

THE UFAW HANDBOOK ON  
The Care and Management  
of Laboratory and  
Other Research Animals

## The Universities Federation for Animal Welfare

UFAW, founded 1926, is an internationally recognised, independent, scientific and educational animal welfare charity (Registered in England Charity No. 207996) concerned with promoting high standards of welfare for farm, companion, laboratory and captive wild animals, and for those animals with which we interact in the wild.

It works to improve animals' lives by:

- promoting and supporting developments in the science and technology that underpin advances in animal welfare;
- promoting education in animal care and welfare;
- providing information, organising meetings and publishing books, videos, articles, technical reports and the journal *Animal Welfare*;
- providing expert advice to government departments and other bodies and helping to draft and amend laws and guidelines;
- enlisting the energies of animal keepers, scientists, veterinarians, lawyers and others who care about animals.

*'Improvements in the care of animals are not now likely to come of their own accord, merely by wishing them: there must be research . . . and it is in sponsoring research of this kind, and making its results widely known, that UFAW performs one of its most valuable services.'*

Sir Peter Medawar CBE FRS, 8th May 1957

Nobel Laureate (1960), Chairman of the UFAW Scientific Advisory Committee (1951–1962)

UFAW relies on the generosity of the public through legacies and donations to carry out its work improving the welfare of animal now and in the future. For further information about UFAW and how you can help promote and support its work, please contact us at the address below.

# Foreword

---

*The UFAW Handbook on the Care and Management of Laboratory and Other Research Animals* is now here again in an 8th edition.

When I was contacted by Robert Hubrecht earlier this year and asked if I would like to write a foreword to this new edition I jumped at the chance. This book has formed an important part of the laboratory research environment throughout the last 50 years and it is a real privilege to be able to make some contribution, albeit a very small contribution, to the 8th edition.

It is important to see this hugely authoritative work in the context of UFAW itself, and the sustained contribution to the improvement of laboratory animal welfare that this organisation has made since its inception. *The Universities Federation for Animal Welfare* was created formally in 1936, although its origins can be traced back farther than that to 1926, when the body from which it evolved, the *University of London Animal Welfare Society*, was founded by Major Charles Hume. It was Hume who laid the foundations for future developments by making it clear that animal welfare must be closely associated with science, and with human and veterinary medicine, but that importantly policy should be based on facts rather than sentimentality. It is still the vision that progress in this area will be best served by ensuring that there is close alignment between scientific progress and animal welfare, so that opportunities to exploit scientific and technical know-how for delivering real improvements are realised quickly and effectively.

Under the guidance of Hume, UFAW led the way in improving animal welfare, among their stated aims being the promotion, by educational and other methods, of interest in the welfare of animals, and enlisting the influence of University 'men and women' on behalf of animals. William Russell, the late and greatly lamented polymath, then came

on to the scene, and joined UFAW from Oxford University in 1954. Some short time later Russell was joined by Rex Burch, and as they say, the rest is history. In 1959 Russell and Burch published their influential book *The Principles of Humane Experimental Technique*, and this year (2009) has seen many appreciations and celebrations of the 50th anniversary of this truly groundbreaking event in the evolution of experimental research.

However, let it not be forgotten, that some 12 years before the Russell and Burch book was published there was another seminal literary event. In 1947 there appeared the first edition of the UFAW handbook, edited by Alastair Worden. That book, which ran to some 368 pages, was also hugely influential and provided a template for best practice for the use of animals in research. From those important beginnings, and through a series of succeeding editions, has evolved this current *tour de force*. This 8th edition is a magnificent achievement and represents a truly comprehensive and authoritative work embracing in 50 very detailed chapters all aspects of animal care and husbandry.

This book, which will serve to inform and guide practice for years to come, is a timely reminder of what UFAW has achieved. The many authors that have contributed to this work, and in particular the editors who have undertaken the Herculean task of producing a volume of such quality, are to be warmly congratulated.

This is an important job well done.

# 1 Introduction

Robert Hubrecht and James Kirkwood

It is widely accepted, and implicit in the legislation of many countries, that animals used in research should be kept as far as possible in a state of good welfare. This duty of care is not only a legal and ethical obligation but is also very often necessary to achieve high-quality science. Animals housed in conditions that meet their needs are much less likely to be stressed, a state which can bias results or result in increased variation between animals as they attempt to cope with the stressor. Therefore, it is often said that good animal welfare is in both the animals' and the scientists' best interests. From the very first edition of the Handbook in 1947, the UFAW Laboratory Animal Handbook has promoted the importance of high standards of care for animals used in research. Indeed, the 1947 edition was the first manual on laboratory animal care and housing ever to be published and was instrumental in stimulating the development of laboratory animal care as a fundamental component of laboratory animal science. Since then, it has remained an internationally valued resource that has helped to refine laboratory animal use and to advance the Three Rs (3 Rs – replacement, reduction and refinement), originally described in 1959 by the UFAW scholars Russell and Burch in the *Principles of Humane Experimental Technique*, and now generally accepted as the key ethical principles under which animal experimentation should be carried out.

