertebrate and a vertebrate sensory system. Recent advances have been made in understanding visual processing (Chrachri & Williamson 2003, 2004, 2005; Chrachri *et al.* 2005; Douglas *et al.* 2005), and the role of polarised vision (Saidel *et al.* 1983; Shashar *et al.* 1998, 2002; Boal *et al.* 2004; Saidel *et al.* 2005; Mäthger & Hanlon 2006). In addition, in the squid *Lolliguncula* a dorsal light reflex has been described (Preuss & Budelmann 1995a) and in cuttlefish a counter-shading reflex (Ferguson *et al.* 1994).

### Equilibrium receptor organs

A tremendous body of data has accumulated over the past 40 years on the anatomy, ultrastructure and physiology of the cephalopod equilibrium receptor organs (statocysts), which include sophisticated receptor systems for the detection of linear (gravity) and angular accelerations (Budelmann *et al.* 1987; for summaries, see Budelmann 1990; Budelmann *et al.* 1997; for the *Nautilus* statocyst, see Neumeister & Budelmann 1997). Special emphasis has been paid to the similarities between the structure and function of the cephalopod and vertebrate hair cells (eg, Budelmann & Williamson 1994; Budelmann 2000), including their ion channels and efferent innervation (Williamson 1995) and transmitter and transmitter-like substances; the latter include nitric oxide (Tu & Budelmann 2000) and cannabinoids (Tu & Budelmann, unpublished). Cephalopod statocysts are known to drive a sophisticated control system for compensatory eye movements; part of its central organisation resembles that of the vertebrate vestibulo-oculomotor reflex pathway and involves four (*Nautilus*), seven (octopods), or 13–14 (cuttlefish and squids) extra-ocular eye muscles (Budelmann & Young 1984, 1993; Neumeister & Budelmann 1997).

### Epidermal lines

The epidermal lines (formerly known as 'Drüsenlinien') that occur on the head and arms of at least some of the coleoid species are analogous to the fish and aquatic amphibian

lateral line systems (Budelmann & Bleckmann 1988; Budelmann *et al.* 1997).

### Neck proprioceptive organ

Similar to the vertebrate neck muscle proprioceptors, cuttlefish and squid have groups of epidermal hair cells on their neck that serve as a proprioceptive neck organ for the control of the position of the head relative to the body (Preuss & Budelmann 1995b).

### Vibration receptors and hearing

Cephalopods are sensitive to vibrational stimuli via statocyst receptors and sense local water movements with their lateral line analogue system (Budelmann & Bleckmann 1988; Williamson 1988; Packard *et al.* 1990; Bleckmann *et al.* 1991; Komak *et al.* 2005). On the other hand, there is much confusion regarding cephalopods ability to 'hear'. Ultimately, this is a semantic issue since the answer depends on the definition of underwater sound and underwater hearing (Budelmann 1992). In conventional terms, cephalopods cannot hear because they do not have a receptor system that is specialised for the detection of the pressure wave of underwater sound.

### Maintenance, culture and laboratory procedures

With the growing interest in cephalopods for research and commercial mariculture, as well as their popularity in public and private displays, knowledge about the maintenance, culture and proper laboratory procedures is of increased importance (Oestmann *et al.* 1997; Sykes *et al.* 2006; Dunlop & King 2008). For advice on optimising the survival of hatchling cuttlefish and squid, see Forsythe *et al.* (1994), Vidal *et al.* (2002a, 2002b) and Sykes *et al.* (2003). With regard to culture density, recent cuttlefish data show that lower stocking density results in better growth (Domingues *et al.* 2003; Correia *et al.* 2005), as does higher water temperature (25°C compared to 17°C; Forsythe *et al.* 2002). On the other hand, lower temperature (15°C compared to 27°C) extends the life cycle (Domingues *et al.* 2002). For the development of memory in cuttlefish, an enriched environment is crucial during their second and/or third months of life (Dickel *et al.* 2000). Crowding of adult cuttlefish should be avoided since it stimulates aggression (Boal *et al.* 1999).

Not surprisingly, the quality and composition of food has been proven to be critical for good growth and survival. Adult cuttlefish show much better growth rates when fed with live or thawed natural prey than when fed with an artificial diet (Domingues *et al.* 2005). Shrimp-based food pellets, although less palatable, produce maintenance growth, whereas a highly palatable fish-based surimi diet (mimicking the meat of lobster, crab and other shellfish) results in poor survival (Castro *et al.* 1993). When fed with live mysid shrimp, grass shrimp, or fish fry, young cuttlefish showed best growth during the first week after hatching when fed with mysid shrimp, and thereafter when fed with grass shrimp; cuttlefish fed with fish fry showed lowest growth rates at all times (Domingues *et al.* 2004). When prey

is maintained for feeding juvenile cuttlefish, prey starvation should be avoided (Correia *et al.* 2009). Although *Sepia* shows an innate food preference, early familiarisation with other food can override this preference (Darmaillacq *et al.* 2006). For the importance of certain elements (including copper and strontium) in the food of octopus, cuttlefish and squid, see Koueta *et al.* (2002) Villanueva and Bustamente (2006) and Iglesias *et al.* (2007).

A comprehensive monograph is now available on invertebrate medicine that includes a chapter on cephalopods (Lewbart 2006) and ethical and welfare considerations for working with cephalopods have recently been summarised (Mather & Anderson 2007; Moltschanivskyj *et al.* 2007).

### Occupational health hazards

Many octopus and, particularly, cuttlefish and squid species may bite, specifically when stressed, disturbed or improperly handled. Their sharp, parrot-like beaks can inflict significant wounds and the saliva can have a variety of toxic effects. The tetrodotoxin-like venom of the Australian blue-ringed octopus (*Hapalochlaena maculosa*) can be lethal to humans (Williamson *et al.* 1996, for a review).

### Cannibalism

Cannibalism is well known in octopuses, cuttlefish and squids when held in captivity. Obvious reasons include a too high stocking density and an inadequate amount of food and shelter. Specifically, when food supply is limited and feeding *ad libitum* becomes a problem, larger animals may prey upon smaller ones when kept in the same tank. In addition, sexual cannibalism has been described in an octopus species on a coral reef (Hanlon & Forsythe 2008).

### Autophagy

Some data (other than anecdotal) are now available on autophagy (self eating) in *Octopus vulgaris*. They suggest that it is caused by either a substance that is released by the animals themselves or, more likely, by viruses or bacteria; stress may contribute to this behaviour but does not seem to be its primary cause (Budelmann 1998).

### Further information and reading

A large number of references to the literature on cephalopods are available from the library service of the Smithsonian Institution Research Information System at <http://sirismm.si.edu/siris/siris-cephalopod.htm>.

The following web pages provide very useful information regarding all major aspects of cephalopod biology, supply and maintenance, rearing, culture and breeding and laboratory procedures (with regard to the scientific accuracy, however, general caution must be taken because of its lack of peer review):

# Cephalopods *Reproduced from the 7<sup>th</sup> Edition*

Peter R. Boyle

---

## General introduction

The popular perception of the cephalopods is represented by the coastal octopus, cuttlefish and squid. These large and active molluscs have a complicated behavioural repertoire. Living in diverse marine habitats they show a wide range of behavioural expression during prey capture, feeding and reproduction. Many parallels with vertebrate behaviour patterns can be recognised, such as hunting, sexual display, attention, conflict and concealment behaviours. In the laboratory, numerous experimental studies have described their remarkable capabilities of sensory discrimination, especially of visual stimuli. They have demonstrated that true learning occurs and is likely to be an integral part of the normal life of an octopus. These qualities of behavioural complexity, sensory discrimination and learning in cephalopods bear comparison with those of many lower vertebrates, and provide ample cause for considering their welfare in the laboratory for humane and scientific reasons.

The anatomy and physiology of cephalopods are very different from those of the vertebrates, so that it is necessary to include considerably more information about their general biology than for the vertebrate subgroups. Historically cephalopods have been considered as difficult animals to keep in captivity, and only relatively recently has much critical attention been given to the necessary handling and maintenance conditions. With even the most commonly held species we are still on a steep learning curve and guidance can be given here only on the general requirements. Precise details will usually have to be left to the judgement of the person responsible and will be to some extent determined by individual experience.

Since 1991, when the UFAW Handbook on the Care and Management of Cephalopods in the Laboratory (Boyle 1991) was first published, the legal position concerning experimental studies on cephalopods in the UK has been altered by the addition of *Octopus vulgaris* to the list of species covered by the *Laboratory Animals (Scientific Procedures) Act 1986* (Home Office 1986a). The effect of this change is that no procedures likely to cause recognisable pain or suffering may be carried out on *Octopus vulgaris* in the UK without valid Personal and Project Licences issued by the Home Office. This species, *Octopus vulgaris*, is the first invertebrate animal for which formal licensing procedures are required in the UK, and the legal position may change in the future simply by the inclusion of additional species to the list

covered by the 1986 Act. The European Union, and possibly other countries, are also considering legislation in this area, and consultation with the relevant authorities will be advisable before commencing any work on cephalopods likely to fall within its scope.

As members of the phylum Mollusca, the cephalopods share certain basic features of their body organisation with the gastropods, bivalves and other molluscs. Molluscs typically produce a hard calcareous shell to protect the body, but the shell originally present in the cephalopods is greatly reduced or lost in the modern forms, as it is in some other molluscan lines, such as many marine gastropods and the terrestrial slugs. The radula, a ribbon of chitinous teeth which functions in gastropods and chitons as a versatile feeding organ for rasping or scraping, is one of the most characteristic molluscan features. It is present, too, in all cephalopods, although its role in feeding may be subsidiary to other structures. Standard invertebrate texts (Russell-Hunter 1979; Barnes 1980; Brusca & Brusca 1990; Willmer 1990) and molluscan reviews (Solem 1974; Yonge & Thompson 1976; Wilbur, 1983–1988; Boyle 1981b, 1987b) will give access to the general features of molluscan organisation and the special points of comparison between cephalopods and other molluscs.

Cephalopods are generally large animals; however, some species attain only very small adult body sizes such as the pygmy octopus (*Octopus joubini*) at 30g total body weight or 40mm mantle length (ML) (Hanlon 1983). Others reach exceptionally large sizes such as *Octopus dofleini*, commonly over 50kg in weight (Hartwick 1983), and the occasional specimens of the giant squid (*Architeuthis* sp.) which have been reliably estimated at 450kg or 18m length overall (Roper & Boss 1982). Typically, however, specimens required for laboratory use will be in the size range 0.25–2.5kg in weight, and thus require substantial space provision and water flow. They are also active and mobile animals. Squids swim constantly by jet propulsion or hover midwater using lateral fins. The octopuses, although generally bottom-dwelling, are very exploratory and prone to escape from tanks. All cephalopods are voracious predators, and with few exceptions will take only living prey. These characteristics of size, activity and predatory habits mean that cephalopods impose many more demands on aquarium space and resources than other molluscs.

Human interest in, and relationship to, cephalopods is of long standing. The classical civilisations of the Mediterranean

had a good knowledge of the various types. Representations of octopus, squid and cuttlefish are commonly found on glazed pots and mosaics of the Greeks and Romans. Aristotle (ca. 330 BC) gave clear descriptions of many aspects of their biology, including details of the specialised mating of the octopus. From mediaeval times to the end of the nineteenth century, however, cephalopods were more likely to be regarded with awe and suspicion as hostile sea creatures capable of sinking ships and drowning sailors. Many of these stories probably resulted from fearfully exaggerated accounts of rare encounters with giant squids. Lane (1957), and to a lesser extent Cousteau and Diolé (1973) provide popular introductions to the general biology of cephalopods and fascinating insights into their interactions with people.

In modern times, numerous aspects of cephalopod biology have been the subject of laboratory research, and cephalopod material has proved exceptionally valuable for studying basic properties of nerve function. Commercial fisheries are operating on a substantial scale and currently about 3 million tonnes are caught annually. Pilot trials to assess mariculture potential have also taken place. These interests have led to a series of review books and workshops in recent years which form the basis for further reading in the cephalopod literature (Messenger & Nixon 1977; Wells 1978; Roper *et al.* 1983; Boyle 1983a, 1987a; Hanlon 1988a; Okutani *et al.* 1993; Boyle & Boletzky 1996; Hanlon & Messenger 1996). Detailed knowledge of their biology and the availability of animals in captivity are still restricted to a few species studied at a relatively small number of institutions. Insights into their life in the wild are even more limited, but are rapidly being improved through the use of underwater video by divers and from submersible vehicles. Although some generalisations about their biology and requirements are possible, these are based on a narrow range of studies and there is much to learn.

We should remember that the majority of cephalopods are offshore and deepwater animals. Probably their range of behaviour patterns and levels of sensory discrimination and activity are quite different from those of their coastal and surface-dwelling relatives. The inclusion of the class Cephalopoda, though, into the remit of this *Handbook* must show that generally more attention is being given to the requirements of invertebrates in captivity. While this may lead to greater demands on the scientists and technicians who need to maintain the variety of animal types currently held for laboratory work, the encouragement to maximise their health and survival must have positive benefits both to the animals concerned and the resulting research.

## Cephalopod biology

### Evolution and classification

Cephalopods as a molluscan class arose early in the Silurian period with distinctive, heavy, external shells (ectocochleate) and are well represented in the fossil record. Some of these shells were very large, reaching 2m across in the case of coiled forms or as straight shells as much as 10m long (Lehmann 1981). Over 10000 species are described from fossils, mainly in the subclasses Nautiloidea and

Ammonoidea. These early types are represented today only by a few species of the single genus *Nautilus* (Figure 50.1). The remaining nautiloids and all of the ammonoids are extinct.

Modern cephalopods, in which the shell remnant is greatly modified or absent completely, appeared relatively recently and all belong to the subclass Coleoidea (Figure 50.1). In Table 50.1 a synopsis of the classification of living subclasses of cephalopods and the main orders of Coleoidea is given, together with a brief description of their characteristic features. The accepted terminology of the external features of cephalopods and diagrammatic representations of the internal anatomy of *Nautilus* and each of the three common living cephalopod types are shown in Figures 50.2–50.5.

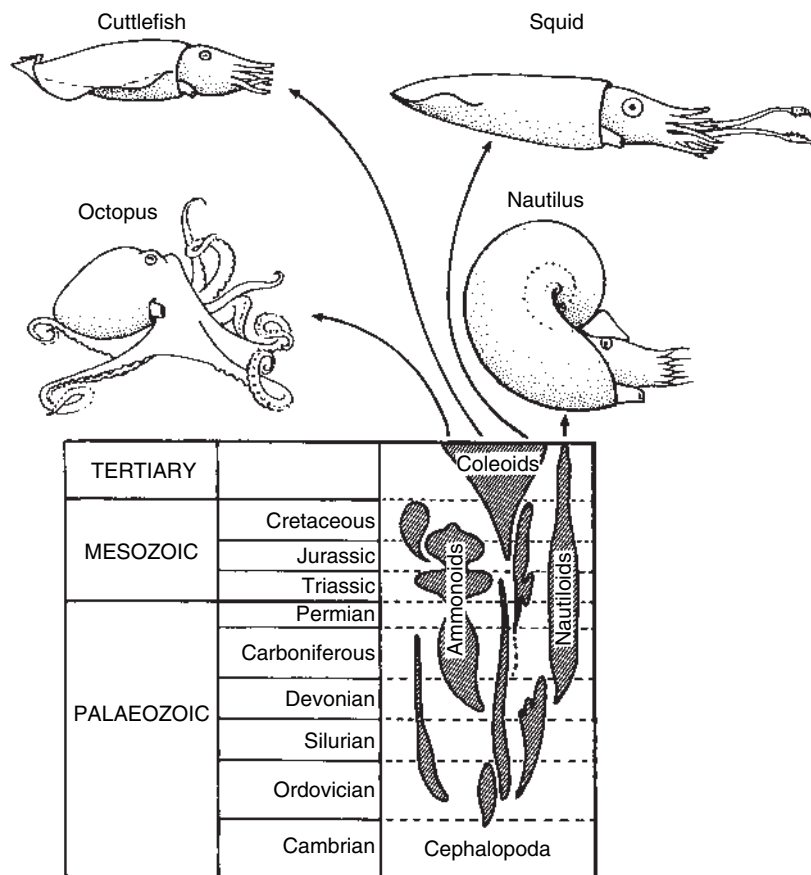

Approximately 650 species of living cephalopods are known (Voss 1977a), a small fraction of the total fossil fauna. The number of species is very unevenly distributed among genera and families. As Voss (1977a) points out, the two genera *Octopus* and *Sepia* are each credited with over 100 species. A few other coastal genera may have an appreciable number of species, for example *Loligo*, but the remainder are scattered throughout a large number of diverse families of mainly deep-sea distribution. This situation has given rise to the speculation that the original cephalopod fauna may have become restricted to the relatively unfavourable habitats of the deep sea (mesopelagic) through competition with the teleost fishes. Only when the lighter, faster, more active coleoid forms evolved were they able to reinvade the more productive coastal and upwelling marine zones. Many of the characteristics of common cephalopods can be interpreted in terms of competition and parallel evolution with fish (Packard 1972). The practical consequences of this situation are that most of our knowledge of cephalopod biology has been gained from relatively few types which, although common and available, may not be particularly representative of the full range.

### Habitat and distribution

Cephalopods are exclusively marine. The squid *Lolliguncula brevis* of the Gulf of Mexico is one of the very few species known to tolerate sea water of lowered salinity (>24 parts per thousand) but cephalopods generally must be regarded as stenohaline.

The few species of *Nautilus* have distributions in the Indo-Pacific region. *N. macromphalus* lives in deep water off the reef edge. Although most common in water of 300–500m, they are caught in traps between 600m and the surface (Ward 1983). They are relatively sluggish animals, relying on the strength of their shell for protection against predators. In the aquarium, eggs are laid attached to a hard substrate, and in the field the adults are found to have been eating benthic crustacea; both of these observations suggest that their normal life is close to the bottom. In recent years, there has been considerable interest in these animals as representatives of a mainly extinct type, and much success in keeping them in aquaria. They are subject to significant fishing pressure in certain localities, and there is some concern for conservation. Ward (1987) gives a comprehen-

**Figure 50.1** Diagrammatic representation of the evolution and radiation of the modern cephalopod types (partly from Packard 1972; Boyle 1981b).

**Figure 50.2** Generalised anatomy of *Nautilus*.

sive account of their biology, and a range of scientific studies is reviewed in Saunders and Landman (1987) and O'Dor *et al.* (1993).

The octopuses (Order Octopoda) are represented by a number of families, only one of which is bottom-dwelling (Table 50.1). It is this family, the Octopodidae which, nevertheless, includes all of the common species and those suitable for laboratory work. Coastal octopuses are common and have worldwide distribution. They are epibenthic, living on or close to the bottom. Normally, they are associ-

ated with stony or rocky habitats where they can both shelter and find a wide range of invertebrate food sources. In fact, many octopus species also live widely distributed over mud or sandy bottoms. By reason of their natural use of holes and crevices, octopuses are by far the most adaptable and amenable cephalopods to hold in captivity.

Cuttlefishes (order Sepioidea) are also characteristic of coastal water. Like octopuses they are active, bottom-dwelling predators which, instead of hiding amongst stones and rocks, are able to bury themselves in the sediment using lateral fins to excavate a depression and to flick sand over their dorsal surface. The best known genus, *Sepia*, the cuttlefish, is also able to 'hover' above the surface, achieving neutral buoyancy from the gas space enclosed in the shell remnant, the 'cuttlebone'. They are widely kept in aquarium conditions. Cuttlefish are common in coastal waters of most temperate and tropical zones, but are not found anywhere in American continental waters (Voss 1977a). They are often loosely referred to as 'squids', but this is inaccurate and the term 'squid' should be confined to members of the order Teuthoidea unless qualified as 'sepoid squid'.

The true squids (order Teuthoidea) are a very large and diverse assemblage of families which differ widely in habitat and distribution. Two suborders are recognised (Table 50.1), both of which include species of importance to commercial fisheries. The Myopsida are typified by squids of the genus *Loligo*. They are relatively inshore squid, sometimes of great seasonal abundance, laying egg masses attached to the

Figure 50.3 Generalised anatomy of a female octopus.

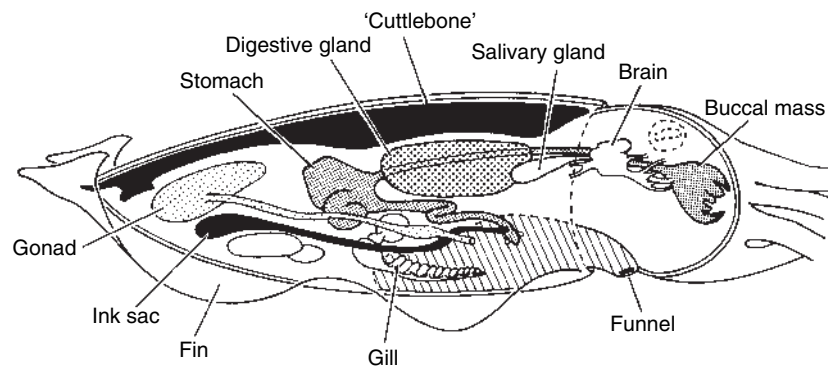

Figure 50.4 Generalised anatomy of cuttlefish.

Figure 50.5 Generalised anatomy of squid.

bottom and completing their life cycle in coastal water. The Oegopsida includes a great many families ranging from obscure deepwater species whose biology is almost unknown, to genera such as *Todarodes* and *Illex* which are characteristic of areas of nutrient-rich upwellings such as the edges of the continental shelf. The oegopsids are migratory over large distances, apparently laying large, amorphous, neutrally buoyant egg masses, and completing their whole life cycle in oceanic water. The squids also are active predators, hunting fish and crustacea in the water column and on

the bottom. This leads to large populations spreading over the continental shelf zones in annual feeding migrations where they may be subjects of important commercial fisheries (Okutani *et al.* 1993). Due to their active lifestyle, rapid swimming and substantial space requirements, there are relatively fewer opportunities for keeping squid alive and healthy in laboratory conditions although some, such as the Caribbean Reef squid (*Sepioteuthis sepioidea*) (Moynihan & Rodaniche 1982), family Loliginidae, are increasingly held in laboratory and public aquaria.

**Table 50.1** Synoptic classification of the class Cephalopoda, listing subclasses, orders and suborders of recent forms and some common genera.\*†

Class Cephalopoda All marine molluscs; bilateral symmetry; well developed coelom; primitively a chambered, external shell, reduced in modern forms. Radula enclosed within chitinous mandibles; ring of prehensile appendages surround the mouth; 1 or 2 pairs of gills; water circulation in mantle cavity expelled through ventral funnel tube for jet propulsion. Centralised nervous system: highly organised sense organs; complex behaviour. Sexes separate; fertilisation internal; sperm contained in complex spermatophores; eggs large and yolky; direct development (no veliger)	<i>Sepia</i> (fam. Sepiidae) <i>Sepiolo</i> (fam. Sepiolidae) <i>Euprymna</i> (fam. Sepiolidae) <i>Sepietta</i> (fam. Sepiolidae)
<b>Subclass Nautiloidea</b> Cephalopods with heavy external chambered shells which may be straight or coiled. Appeared in the Cambrian period and became very numerous in species and individuals throughout warm seas. All now extinct except for one family, the Nautilidae, with restricted distribution in the Indo-Pacific Oceans. Typically for ectocochleate cephalopods the body occupies the terminal chamber of the shell which also acts as a buoyancy organ. Retraction of body into shell displaces water from mantle cavity for jet propulsion. Two pairs of gills and nephridia; head with numerous unsuckered appendages <i>Nautilus</i> (fam. Nautilidae)	<b>Order Teuthoidea</b> Shell reduced to chitinous 'pen' (gladius) lying dorsally. Elongate body usually finned; 8 suckered arms, 2 long tentacles with suckered club; suckers pedunculate and with horny rims, some with hooks. Squids Suborder Myopsida (with transparent corneal membrane) <i>Loligo</i> (fam. Loliginidae) Suborder Oegopsida (without corneal covering), a large assemblage with many families <i>Gonatus</i> (fam. Gonatidae) <i>Illex</i> (fam. Ommastrephidae) <i>Todarodes</i> (fam. Ommastrephidae) <i>Dosidicus</i> (fam. Ommastrephidae) <i>Teuthowenia</i> (fam. Cranchiidae)
<b>Subclass Ammonoidea</b> Chambered external shells, usually coiled and with complex septa and sutures separating the chambers. Very numerous from the Devonian to the Cretaceous periods but now all extinct	<b>Order Octopoda</b> Internal shell drastically reduced and split into two lateral rods. 8 arms only with non-pedunculate suckers. Globular body with or without fins. Octopuses Suborder Cirrata (arms bearing cirri) Deepwater forms with fins Suborder Incirrata (no cirri) A large group with several pelagic families, without cirri and fins. The common octopods dealt with in this volume all belong to the only benthic family <i>Octopus</i> (fam. Octopodidae) <i>Eledone</i> (fam. Octopodidae) <i>Bathypolypus</i> (fam. Octopodidae)
<b>Subclass Coleoidea</b> Modern forms, Devonian period to present. Shell internal and reduced. Muscular fins (absent in incirrate octopods) and muscular mantle forming a sac enclosing the viscera. One pair of gills and kidneys; large mantle cavity; ink sac typically present; skin containing pigment organs, chromatophores, variably expanded by neuromuscular control <b>Order Belemnoidea</b> Internal shell straight and with a solid posterior portion; commonly fossilised; all extinct <b>Order Sepioloidea</b> Calcareous chambered shell present internally and functioning as a buoyancy organ in some ( <i>Spirula</i> , <i>Sepia</i> ); shell greatly reduced to a purely organic pen in others (Sepiolidae, Idiosepiidae); 8 suckered arms, 2 long tentacles with suckered club; suckers pedunculate with horny rims. Includes cuttlefish and sepioids	<b>Order Vampyromorpha</b> 8 long arms united by a swimming web, 2 small tendril-like arms in dorso-lateral position

\*For a full list of recent genera refer to Voss (1977b).