Professor, Sir Harold Himsworth, Honorary Physician to the Queen and a prominent scientist in the study of diabetes, stated in a foreword to the 3rd edition in 1959 that, '*Good intentions and wishful thinking are never enough when faced with natural problems. Knowledge and yet more knowledge is needed.*' Yet it is not always easy to acquire this knowledge. It is hard to shake off the biases of anthropomorphism and anthropocentrism to establish the real requirements of animals. Nonetheless, since the publication of the previous 7th edition, there have been considerable scientific developments in the field of laboratory animal welfare that fully justify the production of this updated volume.

We have included in this edition 10 new chapters on implementing the Three Rs in research, addressing areas that have developed considerably since the last edition and drawing attention to some important general principles. There has been a dramatic increase in the numbers of genetically altered animals used in research, mainly mice, and so we have included a chapter on phenotyping to draw attention to techniques that can be used to better characterise

these animals and identify welfare issues. Good experimental design, which has implications on the numbers of animals used, needs to take account of genetic status and sometimes of housing conditions. Given the importance of these considerations, a general introduction to experimental design is included that we hope will be of use, not only to animal care staff, but also to researchers and those involved in ethical review. The implications of research on wild animals, often not within a closely controlled laboratory environment and in some cases in the field, are not always well understood, and so we have included chapters to address issues relating to these animals. This edition also includes a chapter on the use of non-traditional laboratory animals – those not commonly used in biomedical research.

Since the 7th edition there have been considerable developments in animal welfare research relating to both the methodology of assessing animal welfare and the use of new techniques to judge the importance of environmental provisions aimed at allowing animals to express strongly motivated behaviours. These advances are reflected within the husbandry sections of individual chapters, and in the chapters on assessing welfare and the provision of enrichment. Finally, we have included chapters on: legislation and the oversight of animal experiments – at both local and national level; on training and competence assessment; and on euthanasia.

We have also made other changes. The previous edition was published as two volumes but this time we have reverted to a single volume, which we believe will be more convenient as a source of information. It is not possible to cover all the species used in research around the world but we have provided chapters on the most commonly used species or groups of species. Fish are becoming increasingly used in research, and we have provided updated information in a chapter on general issues common to marine and freshwater fish.

We have endeavoured as editors to ensure that the chapters reflect UFAW's approach to the care and husbandry of animals used in research, however the chapters are the individual authors' work and the views they have expressed should not be taken as UFAW's official opinions. We have included a chapter on chimpanzees although not all countries use or permit their use. As with other species, their inclusion in this book is not meant to imply approval of their use, but is to encourage implementation of high standards of care.

## 2 Introduction

---

It is very important to us that The UFAW Handbook should be an international resource, so we have tried to ensure that the text is not overly biased towards the European situation. However, at the time of writing there has been a recent review of European standards of housing (Appendix A to Council of Europe ETS 123 and Annex II to European Directive 86/609). In addition, changes to the European legislation (European Directive 86/609) are being debated that might affect both its scope and the regulation of animal care. Many chapters make reference to these changes to draw attention to recent views on minimum appropriate standards and possible future legal obligations. It is, of course, the responsibility of those working with animals to ensure that the practices they adopt comply with national legislation relating to health and safety and animal welfare.

It has been our goal to produce an authoritative resource in the tradition of previous editions of the Laboratory Handbook. The best information about animals' needs and how these can be met, is based on well planned and executed animal welfare science studies published in the refe-

reed scientific literature. However, many aspects of animal husbandry have not yet received such detailed scientific investigation and are based on practices that are considered through practical experience to be suitable. To help us to ensure that as far as possible the chapters reflect good current practice and are a guide for future developments, all the chapters in the Handbook have been peer reviewed by anonymous referees. We are enormously grateful to all those who have undertaken these reviews, for their time and expertise and for their advice which has been of great assistance to both editors and authors.

We are also extremely grateful to the authors for their time and energy in distilling the research literature and their practical experiences into concise and valuable chapters, to AstraZeneca for a generous donation towards the production costs, and to Laboratory Animals Limited for their help in promoting this volume. We hope that this Handbook will be a useful resource for all those caring for and working with animals used in science, and that it will help promote good animal welfare and good science.

# PART 1 IMPLEMENTING THE THREE Rs IN RESEARCH USING ANIMALS

# 2 The Three Rs

Jon Richmond

## Opening remarks

The Universities Federation for Animal Welfare (UFAW) promotes the welfare of animals bred, kept and used for experimental and other scientific purposes by:

- adopting a scientific approach to animal welfare, providing evidence-based insights into *'what is meaningful to the animal'*; and
- advocating that *'best welfare is indeed best science'* and that we must *'... aim at well-being rather than at mere absence of distress'* (Russell & Burch 1959).