## Locomotion

All cephalopods make use of a form of 'jet propulsion' in addition to other forms of locomotion. This is achieved by the rapid expulsion of water from the mantle cavity, forcing the animal to move in the opposite direction through the water in a series of jerks.

In *Nautilus* alone, jetting is achieved by the muscular retraction of the body into the terminal chamber of the shell, which displaces water through a fold in the edge of the mantle cavity. In the coleoids, the mantle cavity is enclosed by a flexible muscular wall. There are several orientations of muscle fibres within the mantle musculature (Ward &

Wainwright 1972) which drive the regular inhalent and exhalent ventilatory movements. When water is expelled forcibly, the relatively small cross-sectional area of the funnel gives the jet considerable force and propels the animal in the opposite direction. Maximum velocities for jet propulsion of up to 0.35 m/s have been estimated from laboratory data (Trueman 1975). In the field, swimming speeds of over 20 knots (37 km/h) are known for squid (Trueman & Packard 1968; Packard 1969). The funnel of the coleoids is also capable of being directed backwards as well as forwards, and from side to side, giving considerable manoeuvrability. Generally, the coastal octopods and sepioids (*Sepia*) swim only when actively escaping or making hunting

attacks. The squids, though, are negatively buoyant in the water column and swim continually. Lateral fins in sepoids and squid have an important role in maintaining or controlling orientation during locomotion. Delicate undulatory movements of fins alone are also used for small movements or during hovering.

The normal locomotion of octopods on the bottom is a fast relaxed scrambling or slower, exploratory walking, using the arms and suckers. Muscle orientations in the arms are very complicated (Keir 1982) and, coupled with the hydrostatic spaces provided by the vascular system, permit an unparalleled range of movement. The suckers, which are present along the full length of each arm as a single (*Eledone*) or double row (*Octopus*), can exert a powerful holding force on substrate or prey, up to 100 times body weight (Trueman & Packard 1968). The strength and speed with which arms and suckers can be used make the octopus both a powerful predator and a potentially difficult animal to catch and handle.

### Shell and buoyancy

The shell of *Nautilus* is divided into a series of chambers by calcareous septa or partitions (Figure 50.2). Sections of the fossil ammonites and nautiloids also show a series of internal partitions, and it is presumed that the role of the shell in *Nautilus* is similar to that in the fossil groups. The shell is heavily calcified and protects the animal from predatory attacks by large fish. Evidence from broken and repaired shells, in both modern nautiloids (Saunders *et al.* 1987; Ward 1987) and fossil ammonites (Lehmann 1981), points to an important role for the shell, albeit not always completely effective, in defence against their predators.

The body of *Nautilus* occupies only the last and largest chamber of the shell. With growth, the shell enlarges at the free edges and internal partitions form successively. The space enclosed by the internal partitions of the shell is partly gas space and partly fluid-filled. The gas is a mixture closely related to the composition of air and contained at a pressure of around 0.7–0.9atm (Denton 1974). This gas space is normally sufficient to reduce the average density of the *Nautilus* to that of the surrounding sea water (relative density 1.025–1.029). In other words, the positive buoyancy contributed by the gas space just balances the sinking tendency of the animal's tissues and the heavy shell. Since the rigid shell resists the hydrostatic pressure of the surrounding water, the pressure and volume of the contained gas space is independent of depth. *Nautilus* can therefore remain neutrally buoyant throughout its depth range without making significant changes to the mass of the contained gas. A strand of living tissue, the siphuncle, connects the body of the animal to the fluid column contained in the chambers and allows minor adjustments of the gas space to be made by alterations in the osmotic differential between the body fluids and chamber fluid (Denton & Gilpin-Brown 1966). The physiology of the cephalopod buoyancy system differs profoundly from that of the teleost fish (Denton & Gilpin-Brown 1973; Denton 1974).

All the modern cephalopods (Coleoidea) have lost the external shell and its protective functions. Instead they rely

on their abilities to alter the pattern and texture of the skin to disguise themselves to an extraordinary degree, and on rapid locomotion for escape. Remnants of the ancestral shell remain. In sepoids such as the cuttlefish (*Sepia*) and the open-ocean sepolid (*Spirula*), the internal chambered shell also functions as a buoyancy device (Denton & Gilpin-Brown 1961a, 1961b, 1971; Denton & Taylor 1964) allowing *Sepia* to 'hover' motionless before darting forward to strike a prey organism.

The squids have no gas-filled spaces and most of the surface-living 'muscular' forms need to swim continually. The shell is reduced further to a chitinous rod, the 'pen' or gladius, lying dorsally in the mantle which gives rigidity during the convulsive contraction phase. A number of deep-water forms achieve neutral buoyancy by reduction in the protein content of their tissues and accumulation of a low-density solution of ammonium chloride (Denton *et al.* 1969). Octopuses have no significant remnant of the shell, although possibly it is represented by chitinous 'stylets' located in the mantle on either side. These occur where the head retractor muscles insert into the mantle musculature and where they form an anchorage point for the muscles.

### Feeding and digestion

All cephalopods actively catch and eat live prey. A very wide range of prey items has been recorded (for reviews see Boletzky & Hanlon 1983; Nixon 1987; Rodhouse & Nigmatullin 1996). Generally, sepoids take crustacea living on or near the bottom, while squid eat mostly crustacea and fish. In both these groups hunting is essentially visual (Messenger 1968, 1977). The cephalopod manoeuvres into a position from which it can strike at the prey by very rapid extension of a pair of tentacles coupled with a rapid jet-propelled forward lunge. These tentacles are suckered only at the tips (tentacular clubs), unlike the eight arms which are usually suckered along their full length. Once trapped, the prey is drawn in towards the mouth and bitten into by the chitinous beaks (mandibles). Bite-sized pieces of flesh are swallowed. Squid feeding in a shoal of fish will often only take one or a few bites before releasing one and catching another (Bradbury & Aldrich 1969).

Octopods feed on a greater variety of prey species, and their diet is probably determined as much by prey availability as predator preference (Ambrose 1983, 1984). Large crustacea such as lobsters and crabs are taken, and octopuses may be significant predators on commercial crustacean fisheries (Boyle *et al.* 1986). Molluscs, worms, fish and other groups are also frequent in the normal diet, but not commonly fed in the aquarium. Octopus prey is also located visually (Wells 1962, 1978) but chemical cues also probably have a role (Wells 1963; Boyle 1983c, 1986a; Chase & Wells 1986).

After capture by an octopus, crustacean and molluscan prey are dealt with in a lengthy and complicated way. Characteristically, flesh is removed from the exoskeleton or shell very cleanly (Arnold & Arnold 1969; Wodinsky 1969; Altman & Nixon 1970). Partly this could be due to delicate movements of the beaks, radula and suckers, but it is generally accepted that octopuses also use secretions from the

posterior salivary glands to immobilise the prey and probably to loosen tissues by extracellular enzymic digestion (Nixon 1979, 1980, 1984; Boyle & Knobloch 1981; Nixon & Boyle 1982; Grisley & Boyle 1987; Boyle 1990; Grisley *et al.* 1996).

After ingestion, the already fragmented meal enters a rather short digestive tract consisting of a crop, stomach, caecum and intestine. Some digestion takes place within the lumen of the gut, but most digestion and absorption take place in the large digestive gland (Boucaud-Camou *et al.* 1976; Boucher-Rodoni & Mangold 1977; Boucaud-Camou & Boucher-Rodoni 1983; Boucher-Rodoni *et al.* 1987). Entry into the gland of food particles and the egress of excretory material into the gut lumen occur through a pair of short ducts connecting the digestive gland to the junction of the stomach and caecum. Long strings of pigmented faeces (the residues of the digestive process, usually pink-brown depending on diet composition) bound by mucus, are released from the anus into the exhalent water flow.

### Excretion

Digestive excretion occurs by the release of pigmented material from digestive gland cells into the lumen of the gut (Boucher-Rodoni *et al.* 1987). Excretion from the blood system occurs via excretory tissue surrounding the lateral venae cavae (Schipp & Boletzky 1975). The main venous return from the anterior part of the body, the anterior vena cava, divides into two lateral venae cavae before entering the branchial heart of each side. The excretory cells (kidney tissues) are grouped into flocculent masses (renal appendages) sited on fine diverticulae of the lateral venae cavae. The urine is formed, probably by ultrafiltration and secretion, into a coelomic pericardial space, from which it drains into the mantle cavity through a short duct and renal papilla. Little is known about the composition and flow of urine.

A remarkable feature of the excretory organs of many cephalopods is their infestation by minute organisms, the dicyemid mesozoans. The relationship is apparently symbiotic, causing no harmful effect to the host and providing the only known habitat for the mesozoans.

### Respiration and circulation

Respiratory exchange with the environment occurs through well vascularised gills suspended in the mantle cavity. In *Nautilus* there are two pairs of gills, but in all the coleoids there is only a single pair (dibranchiate). Due to the orientation of gills within the lumen of the cavity, water flows between the lamellae of each gill in the opposite direction to the flow of blood through the tissue, a countercurrent system which maximises the exchange of gases (Wells & Wells 1982).

Measurements of metabolic rates of cephalopods vary widely. This is partly because of the wide range of species and temperatures which are compared, and because of the inherent difficulty of obtaining a non-active or routine value for oxygen consumption in these animals. Figures collected by O'Dor and Wells (1987) and Wells and Clarke (1996) from

many sources suggest routine oxygen consumptions mostly in the range 100–500 mlO<sub>2</sub>/kg/h for squid and 10–100 mlO<sub>2</sub>/kg/h for octopuses. The smaller number of estimates for sepioids and *Nautilus* fall within the octopus range. Two factors substantially increase the metabolic rate. Swimming or other violent movements rapidly increase metabolic rate to two to three times the resting value as do the energy demands of digestion in the 6–8 h following a meal (O'Dor 1982; Wells *et al.* 1983a, 1983b, 1983c).

Oxygenated cephalopod blood is blue-coloured due to the presence of the copper-containing respiratory pigment haemocyanin. This high molecular weight compound (>10<sup>6</sup> daltons) is in solution and not contained within specialised cells as is the case with the vertebrate erythrocyte. The circulatory system is a complex arrangement of vessels (arteries, veins and sinuses) through which the blood is driven by several contractile elements (Figure 50.6).

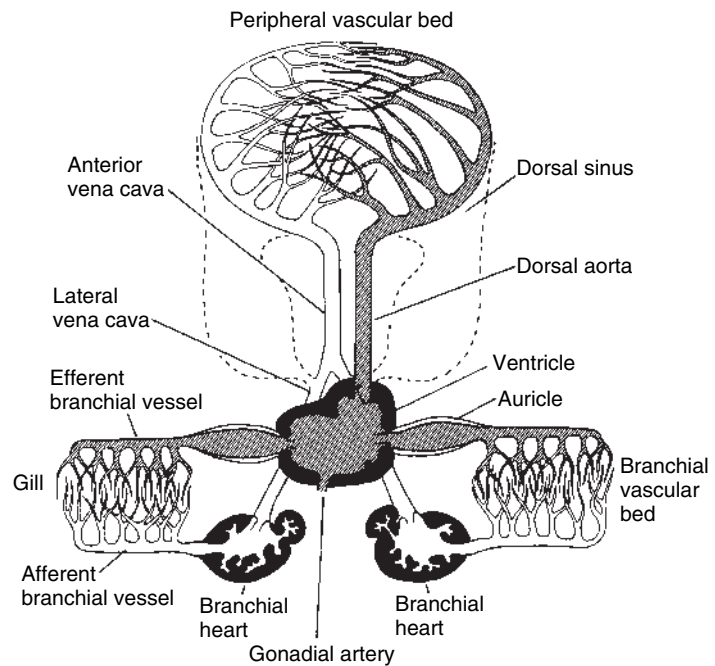

Venous return blood mostly collects into the anterior vena cava. This divides into two lateral venae cavae (surrounded by kidney tissue) supplying blood to the contractile branchial heart of either side, from which the gill is supplied. The lateral venae cavae and gills are also contractile and probably contribute as much to movement of the blood as do the branchial hearts themselves (Smith & Boyle, 1983). From the gill, oxygenated blood enters the auricle of each side and into the heart (systemic heart). This powerful contractile organ is capable of high systolic pressures. It pumps blood out to the tissues mainly through the aorta, but with lesser flows through the abdominal and genital arteries.

### Nutrition and energy

Cephalopod growth rates, in captivity and in the field, are high. Figures for aquarium growth of many cephalopod species (mostly octopods) have been collected by Forsythe and Van Heukelem (1987). At small sizes (<10g) instantaneous growth rates (percentage increase in body weight per day) are around 4–6%, ranging up to a maximum of 12% (*Sepia subaculeata*). At body weights up to 100g, growth rates are lower but commonly in the range 2–4%. In part, these growth rates result from a very high gross growth efficiency (the conversion of food intake to growth). Many authors record growth efficiency values for octopuses in the range 40–60% with extremes of 20–80% on a wet-weight basis.

O'Dor and Wells (1987) and Wells and Clarke (1996) have summarised information on the nutritional requirements and energy requirements for cephalopods. They point out that, even on a calorific basis, the growth efficiency of cephalopods is only slightly less than the wet-weight figures suggest. The diet of cephalopods is highly proteinacious, low in carbohydrates and lipid. In addition, there is some evidence that cephalopods are hardly able to absorb and metabolise lipid. They apparently operate very largely a protein economy in which proteins are the principal energy source as well as providing the basic requirements for growth.

All studies of growth and lifespan suggest that cephalopods of all types (except *Nautilus*) are surprisingly short-lived, perhaps 1–2 years being the average range of lifespan for most of the better known species. In terms of food

**Figure 50.6** Generalised cephalopod circulatory system (after Smith & Boyle 1983).

requirements, O'Dor and Wells (1987) calculate that octopods probably consume 2.5–3 times their body weight over a lifetime. Squid, in contrast, are calculated to need as much as four times their body weight during the first 9 months (O'Dor *et al.* 1980). Their consumption is inevitably higher due to the energy demands of a more active lifestyle and leads to interesting speculations over the fuelling by cannibalism of the long migrations undertaken by many squid species (O'Dor 1988).

### Nervous system

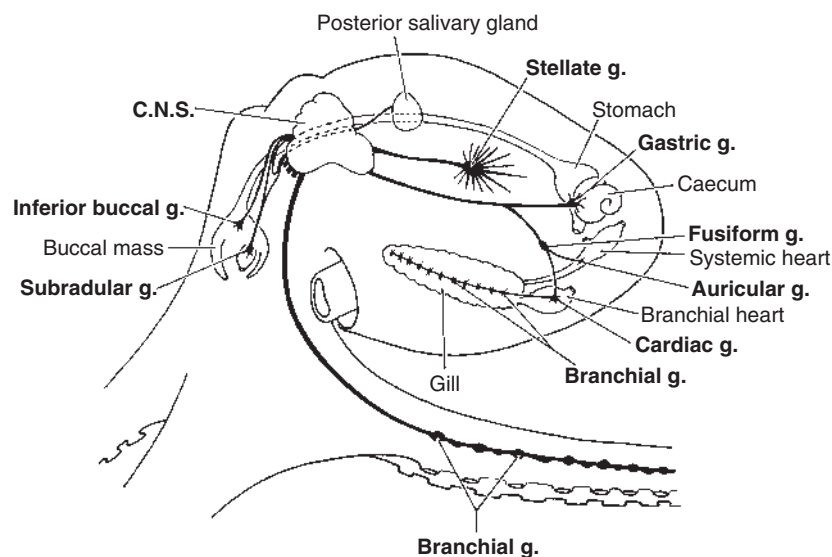

The central nervous system of all cephalopods is a more or less compact mass of nerve cells. This, the brain, is located between the eyes and is enclosed in a tough cartilaginous cranium. For *Octopus* there are an estimated  $1\text{--}2 \times 10^8$  nerve cells. A great deal of information is available on the neuro-anatomy of the system (Young 1971; Wells 1978) and the division of function between the many lobes.

In general terms, the suboesophageal areas of the brain are concerned with the control of groups of muscles. There are clear divisions of function between various lobes, and each of these areas can be identified as lower or intermediate motor centres. Groups of muscles known to be controlled from centres in the suboesophageal brain include those of the arms, mantle, head, funnel, fins and chromatophores. These divisions of function were established largely by stimulation experiments (Boycott 1961) coupled with the results of nerve sections and degeneration (Young 1971). Higher motor centres, which coordinate the actions of several groups of muscles, are located in lateral and supraoesophageal areas of the brain. Some regions are allocated to receptor information and analysis. Most notable of these are the optic lobes, large ganglionic masses located laterally on each side of the brain and receiving large numbers of small optic

nerves. Many of the features of the neural organisation of cephalopods bear comparison with those of the vertebrates (Young 1967, 1971; Packard 1972; Hanlon & Messenger 1996).

In addition to the brain is a series of peripheral ganglionic masses. These are very extensive and contain enormous numbers of nerve cells with functions restricted to the organ systems where they are located. For example, there are an estimated  $3 \times 10^8$  in the nerve cords of the arms alone. The main ganglionic masses in a typical octopod are shown in Figure 50.7. It is important to note that this degree of peripheral nervous organisation confers some degree of local autonomy of movement. Thus, certain movements of the arms (Rowell 1963, 1966), mantle (Gray 1960; Wilson 1960b; Boyle 1976) and buccal mass (Boyle *et al.* 1979a, 1979b) take place in isolation from the central nervous system.

Of great interest to physiologists is the giant fibre system of the squid, a connected assembly of single fibres with diameters of up to almost 1 mm (Young 1939; Martin 1977). Mediating the rapid escape response, the giant fibre system provides simplified nervous transmission from the brain (first- and second-order giant cells) to the stellate ganglion, and from there to the mantle musculature (third-order giant fibres). The significance of this system to the behaviour of squid seems to be threefold (Bullock & Horridge 1965): it is a simple method of triggering a supremely important evasive reaction; use of giant fibres gives an appreciable gain in the speed of reaction; and gradation of the fibre diameter of the third-order giants allows differential rates of conduction and synchronous contraction of the full length of the mantle. The 'giant fibre' commonly referred to is the third-order giant which runs the furthest distance of the mantle. The exceptional size of these fibres has allowed many important advances to be made in understanding the basic properties of nervous transmission (see Tasaki 1989).

**Figure 50.7** Sketch plan of the principal ganglionic masses (g) of an octopus (from Boyle 1986b).

### Sense organs

The skin of cephalopods, particularly of the suckers and lips, is liberally supplied with receptor cells responsive to tactile and chemical stimuli. Octopuses are responsive to a very light touch on almost any part of the surface, and may be taught to discriminate between objects which differ only in the quality of surface texture (Wells & Wells 1957; Wells 1964a, 1964b). Mechanically sensitive cells are known also to be located within the blocks of somatic muscle (Alexandrowicz 1960; Graziadei 1965; Boyle 1976), where they are presumed to play a role in providing the sensory feedback necessary for the control of movement. Chemical senses are also thought to be associated with dispersed single cell receptors.

Discrimination between objects can be made on the basis of chemical differences (Wells 1963; Wells *et al.* 1965) and responses to waterborne chemical stimuli have been described in octopuses (MacGinitie & MacGinitie 1968; Joll 1977; Boyle 1983c, 1986a; Chase & Wells 1986).

Cephalopods have large camera-type eyes placed laterally and dorsally. There is a highly refractile spherical lens which focuses light onto a retina of receptive cells (*Nautilus* operates on the different principle of the 'pinhole' camera). General accounts of cephalopod behaviour, and experimental studies on prey capture (Messenger 1968, 1977), confirm the importance of visual input to cephalopods. There are also well known examples of the role played by visual stimuli in sexual recognition by *Sepia* (Tinbergen 1939; Corner & Moore 1981). Visual acuity is high (Packard 1969) but, rather surprisingly, and after a history of uncertainty, octopuses have been shown to be colour-blind (Messenger 1979).

### Colour and texture

The pigmentation of cephalopod skin is contained within unique cellular chromatophore organs. These consist of an intracellular, elastic sac which contains the pigment, into which is inserted a series of 25 or so muscle fibres arranged

radially (Cloney & Florey 1968). When these muscles contract, the pigment sac is expanded and imparts its colour to the skin surface. When the radial chromatophore muscles relax, the elasticity of the pigment sac causes it to retract to its smallest size. The pigment area is then too small to provide skin colour and the animal appears white by reflection from the muscle surface. The coloured appearance of the cephalopod skin is extended and complicated by the presence of chromatophores of different pigment hues, and by static reflecting bodies deeper in the skin (iridophores, leucophores) which can produce additional colours by differential reflection (Packard & Sanders 1969).

Much attention has been given to the neural mechanism underlying control and coordination of the chromatophores (Florey 1969; Florey & Kriebel 1969; Packard & Sanders 1969; Packard 1973, 1982; Boyle & Dubas 1981; Dubas & Boyle 1985; Hanlon 1982, 1988b). The patterns produced have been classified and related to cryptic or display functions (Packard & Hochberg 1977; Moynihan & Rodaniche 1982; Hanlon & Hixon 1980; Roper & Hochberg 1988; Hanlon & Messenger 1988; Hanlon 1988b). The cryptic functions of pattern display are usually enhanced by modifications to the outline and texture of the octopus by superficial skin muscles. The review of cephalopod behaviour by Hanlon and Messenger (1996) provides a modern synthetic treatment of information on the uses of colour and texture by cephalopods, together with many original photographs and drawings.

Luminescent organs are known from many mid- and deepwater cephalopod species (Herring 1977). Light production is due to symbiotic bacteria located in pockets at specific sites characteristic of each species, or released into the water as a luminescent cloud. Little is known of the control and activity of these organs, but it is commonly held that they have roles in camouflage and/or intraspecific signalling.

### Inking

Typically all coleoids have an ink sac. This is a muscular bladder located ventrally and opening into the exhalant

water flow at the base of the funnel. Discharge of ink usually occurs when the cephalopod is being pursued by a predator. It is not dispersed in the water, but tends to form a discrete dark mass. Its role is not as a screen but as an object to hold the attention of a pursuer while the cephalopod makes a rapid change in direction. This manoeuvre is often effective in gaining the extra few seconds necessary to make an escape. In captivity, startled or stressed animals will frequently eject ink.

## Reproduction

In cephalopods, the sexes are separate (dioecious), and fertilisation is achieved by direct mating. Reviews of the details of reproduction are available by Arnold and Williams-Arnold (1977), Wells and Wells (1977) and Mangold (1987).

In the male, ripe sperm are packaged into complicated spermatophores and stored in a special spermatophoric (Needham's) sac until mating occurs. The male transfers sperm to the female by passing ripe spermatophores along a muscular groove in one arm which becomes modified for this function (the hectocotylus, hectocotylised arm) at sexual maturity. The course of fertilisation then varies among different cephalopod types. Sperm may be held by the female in special pouches at the base of the arms or within the mantle cavity (sepioids and squid), or enter the female genital tract and lodge in the oviducal glands (*Octopus*), or even pass into the ovary itself (*Eledone*). These mechanisms allow the possibility of opportunistic matings and sperm storage in cephalopods. The longest interval between mating and egg laying was recorded in *Octopus tetricus* at 114 days (Joll 1976). Sexual maturation is under the control of hormone(s) released from small bodies called optic glands located on the optic tract (connecting optic lobes to the brain) (Wells & Wells 1959; O'Dor & Wells 1973, 1975, 1978). At the onset of sexual maturity, there is an apparently rapid process of gonad growth, yolk secretion and ripening of accessory glandular systems. After reproduction, both males and females die. The immediate causes of this apparently universal mortality are not clearly understood, but it is as if the sequence of physical changes brought about by the optic gland hormone(s) cannot be reversed. Some direct evidence for this hypothesis is available from experiments in which the optic glands from mature octopuses were excised; their gonads regressed, while feeding and growth was resumed (Wodinsky 1977; Tait 1986).

These consequences of reproduction clearly have profound importance to the survival and lifespan expected of octopuses in captivity and will be discussed in more detail later.

## Supply and maintenance

A standard terminology was adopted by Boletzky and Hanlon (1983) to describe the various phases of holding cephalopods in captivity.

- *Maintenance* Holding wild-caught late juvenile or adult stages at the same approximate developmental

stage for varying periods of time, with no specific intention of growing them to more advanced stages.

- *Rearing* Growing a cephalopod over a certain period of time without reaching production of a second generation.
- *Culture* Growing a cephalopod at least from hatching through the complete life cycle (juvenile and adult stages, sexual maturity, mating and egg laying), to hatching viable young of the first filial (F1) generation.

Although the term culture is also used collectively to refer to the whole process, these aspects of holding cephalopods in the laboratory will be dealt with separately.

## Research and display roles

The most common reason for holding cephalopods in captivity is for scientific research into various aspects of their biology. The previous chapter has outlined some of the many special features of these animals, which are far from being fully understood. Active experimental research in the fields of physiology and biochemistry require supplies of healthy animals to the laboratory. Often these are provided at marine stations where there is good access to wild-caught specimens and they need not be held long in the aquarium.

One advanced and specialised area of investigation involves the use of squid giant nerve axons for research into the basic biophysical mechanisms of nerve action. Giant fibres were first described in *Loligo* by Williams (1909) and rediscovered independently in *Sepia* by Young (1934). For the squid or cuttlefish, the giant fibres form part of the rapid escape mechanism which, by simultaneous contraction of mantle and retractor muscles, ensures maximum jet propulsion. For the experimenter these exceptional cells (almost 1 mm in diameter) have allowed great advances to be made on the electrical and chemical properties of nerve. For several decades, preparations of these nerve fibres have been very productive and there is still steady demand for them at laboratories such as Plymouth and Woods Hole (Gilbert *et al.* 1990).

Laboratory research into processes such as growth, reproduction, feeding and metabolism, needs animals to be held in captivity for substantial periods of time. These aspects of biology, central to understanding the life cycle, have recently attracted more interest. This is due to greater recognition of the ecological role of cephalopods as food for higher trophic levels, such as whales and seabirds, as predators themselves on a wide range of other marine species, and as major commercial fisheries worldwide (Clarke 1966). It is these life cycle and metabolic studies which have resulted in more attention being given to the long-term maintenance of cephalopods which, in turn, is relevant to their fisheries exploitation and potential for commercial mariculture.

Public interest in live cephalopods is always high. Many public aquaria find it profitable to keep some on display (Vevers 1962), particularly large species such as *Octopus dofleini* (Anderson 1987). There is also a limited aquarium trade in small octopus species for the home aquarium market, but the practical difficulties of keeping the animals

from escaping, of supplying live food, and the naturally short lifespan restrict the circle of customers to the real enthusiasts.

### Species held in captivity

Boletzky and Hanlon (1983) collected information on some 45 cephalopod species which had been maintained in open seawater circulation systems. A further eight species could be added which had been kept only in closed (recirculating) systems, and new reports continue to add species which have been successfully maintained (Hanlon & Forsythe 1985; Lipinski 1985; Anderson 1987). At present it is likely that over 60 species have been maintained in laboratory conditions, representing almost 10% of the total number of cephalopod species.

Most of those which have been successfully held in captivity are benthic octopods and sepioids. These orders adapt relatively easily to aquarium conditions, provided water quality is adequately maintained, suitable substrate material is present and appropriate prey are provided. In contrast, few squid species have been kept alive for any period of time. As pelagic animals, adapted to live in open water, they readily dash into the sides of aquarium tanks. Damage to the skin surface resulting from this behaviour is usually the prime cause of early death. Advances have been made in keeping squid species in captivity, but their maintenance is undoubtedly a more demanding and specialised task.

Those species most successfully held in captivity come from a narrow range of coastal genera. Particularly widely kept are the cuttlefish *Sepia* and a range of smaller sepiolids such as *Euprymna*, *Sepioloa*, *Sepietta* and *Rossia*. Many species of *Octopus* and other octopod genera, such as *Hapalochlaena* and *Eledone*, are also readily maintained. Of the squids, most attempts to keep laboratory stocks relate to members of the Lolliginidae, such as *Sepioteuthis*, *Loligo*, *Lolliguncula* and *Alloteuthis*, although some success has been reported for ommastrephid squid such as *Illex illecebrosus* (O'Dor *et al.* 1977) and *Todarodes pacificus* (Sakurai *et al.* 1993).

In most laboratory situations, the choice of species will be determined by the availability of wild-caught animals. Information regarding the worldwide distribution of cephalopod types is available in Roper *et al.* (1983) and Nesis (1987). Other publications which will be helpful in reviewing the species likely to be amenable for laboratory maintenance in a particular region include Boletzky *et al.* (1971), Arnold *et al.* (1974), Boletzky (1974), Boletzky and Hanlon (1983), Hanlon and Forsythe (1985), Hanlon *et al.* (1983), Lipinski (1985), Yang *et al.* (1986) and Anderson (1987).

### Capture methods

All cephalopods have a soft delicate skin surface, easily damaged by any form of mechanical abrasion. They are readily bruised by rough handling, striking against hard objects and excessive muscular stretching. Skin damage, or subcutaneous bruising on any scale, is rarely survived in captivity for more than a few days. It follows that capture

of juvenile and adult forms from the wild results in high mortality, and considerable care is needed if viable animals are to be returned to the laboratory.

Benthic octopods and sepioids are commonly obtained by commercial fishing gear. Trawls of various kinds will catch these species along with a wide variety of other organisms. The majority of cephalopods caught by moving gear will be already dead or too damaged to survive; nevertheless, because these commercial gears are readily available they still provide the main source of supply at many laboratories. Despite the disadvantages, many studies on aquarium-maintained octopuses (Mangold & Boletzky 1973; Boyle 1981a), sepioids (Boletzky *et al.* 1971) and squid (Hanlon *et al.* 1983; Hulet *et al.* 1979; Lipinski 1985) have been based on trawl-caught specimens. Commercial trawl gear is generally too large, the hauls of too long duration, and their contents too mixed, to capture cephalopods in good condition. Better results will be obtained using, for example, small beam trawls for short hauls (15–20 minutes).

For octopods, the use of traps or pots is much better. In shallow water, fishermen frequently set lines of earthenware pots on the bottom specifically to capture octopuses. Because of the natural tendency for octopuses to establish 'homes' and because natural shelter is limited, they tend to take up residence in the pots. When the pots are lifted at intervals of 2–3 days the octopuses may be captured undamaged. Although principally a method of artisanal fishing, pot-caught octopuses provide the main supply of specimens at major laboratories such as the Zoological Station, Naples. As active predators, octopuses also tend to enter the traps set commercially for crustacea such as crabs and lobsters. Cephalopod predation on trapped crustacea may be a significant commercial nuisance (Ritchie 1972; Boyle 1986c; Boyle *et al.* 1986), but it also provides a means to capture undamaged octopuses.

A small number of species in warm, temperate and tropical areas useful for laboratory studies may be hand collected on the shore in pools or under rocks. Hand collection underwater by SCUBA diving is also an effective method in certain locations.

Methods for the commercial capture of squid are diverse, highly evolved and vary in different parts of the world. They include the use of bottom and pelagic trawling, seine nets of various types, gill nets, lift nets, traps and wide use of jigging lures, both with and without the use of lights. Specialised reviews such as those of Hamabe *et al.* (1982), Rathjen (1984), Roper *et al.* (1984) and Rathjen and Voss (1987) should be consulted for details. Although some trawl-caught squid may be suitable for maintenance in aquarium conditions (Lipinski 1985) the best specimens will be obtained by the use of jigged lures with barbless hooks operated mechanically or by hand. Fishing at night using strong lights attracts squid to the surface where they see and attack the lures. They may also be caught individually in dip nets from the ship (Hanlon *et al.* 1978, 1983) and in either case these squid will provide the best specimens.

Eggs of octopods, sepioids and myopsid squid are laid in protective capsules and attached to hard surfaces on the bottom, or sometimes on objects such as buoys or ropes. The egg capsules are usually quite hardy, and whether collected by hand or bottom-trawling gear, they can provide useful

laboratory material. Alternatively, mature adults brought into the aquarium may spawn there.

### Handling and transport

As previously mentioned, every effort must be made to avoid skin damage and bruising. The skin is easily damaged by dry surfaces, and cephalopods of all types must be kept continuously moist and exposed to the air for minimal periods.

Small octopuses and sepioids can be placed temporarily in containers part-filled with sea water, but this must be changed with some regularity if temperature, pH and oxygen content are not to alter substantially. For transport over distances taking more than an hour or two, special arrangements must be made. Small numbers of small individuals may be carried in cool boxes with only sufficient water to cover the animals. To promote individual survival, particularly in the case of larger specimens, each animal should be contained in a polythene bag about one third full of sea water. Air, or better still oxygen, fills the remaining space. The bags are sealed and kept cool. Survival for 8–10 h is easily possible in these conditions.

Animals captured at sea are best held in deck tanks of sea water continuously pumped from the ocean. On entering most harbours it will usually be necessary to stop the pump to avoid contaminated harbour water. Squids can also be held in this way, providing there is sufficient tank space, but some authors (Flores *et al.* 1976; Lipinski 1985), recommend that they are contained individually or in small groups within perforated plastic bags floating in the main tank. Small octopuses, large benthic hatchlings or egg masses can be readily transported by these methods over long distances and shipped as unaccompanied packages on public transport.

Notably in Japan, where the price paid for live marine species at commercial fish markets greatly exceeds that for the freshly dead, methods of bulk live transport have been developed. With total journey times of up to 20 h, before live display at the Tokyo fishmarket, the water conditioning in these transport facilities must be of a very high order. Specialised fish restaurants in Japan may also display live squid species in the short term for inspection by their customers.

### Water quality

Sea water aquarium systems are basically of two types. At marine laboratories, close to the sea, an open system may be available, whereas at inland sites a closed or recirculating system is usual, in which a fixed volume of water is pumped from a reservoir through the holding tanks with varying degrees of conditioning. Some laboratories operate an intermediate system in which there is continual replacement of a portion of water volume of a recirculating system. The provision of these systems and the maintenance of water quality are discussed in the 7th edition of the UFAW Handbook (Poole 1999) and extensively covered in specialised works (Spotte 1979a, 1979b; Hawkins 1981) although

detailed designs specifically for cephalopods have also been published (Forsythe & Hanlon 1980; Hanlon & Forsythe 1985; Hanlon 1990; Yang *et al.* 1986).

Captured cephalopods should be treated as fish in so far as their requirements for the main parameters of water quality: temperature, salinity (parts per thousand), hydrogen ion concentration (pH), oxygen (O<sub>2</sub>), and levels of dissolved nitrogen as ammonia (NH<sub>3</sub>), nitrite (NO<sub>2</sub>) and nitrate (NO<sub>3</sub>). The water temperature should be held close to the ambient. Little is known about temperature acclimatisation in cephalopods, but the experience of most workers suggests that they will survive best if aquarium temperatures are not more than a few degrees different from the environmental water temperature.

Cephalopods are stenohaline, that is, living in a narrow salinity range, close to full strength sea water (34–36 parts per thousand). Only the squid *Lolliguncula brevis* (Hendrix *et al.* 1981) of the Bay of Mexico, is known to tolerate significantly lowered salinities (>24 parts per thousand). The aquarium sea water must be held at around 34–36 parts per thousand. Cephalopods are sensitive to acidity and the pH should be held above 7.5, preferably within the range of open sea water (pH range 7.8–8.2), and low pH levels corrected if necessary by addition of sodium bicarbonate. Dissolved oxygen levels should be maintained close to saturation levels by forced aeration. Squids especially are active swimmers, normally living in fully aerated sea water, although some benthic octopods are quite tolerant of reduced oxygen levels.

As with fish, it is the build-up of nitrogenous excretory products which poses the main problem for closed seawater aquaria. Boletzky and Hanlon (1983) recommend the adoption of Spotte's (1979a) standards: <0.10 mg/l ammonia, <0.10 mg/l nitrite, <20.00 mg/l nitrate. However, higher nitrate concentrations are tolerated by some octopuses, for example *Eledone cirrhosa* (50 mg/l nitrate; Boyle 1981a), *Octopus joubini* and *O. digueti* (100–200 mg/l nitrate; Forsythe, 1984; DeRusha *et al.* 1987). These levels have been measured for relatively few species, and range of tolerance levels is not established.

### Space requirements

There are no absolute space requirements for cephalopods. Sedentary benthic species can be held individually in very small enclosures provided there is a sufficient rate of water exchange to maintain water quality (Wells *et al.* 1983b; Boyle 1983c, 1986a). Octopods and sepioids quickly establish themselves in aquarium tanks of modest dimensions. Circular tanks of 1 m diameter (0.6 m deep) will provide adequate space for five to ten sizeable *Eledone cirrhosa* (250–1000 g) while tanks of 2 m diameter (0.6 m deep) will house 20–30. Factors such as activity and aggression will also determine the number which can be held together.

In small recirculating systems (2600 l) with biological and mechanical filtration, physical adsorption ('protein skimmers') and ultraviolet (UV) sterilisation, Hanlon and Forsythe (1985) were able to hold a maximum octopus biomass of 15 kg. Sustained levels of ammonia-nitrogen and nitrate-nitrogen of up to 0.20 mg/l were tolerated. Nitrate-

nitrogen could be held at 500 mg/l, although it was felt that levels over 100 mg/l were affecting reproductive success. Clearly, the holding capacity of any aquarium system is more related to its ability to control water quality rather than absolute space requirements of the animals.

Squids require more area in which to swim, and some laboratories have provided tanks or raceways of substantial volume to accommodate this activity (Matsumoto 1976; O'Dor *et al.* 1977; Matsumoto & Shimada 1980; Yang *et al.* 1986). In any case, the sides of the tanks need to be marked with a bold contrasting pattern to provide sufficient visual cues for the squid to avoid hitting the boundaries. While octopuses quickly adapt to captivity and will become tame, wild-caught squid remain very nervous animals which must not be exposed to sudden stimuli such as lights, movements and vibration.

### Housing and substrate

Squids require no special substrate or housing, but low light intensities and shielding from external disturbance are preferred. The seawater drain should be covered with netting to prevent animals becoming trapped there. Plastic sheeting or netting should cover the top of the tank to prevent the occasional animal jetting out and to reduce visual disturbance from movements round about. Constant diffuse overhead illumination is provided to give 10–15 lux in the middle of the water column (Yang *et al.* 1986). Ideally, glass or plastic underwater observation panels should be let into the sides of the tank. The inside tank walls must be painted with an irregular mottle pattern. Moveable black plastic or net curtains may be used as temporary internal partitions to confine the squid to portions of the tank from which they may be gently caught with a lift net, or where they will be less disturbed by tank cleaning operations.

Cuttlefish and sepiolids also may be kept without special substrate, but they will make use of sediment of the right grade on the tank floor. These animals normally partially cover themselves with sand and will thrive well if this is provided. Octopuses should be given plenty of shelter in the form of earthenware flowerpots, pieces of plastic pipe, etc. They will use these objects as temporary 'homes' or 'dens' from which they will make hunting forays (Boyle 1980; Mather 1980).

Since all cephalopods are carnivorous, uneaten food will quickly decompose and must be promptly and rigorously removed from the tanks. The presence of a clutter of pipes and pots in octopus tanks is a nuisance when cleaning, but this cannot be avoided because the provision of shelter for the octopuses allows a much higher stocking density.

However well housed, octopuses are particularly prone to escape from aquarium tanks, presumably a consequence of exploratory hunting activity. Loose lids are of little value because the octopuses will easily lift them and push their way out of the tank. For large tanks a convenient solution is to line the wall above the water level with soft upholstery foam overlapping the tank rim onto the outer surface. Suckers cannot grip on this surface and so octopuses cannot climb the sides (Boyle 1981a). Small species can be prevented from climbing out by gluing a strip of plastic turf

around the inside wall above the water line. The alternative to these methods is the provision of strong, close-fitting lids, firmly fixed to the rim of the tank. The precise design of lids depends on the preference of the aquarium manager and the practicalities of each particular situation. A cheap and effective solution to escape problems, particularly where large and powerful species like *Octopus dofleini* are concerned, is to use fishing net of an appropriate mesh tightly tied under the rim of the tank.

### Health hazards

The normal feeding methods of octopuses can pose something of a health hazard to human handlers. Many species of octopus are known to bite with the beaks and to inflict an appreciable wound. More important is the injection into the wound of saliva containing a wide variety of pharmacologically active compounds and having several toxic effects in vertebrates (Halstead 1965).

In the small Australian octopod *Hapalochlaena maculosa* the toxin of the saliva, known as 'maculotoxin', has effects in vertebrates indistinguishable from the puff adder venom tetrodotoxin in blocking the sodium channels of nerve cell membranes and preventing passage of action potentials (Dulhunty & Gage 1971; Crone *et al.* 1976; Cariello & Zanetti 1977). This species has been the cause of human fatalities (Flecker & Cotton 1955).

Other octopuses have been known to bite human handlers, certainly *Octopus vulgaris*, *O. briareus*, *O. fitchi*, *O. rubescens*, *O. macropus* and *Eledone cirrhosa*. It may be assumed that, given the opportunity, most species will bite. The effects are always painful, often described as like a severe bee sting, and some victims have reported other effects such as pain and partial paralysis extending well beyond the site of the bite. Sensitivity to the toxins may differ between individuals, but clearly it is desirable to avoid these incidents. Fear of being bitten and the natural tendency of the octopus to grip the handler with arms and suckers tend to make the inexperienced person nervous. As far as possible, the octopus should not be allowed to bring the mouth area firmly into contact with exposed skin of the handler or to crawl freely over the skin surface. Some practice and experience is usually necessary before octopuses can be handled firmly but with confidence and safety.

A further potential health hazard may arise from infections of skin lesions of cephalopods. These lesions are not uncommon in wild and laboratory-held animals, although no cases of resulting human infection have been described; R.T. Hanlon (personal communication) reports that potentially pathogenic micro-organisms have been cultured from this source. It is also noted that the occurrence of larval nematodes of the genera *Ascaris* and *Anisakis* in cephalopods could also constitute a human health risk if consumed (Hochberg 1983).

### Rearing

The term rearing is taken to include the growth and healthy maintenance of cephalopods for any period of time, short of

reaching a second generation, and not specifically to the rearing of hatchlings or juveniles.

### Feeding and food supplies

As cephalopods are carnivores and normally exclusively predatory, feeding in captivity requires continuous supplies of live food. No artificial diets are routinely available. The reviews of Boletzky and Hanlon (1983), Nixon (1987) and Rodhouse and Nigmatullin (1996) assemble virtually all the information presently available on the diets of cephalopods in the field and aquarium.

Most octopuses will capture and eat almost any type of crustacean of appropriate size (crabs, shrimps, squat lobsters, etc). Many species, for example *Octopus vulgaris*, *O. bimaculatus* and *O. dofleini*, will also readily take a variety of gastropod or bivalve molluscs. Squid and cuttlefish will catch fish and pelagic crustacea such as euphausiids. Apart from the special attention required for hatchlings and small juveniles (Villanueva 1994), policy with provision of food should be to supply a choice of prey from the species range likely to be available in the natural habitat and of a size readily tackled by the cephalopod. Octopuses are certainly capable of killing crustacea of their own size, but as a general guide, suitable prey organisms would be not more than about 10% of the mass of the cephalopod predator.

Like many marine invertebrates, octopuses can survive without food for periods of at least several weeks, but feeding rates of healthy, growing cephalopods are high. For cool temperate, warm water and tropical species, daily rates of food intakes for octopods range from 1–10% of body weight, and up to 15% of body weight for some squid (O'Dor & Wells 1987). Flesh retrieval from crabs is around 50% of the gross body weight. Therefore, to fuel even a 5% feeding rate for a 500g octopus, at least 50g of crab will have to be supplied daily. Except where measured levels of food intake are required, food should be supplied *ad libitum*. Live food supply on this scale places significant demands on collections made in the field, or from commercial supply at high expense. Octopuses will attack and eat dead food, such as pieces of sardine when presented on a thin skewer and moved about. This technique has been regularly used to present rewards in training experiments (Wells 1962). Squid will also take dead food, for example, Bradbury and Aldrich (1969) fed captive *Illex illecebrosus* on dead capelin (*Mallotus villosus*). *Nautilus*, in particular, takes dead food and probably is a regular scavenger in the field (Haven 1972). Despite these exceptions, for most practical purposes, keeping and growing live cephalopods will entail regular supplies of live prey of suitable species.

### Growth

High food intakes, coupled with exceptional rates of gross food conversion efficiency, result in very high growth rates. Growth conversion efficiency (that is the growth increment expressed as a percentage of the food intake over the same period), ranges normally between 40% and 60% on a wet-

weight basis, or even higher for octopods, and somewhat lower for squid, 25–40% (O'Dor & Wells 1987). This means that for even a relatively slow-growing species such as *Eledone cirrhosa*, 100g of crab meat ingested results in 40g of octopus growth (Boyle & Knobloch 1982).

Various mathematical expressions have been used to describe cephalopod growth (Forsythe & Van Heukelem 1987). Growth in laboratory-held octopuses generally follows two phases: an early phase, best described by an exponential relationship, during which most of the adult size is achieved, followed by a much slower logarithmic growth phase. During the early part of the first phase, maximum instantaneous growth rates (the percentage increase in body weight per day) range from 4–8%. Animals nearing their adult size are more likely to be growing at 1–2% per day or less.

Where field data are available, growth rates are correspondingly high, leading most authors to believe that the aquarium growth performance is not abnormal. There are, however, wide differences between individuals, and many animals brought in from the field will not begin to feed as readily or grow as fast.

### Lifespan

The second, slower phase of cephalopod growth marks the onset of sexual maturation and the beginning of the end of its life. The physiological changes associated with the final stages of gonad growth and vitellogenesis do not seem to be reversible. In the field, after spawning, the females die almost without exception, although individual 'spent' animals may linger on for a number of weeks. While many of these animals fall to predators or disease, the basic cause of death seems to be endogenous and associated with breakdown of somatic proteins. Less is known about the male life cycle, but they are generally assumed also to die after the first breeding season. While there may be some exceptional species which will spawn several times in a period of months, such as *Octopus chierchiae*, feeding and growing in the intervening periods (Rodaniche 1984), this pattern of breeding and death means that the survival of individual cephalopods in captivity is naturally limited. The degree to which very large species such as the giant squids (*Architeuthis* sp.) conform to these generalisations is not known, but really large octopods (*O. dofleini*) are estimated to live from 3 to 5 years (Hartwick 1983).

Neither the environmental and ecological influences, nor the immediate physiological factors controlling maturity and death, are properly understood. Clearly the lifespan of individuals in aquarium conditions will be quite short. Estimates of 1–2 years' lifespan are common for the medium-sized cephalopods (Boyle 1983a). In practice, the term of survival in the aquarium will be normally less than a year. Maximum survival periods recorded for representative species held in the aquarium are: *Eledone cirrhosa*, 240–270 days (Boyle & Knobloch 1984b); *Octopus joubini*, 331 days (Forsythe, 1984); *Octopus digueti*, 258 days (DeRusha *et al.* 1987); *Octopus maya*, 229 days for females, 360 days for males (Van Heukelem 1983); *Octopus bimaculoides*, 404 days (Forsythe & Hanlon 1988); *Octopus briareus*, 505 days (R.T.

Hanlon & M.R. Wolterding, personal communication); *Loligo opalescens*, 248 days (Yang *et al.* 1986).

Many cephalopods which reach full maturity in the aquarium apparently will not spawn normally, but this does not seem to prolong survival since such 'egg-bound' females will usually die within a few weeks (Boyle & Knobloch 1983, 1984a). There is some suggestion that aquarium conditions themselves, whether through higher temperatures, lower feeding or growth rates, promote increased gonad growth at smaller sizes (Boyle & Knobloch 1984b).

### Damage and disease

Wild-caught cephalopods are particularly prone to mechanical damage. Cuts and abrasions of the skin inflicted by nets or rough handling are a frequent cause of mortality, especially in squids, usually within a few days of capture (Summers & McMahon 1970; Hulet *et al.* 1979). Lesions of the skin may also develop in aquarium-held octopuses, often at the most posterior part of the mantle (Boyle 1981a). Octopuses are more hardy than squid, but they also suffer from rough handling. Internal damage to muscles from bruising shows as conspicuous swellings, coloured blue from leakage of blood containing the copper-based respiratory pigment haemocyanin. Nerve damage may be evident from paralysis of one or several arms, an asymmetrical stance, the head not held level, or patches of skin permanently white where chromatophores are no longer working.

In the field quite major injuries are survived. Healthy individuals are captured which have had several arms amputated and are in the process of regenerating. Multiple healed scars are also frequently found. In the aquarium, however, these cuts, abrasions and lesions rarely heal. The animal becomes infected and dies.

Long-term laboratory-held octopuses have been observed to develop ulcerations on the skin. These spread rapidly in the epidermis, enlarging and deepening to affect the dermis and underlying muscle tissue. Unless quickly treated these ulcerations are invariably fatal within 2–4 days. Thraustochytrid and labyrinthulid fungi have been isolated from skin lesions in *Eledone cirrhosa*, but it is not clear whether these organisms are causal agents or secondary infections (Polglase 1980).

At least five types of bacteria have been isolated from lesions in *Octopus joubini* and *O. briareus* (Hanlon *et al.* 1984), and similar numbers from ulcerated tissue in the squid *Lolliguncula brevis* (Ford *et al.* 1986). In laboratory-reared octopuses, the ulcers developed only in groups of animals in high-density cultures. Individually held animals were not affected. *O. joubini* experimentally infected with *Vibrio alginolyticus* developed skin ulcers within 2 days. Treatment with several antibacterial agents showed that periodic dipping in solutions of nifurpirinol at a range of concentrations was effective in reducing mortality and complete healing was achieved in some animals.

The incidence of infected skin lesions is much higher in intensively reared laboratory animals. Trials have shown that some treatments with antibacterial agents can be effective (Hanlon *et al.* 1984; Forsyth *et al.* 1987), but the methods are still a long way from routine application. In the mean-

time, skin infections are a potential problem in any intensive system.

### Parasitism

Cephalopods carry a wide variety of parasites and symbionts (Overstreet & Hochberg 1975; Hochberg 1982) which include viruses, bacteria, fungi, sporozoans, ciliates, dicyemids (mesozoa), monogeneans, digeneans, cestodes, acanthocephalans, nematodes, polychaetes, hirudineans, branchiurans, copepods and isopods (Hochberg 1983).

Apart from the potentially pathogenic micro-organisms described in the previous section, none of this range of parasites are known to cause special problems in captive cephalopods. However, Hochberg (1983) points out that since larval nematodes of many species, including those of the genera *Ascaris* and *Anisakis*, are known from many cephalopod types, a potential human health risk exists. Squids probably function as intermediate hosts for many nematode life cycles, which are then completed when they are consumed by marine mammals.

In areas of the world where uncooked fish and squid are regularly eaten, anisakiasis can be a human health problem in which ascaridoid nematodes cause ulcers and lesions in the digestive tract. Although no direct evidence implicates squid in its transmission, the parasite load of cephalopods must be considered a risk if the flesh is eaten raw or partially cooked.

### Cannibalism

Where cephalopods are held collectively, some cannibalism may occur. Small octopuses may be killed and eaten by larger ones, but the incidence of this behaviour depends very much on the size range of animals held together, the stocking density and provision of adequate food and places of shelter. Suitable husbandry can avoid the problem altogether. In the field, the diet of many cephalopods includes smaller representatives of their own species (Nixon 1987). In certain squids, eg, *Illex illecebrosus*, it appears that during long migratory journeys the smaller members of the shoal form a normal and major component of diet for the larger animals (Squires 1957; O'Dor & Wells 1987).

Animals which are sick or dying are commonly eaten by others in the tank, even while still alive. Injured animals, particularly those with damaged blood or nerve supplies to an arm, will even eat their own necrotic tissue (autophagy). Laboratory-held animals in this condition should always be killed.

### Culture and breeding

#### General considerations

The culture and breeding of cephalopods in laboratory conditions is not widely undertaken. There are many examples of cephalopods raised in captivity from eggs brought in from the field or laid in the aquarium, but regular success

requires either specially favourable conditions of open seawater circulation or considerable effort to maintain high-quality closed circulation systems. In either case, apart from the practical difficulties of handling small hatchling animals, the main problem is the supply of sufficient live food of suitable type and size.

On the positive side, except for squids of the family Oegopsidae whose eggs drift freely in the water, cephalopod eggs are large, well protected by egg membranes and easily handled. They are normally attached to hard surfaces. Again with the exception of some oegopsid squids, there are no specialised larval forms which undergo distinct metamorphosis. The hatchling is a miniature adult capable of using its arms and swimming in an essentially adult fashion. In many of the sepoid and octopod species the hatchling is bottom-living immediately. Some species which are benthic as adults have a planktonic juvenile phase of variable duration and the term 'paralarva' has been proposed for these planktonic young (Young & Harman 1988). The review of Boletzky and Hanlon (1983) lists all the cephalopod species for which either maintenance or rearing had taken place at that time and identifies those species with benthic young.

Potentially, these benefits of large size, hardiness and benthic young should be very helpful in developing culture and breeding programmes (Hanlon 1987). Very little is known about the juvenile stages in the field (but see Mangold & Boletzky 1985), so this approach is likely to be increasingly useful for completion of life cycle studies.

## Maturation

Maturation in females is largely a process of gonad growth by yolk accumulation. The later stages take place rapidly under the influence of the gonadotrophic hormone(s) from the optic gland. Feeding and growth rates of female octopuses in the aquarium decline quickly with the onset of maturation; they become relatively sluggish and may deposit small numbers of eggs, attaching them to the sides of the tank or other hard objects. At this point the female is seeking a suitable place for egg laying, usually within a pot or tube or under an overhang of stones. The single, median ovary, which originally contributed about 0.25% of body weight has now grown to occupy close to 25%.

Fully mature animals can often be recognised by the white appearance of the ovary through the muscle wall and the changed outline of the mantle. Maturity scales based upon the relative enlargement and appearance of the ovary and other components of the reproductive system have been devised for many species. Where it is necessary to evaluate reproductive condition in living animals, the mantle musculature can be simply inverted to expose the gonad, under anaesthesia, after cutting the mid-ventral septum. This simple operation should cause little stress, and the examination may be repeated on successive occasions. The paired oviducts leading from the ovary will be packed with ripe eggs in the final stage of maturity.

The pattern of maturation is similar in squid, except that the oviduct is single and on the left-hand side. These animals will rarely survive anaesthesia or internal examina-

tion and surgery. Assessment of maturity is a matter of external appearance of colour and shape (above), and development of the hectocotylus in males (see Sexing section).

The male system in all cephalopods is more complicated. Ripe sperm from the testis pass into the proximal vas deferens. Here, in specialised glandular areas they are packaged into discrete spermatophores. Finished spermatophores are then stored in a spermatophoric sac. The mature male will usually have ripe spermatophores lodged in the distal portion of the vas deferens, the excurrent duct (incorrectly 'penis'), ready for transfer to a female. Males are sexually mature over a wider range of body size than females, and thus appear ready to mate over a greater portion of their lifespan. The total mass of ripe testis and full spermatophoric sac does not usually contribute such a large proportion of body mass as the female ovary.

## Sexing

Males and females may be distinguished externally by the presence of modifications to the arm of the mature male used for sperm transfer during mating. In octopods it is the third right arm (counting from the dorsal mid-line) which becomes thickened; a fold in the skin along the arm develops and the tip usually becomes modified and hook-like. The precise form of this hectocotylised arm or hectocotylus, which in myopsid squid is the fourth left, is often a species characteristic.

In immature animals, or where a more precise assessment of maturity state is required, no alternative to an internal examination is currently in use. Sepioids and teuthoids can only be examined after death, but octopods can be anaesthetised and the mantle sac inverted. In octopods, even the most immature animal can be sexed in this way – the paired oviducts always being distinguishable from the single male excurrent duct; squid are more difficult because both oviduct and excurrent duct are singular, and located on the left side.

## Mating

Octopuses frequently mate in aquarium conditions. The usual approach is for the male hectocotylus to be inserted into the mantle cavity of the female. Peristaltic and 'pumping' movements of the male arm transfer spermatophores to the female. In *Octopus vulgaris*, the sperm enters the oviducts and lodges in the oviducal glands (Frösch & Marthy 1975), while in *Eledone cirrhosa* spermatangia (ruptured spermatophores) travel all the way into the ovary (Boyle 1983b). Fertilisation is then truly internal and its timing is essentially determined by the female.

Female sepoids and squid have various methods of holding sperm transferred from the male, in buccal membranes or within the mantle cavity. In oegopsid squid, spermatophores may be held in the buccal membrane of the female (*Todarodes*) or attached to the base of the gills (*Illex*). Mating takes place usually in a 'head to head' position, and in some species (*Loligo opalescens*) there may be dense spawning aggregations.

Mating in cephalopods is always one to one, although each individual may perform a series of matings with different partners. Underwater video observations show that while single male and female pairs are formed at mating, small 'sneaker males' may successfully fertilise the same female during the egg-laying process (Hanlon & Messenger 1996). This paired mating is in sharp contrast to most aquatic molluscs which liberate both male and female gametes into the water. Little is known of the stimuli required for mating. Mature male *Octopus* mate readily with mature females in the same tank. Other species such as *Eledone cirrhosa* are more reticent. *Sepia officinalis* and loliginid squids such as *Sepioteuthis sepioidea* and *Loligo opalescens* are known to exhibit chromatophore displays characteristic of sexual maturity and mating. These presumably function as intraspecific visual signals and, incidentally, are another method of externally distinguishing the sexes (Tinbergen 1939; Corner & Moore 1981; Moynihan & Rodaniche 1982; Hanlon & Messenger 1996).

### Egg laying

Many sepoid and octopod species will lay viable eggs in aquarium conditions. Usually this occurs when gravid females, close to egg laying, are brought in from the field, but a number of species, mostly those with large eggs (Hanlon & Forsythe 1985), have successfully laid eggs after long-term rearing.

Sepioids lay small numbers (25–1000) of large eggs (1–10 mm in diameter) usually within a period of a few weeks. They are individually deposited, firmly fixed to a hard substrate, each enclosed in a tough sheath which considerably increases the size of each egg. Octopods may also lay large eggs, ranging in size from about 2 mm in length (*Octopus vulgaris*) up to 12–15 mm (*O. bimaculoides*, *O. briareus*, *Eledone moschata*, *Bathypolypus* spp.) or even larger in some Antarctic species. Estimates for total fecundity in octopods range from minima of 25–50 (*O. joubini*, *O. australis*) to well over 100 000 (*O. vulgaris*, *O. tetricus*, *O. cyanea*). The eggs are in strings, attached usually in the protection of rocks or an overhang. Egg laying is completed in less than a day or may take several weeks. Females of many species are known then to brood the egg mass, blowing sea water over it, keeping the eggs clear of epigrowths and protecting them against predators. This behaviour usually continues until hatching of the juveniles is completed. Myopsid squid (*Loligo*) also lay benthic egg masses in the form of a cluster of finger-like capsules, each containing perhaps 100 eggs. These are commonly retrieved from spawning grounds by trawlers, but may also be laid in the aquarium (Yang *et al.* 1986). Oegopsid squid, in contrast, lay large, diffuse egg masses, neutrally buoyant in the water column, and consequently their eggs are rarely available for culture (but see Balch *et al.* 1985).

Egg masses to be cultured need gentle circulation of clean aerated sea water. Commonly used methods to achieve this include suspending the egg masses in water from threads across the tank, or in containers such as net bags or floating plastic strainers. Direct agitation from stirrers or aeration bubbles should be avoided, and low light levels should be maintained.

### Hatchlings

Development time in the egg depends on species and temperature, and ranges from less than 10 to over 100 days. At hatching the developed embryo actively breaks out of the enclosing egg coats using a special hatching gland (Boletzky 1987a).

Hatchlings need to be reared in separate facilities, away from adults and other potential predators. A series of replicated small tanks provide security and are easily managed, although growing squids require increasing space to swim. These early stages are vulnerable to excessive water movement or to strong aeration. Inflow and outflow pipes should be screened with fine mesh net, and aeration arranged so that hatchlings are not exposed to bubble streams.

Hatchlings are immediately active, feeding on the remains of the yolk provision for the egg. After a period of half a day to about a week (depending on species and temperature) they will begin to feed on live food. At this point a variety of appropriately small crustacean food must be supplied, such as *Artemia*, copepods, mysids, shrimps and newly metamorphosed crabs. Those species with particularly large eggs and benthic hatchlings are easier to feed at this stage because of the wider range of acceptable food species. Boletzky (1987b) provides a useful account of juvenile behaviour characteristics, and Vecchione (1987) gives an account of their ecology together with a summary of the early feeding and growth characteristics of a number of species.

Villanueva (1994) has shown that with attention to the size of food organisms required by the hatchlings, easily maintained laboratory cultures of crabs producing larval zoea of appropriate dimensions, can provide continuous food supplies. He found that hatchlings of *Octopus vulgaris* successfully fed and grew on zoea of the crab *Pagurus prideauxi*. Similarly, the squid *Loligo vulgaris* could be reared through the first feeding stages on a diet of *P. prideauxi* zoeae supplemented with those from another crab *Dardanus arrosor*. These practical and controllable methods of live food supply could be a significant step towards more laboratory rearing of cephalopods and reduced dependence on wild-caught animals.

The requirement for high-quality sea water is particularly great for hatchlings. Although mortality in the egg stage is remarkably low, early rearing trials with artificial sea water produced a high proportion of defective juveniles. Particularly problematic was the inability to control orientation, resulting in uncoordinated walking and corkscrewing or somersaulting while swimming. These so called 'spinner' cephalopods were found to have defective statolith production and statocyst development (Colmers *et al.* 1984). The cause of the problem was discovered to be a lack of strontium in the artificial sea water leading to inadequate mineralisation and could be rectified simply by the addition of the correct trace elements (Hanlon *et al.* 1989).

### Laboratory procedures

#### Handling

The general requirements of handling cephalopods captured from the sea have been discussed already (see

'Handling and transport'). Apart from the aspects of mechanical damage by rough handling, or self-inflicted damage from striking the tank walls, little attention has been given to more subtle stress effects.

Marine fish are prone to severe physiological consequences of handling stress (Wardle 1981; Potts 1987). Changes in plasma levels of glucose, catecholamines, corticosteroids and adrenaline or noradrenaline lead to hyperglycaemia, elevated lactic acid levels and osmotic effects which may persist for several weeks. The principal causes of these stress effects seem to be the mechanical handling itself, exposure to air for even short periods, low oxygen levels and higher levels of temperature and ammonia.

Laboratories working with cephalopods select out obviously damaged animals and those behaving abnormally, but little or no allowance has been made for the physiological effects of stress. Twenty-four hours in the aquarium is often considered sufficient time for acclimatisation and, for longer-term studies, animals which are feeding regularly are adequate. For many experimental purposes, animals are used immediately after capture. By comparison with fish it might be assumed that, in cephalopods, with their complex behaviour and neural and hormonal control systems, there will be substantial physiological consequences of capture from the wild and laboratory management. No studies are yet available to give guidance as to the significance of these stresses, although there is some evidence to suggest that long-term residence in aquarium conditions leads to changes in maturity (Boyle & Knobloch 1984b) and enzyme activity (M.S. Grisley & P.R. Boyle, unpublished observations) in *Eledone cirrhosa*. The present tendency is for researchers to use wild-caught animals as soon as possible after capture, allowing perhaps only a 3–5-day period of acclimatisation, and more or less ignoring the possibility of longer-term physiological stress effects. Studies aimed at identifying and defining stress effects are urgently needed.

Octopuses in the laboratory may be handled directly or by hand nets. As far as possible, handling should take place under water. Certainly the skin should never be brought into contact with dry absorbent surfaces. Some species, notably *Octopus vulgaris*, are relatively tough and will stand a much greater degree of handling than more delicate octopods such as *Eledone cirrhosa*. Very large species such as *Octopus dofleini* need special care, coaxing the animal rather than forcing it into buckets or nets for transport to tank or to laboratory.

### Identity marking

Identity marking of individuals over a long holding period has been rarely attempted, largely because the soft body and delicate skin are not conducive to the attachment of tags. In the field, individual *Octopus dofleini* have been successfully identified by attaching numbered plastic disks on either side of an arm connected through the musculature by a nickel pin (Hartwick *et al.* 1984). Large-scale capture/recapture tag studies have also been successful in Japanese and South African squid fisheries.

In the laboratory, most workers have relied on keeping octopuses in separate enclosures. Where every individual

held collectively in stock tanks has to be identified, subcutaneous injections of coloured latex have been used (Boyle & Knobloch 1982). Under anaesthesia, small amounts of latex containing dye (eosin) are injected beneath the ventral mantle skin to form a series of spots, each 2–3 mm in diameter. Using right and left sides, a relatively small number of dots can be used to provide a coded identification mark. These latex implants are inert: among hundreds of *Eledone cirrhosa* marked in this way only in a very few cases was any local reaction seen and, unlike the direct injection of dye, the implants do not disperse or fade. The disadvantage is that, in most cases, the animals have to be caught and handled before their identity can be read with confidence. The use of small (3.5 mm × 1.5 mm) numbered plastic tags implanted under the skin in chromatophore-free areas has also been evaluated. These implanted tags do not appear to cause any adverse reaction, but may be lost from the entry puncture if not implanted sufficiently firmly, and also require the animal to be handled before the tag can be read. Mutilation tagging is not acceptable.

### Anaesthesia

Only anaesthesia by immersion has been used for cephalopods. Anaesthesia by injection has not been attempted. The following techniques apply mainly to octopods and sepoids. Squids will not normally recover from handling or surgery under anaesthesia, but animals in really good condition may be briefly anaesthetised in ethanol (in sea water) for weighing or photography (Hanlon 1982; Hanlon *et al.* 1983).

Octopuses may be readily and reversibly anaesthetised by transfer to a container of sea water containing anaesthetic. Depth of anaesthesia is controlled only by its concentration and the period of immersion. Signs of anaesthesia are the progressive loss of activity and paling of the skin. Ventilatory movements slow down and stop, at which point anaesthesia is considered complete. Thereafter, only local movements of arms and skin will take place, or reflex contraction of the mantle if the stellate ganglion is stimulated, and there is no coordinated or directed activity.

Since fully anaesthetised animals have stopped breathing, they will begin to asphyxiate from that point, even though the heart and circulation may be functioning. This sets a strict limit on the period of time for which an octopus may be held under anaesthesia: 10–20 minutes is considered to be the safe limit before the animal must be returned to clean aerated sea water. Recovery can be assisted by flushing water through the mantle cavity and massaging the musculature; 2–5 minutes should be sufficient for full recovery.

A small variety of anaesthetics has been tried. Originally, urethane (ethyl carbamate) 3% in sea water was used, but is now replaced by ethanol (or industrial methylated ethanol, IMS) 2–2.5% in sea water at ambient temperature. Andrews and Tansey (1981) compared the effects of these chemicals with the use of cold sea water alone (3–5°C) as anaesthetics for *Octopus vulgaris* at Naples. They found all three methods to induce anaesthesia within 2–5 minutes using cessation of respiration and loss of chromatophore tone as the main cri-

teria. The action of cold water is arguably analgesic rather than anaesthetic, probably affecting the animal in a fundamentally different way from urethane or alcohol. They observed that in urethane, and to a lesser extent in alcohol, a proportion of the octopuses tested attempted to climb out of the bucket containing the anaesthetic or inked violently. *Eledone cirrhosa* at the considerably cooler temperatures of Aberdeen, also shows signs of distress in urethane, whereas alcohol appears to cause little stress and inking very rarely occurs.

The traditional anaesthetic for marine invertebrates, magnesium chloride, has been evaluated for its effects on *Octopus vulgaris* and other cephalopods (Messenger *et al.* 1985). Made up as an isotonic solution by mixing 7.5% MgCl<sub>2</sub>·6H<sub>2</sub>O (in distilled water) with an equal volume of sea water, this simple salt was found to be an effective anaesthetic for cephalopods and, importantly, seemed to have minimal traumatic effect. It may be especially useful for animals such as *Sepia* which commonly react to handling by violent inking, and squid (O'Dor & Shadwick 1989).

The use of anaesthetics in cephalopods is at a relatively primitive stage. Little is known of the central effects of these compounds and the parameters of adjustment of anaesthetic type or concentration to cephalopod species and body size. For many types of chronic physiological procedures or long surgical techniques, continuous control over anaesthetic level is clearly desirable, but as yet there have been no attempts to establish methods of continuous and controllable anaesthesia.

### Euthanasia

The simplest and most effective way of killing an octopus is terminal anaesthesia. Whichever anaesthetic is used (see Anaesthesia section), respiratory movements stop within 5–10 minutes. If left in the anaesthetic the animal will quickly asphyxiate. Under anaesthesia the brain may then be destroyed to ensure that no recovery is possible.

If it is necessary to kill an octopus without anaesthesia, some skill and practice is required. When the animal is placed on a smooth surface the arms and suckers will adhere. The mantle and viscera of the octopus are then gently pulled to stretch the body. One finger of the other hand can then readily locate the cranium, directly between the eyes. Using a sharp scalpel the brain is first bisected with a cut downwards and forwards. This is immediately followed by lateral cuts on each side to sever the brain from the optic lobes and further transverse cuts disconnect the brain tissue from major peripheral nerves. Squid are usually killed simply by decapitation, cutting between the head and mantle.

### Embryological techniques

Numerous zoologists have studied the embryology of cephalopods *in vivo*. The eggs of many species are exceptionally large, and in many cases the details of embryogenesis can be followed through the transparent egg coats. Such investigations are largely outside the scope of this chapter

and reviews may be found in Marthy (1978–1979, 1982) and Boletzky (1987a, 1988).

### Concluding remarks

Compared to the extent of information and wealth of detail available for laboratory vertebrates, the cephalopods are poorly served. This is due to a combination of factors, largely because they can be still treated as wild animals, only temporarily resident in the laboratory. Also, as invertebrates, little attention is customarily given to the refinements of condition and management so long as survival is adequate for the purpose.

Interest in long-term laboratory-held cephalopods is increasing because of their biological importance as advanced invertebrates bearing comparison with vertebrates, and for their ecological and fishery significance. It is also the case that the health, housing and maintenance of all animals held for scientific purpose is of interest and importance generally. These new influences will progressively improve the levels of handling and maintenance expected for these fascinating invertebrates.

### Acknowledgements

I gratefully acknowledge the help with the collection and management of octopuses over many years by staff of the Zoology Department, Aberdeen, especially Tom Craig, Gillian Robertson, Steve Adams, Steve Hoskin and Duncan Wood. Many students and co-workers have contributed to our knowledge and experience of aquarium-held animals here, especially Daniela Knobloch, Peter Smith, Françoise Dubas, Maxine Grisley, Rachel Austin, David Chevis, Lorraine Young, Katharine Kelly and Linda Key.

I am grateful to colleagues for comments on and corrections to the first edition of this article (Boyle 1991).