In 1954 UFAW commissioned work by William Russell and Rex Burch which led to the publication in 1959 of *The Principles of Humane Experimental Technique* (Russell & Burch 1959). Russell and Burch demonstrated that high standards of animal welfare underpin good science, indeed that better welfare facilitates better science, arguing that *'... humanity can be promoted without prejudice to scientific and medical aims'* and *'... the humanest possible treatment of experimental animals ... is actually a prerequisite for successful animal experiments'*. They advised that:

*... If we are to use a criterion for choosing experiments to perform, the criterion of humanity is the best we could possibly invent ... The greatest scientific experiments have always been the most humane and most aesthetically attractive, conveying that sense of beauty and which is the essence of science at its most successful. ...*

That is, the Three Rs (3Rs) are part of mainstream science, not something separate from it.

This chapter provides an overview to the Three Rs of humane experimental technique as they have evolved in the half-century since Russell and Burch's landmark publication, focusing on general principles, as a prelude to the more detailed and context-specific material contained in later chapters.

## Introduction

The use of animals for scientific purposes is an emotive and sensitive issue, and must be conducted with care and compassion. Whilst there are national and cultural differences in the precise language used, and the protection offered, it is now generally accepted that some animals, such as the

vertebrates, are likely to be able to experience pain, suffering and distress. All of those involved in the care and use of live animals for scientific or other experimental purposes have a moral, and in many cases a legal, obligation to minimise any justifiable suffering caused.

It is generally accepted that animal studies should only be undertaken when all of the following conditions are met:

- the scientific objectives are timely, of sufficient importance and attainable;
- there is no non-sentient replacement alternative;
- all relevant and practical reduction and refinement strategies have been implemented;
- the design and conduct of the study minimises the animal welfare cost as reflected in the total pain, suffering and distress that may be produced, and not simply the number of animals used;
- the scientific and societal benefits are maximised.

Animal welfare is a complex issue: it comprises not only the health of an animal, but also its state of well-being. It has both physical and psychological dimensions and can be compromised not only by the infliction of that which is unpleasant, but also by the denial of that which is pleasurable.

Implementing humane experimental technique requires: knowledge and understanding of behaviours and findings in normal animals; the impact of care systems and scientific procedures; how welfare can be evaluated; and the development and application of informed, practical solutions.

The acceptance of the principles of humane experimental technique established by Russell and Burch (1959) led to a period of reducing animal use and significant welfare gains, at a time of increasing investment and rapid advances in the biomedical sciences. However, the use of animals for experimental and other scientific purposes is again increasing, primarily due to the production and use of genetically altered animals (Home Office 2007). The established principles of humane experimental technique are, nevertheless, sufficiently wide-ranging and flexible to be applicable to this class of animal use not foreseen at the time of Russell and Burch's publication.

There is a need to ensure, as new technologies and trends emerge and new and revised regulatory requirements are introduced, that the principles of humane experimental

technique inform strategic thinking, regulatory frameworks and scientific and husbandry practices.

### Model systems

Early scientific use of animals was generally curiosity-driven, and involved demonstrating biological phenomena without necessarily having practical applications in mind (Barley 1999). The imperative subsequently shifted towards understanding the underlying mechanisms and regulation of observed phenomena. We are now largely in the era of 'deductive science': formulating and testing hypotheses with practical applications, with the results being widely published. These differing approaches to science are still reflected in the types of studies undertaken and animal models used (Festing 2000):

- exploratory models generate knowledge without necessarily being relevant to any immediate practical application;
- explanatory models elucidate the mechanisms;
- predictive models allow problem solving and decision making.

### The high-fidelity fallacy

For the most part, animals in science are now used to model complex and dynamic biological systems. Both animal and non-animal models mimic only limited aspects of the human condition or other system of interest (Sams-Dodd 2006) and this must be kept in mind when the most appropriate model is selected, and findings analysed, interpreted, generalised and extrapolated.

Russell and Burch (1959) warned of the 'high-fidelity fallacy': the false assumption that high fidelity (the closeness in biological terms of a model system to the actual system of interest) equates to a sound model system. Non-human primates can be considered to be high-fidelity models of man as '*in their general physiological and pharmacological properties*' they are '*more consistently like us than are other organisms*'. However, any instinctive preference for high-fidelity models '*ignores all the advantages of correlation*', whereby '*the responses of two utterly different systems may be correlated with perfect regularity*'. High-fidelity models are not necessarily required in practice as what is essential is not that a model system 'looks like' the system of interest, but that it behaves like it. High-discrimination models are the required scientific tools. This is a key concept. The essential quality of a good model system is high discrimination: its ability, in the context of a defined biological process or outcome, to produce responses which correlate with the response of the system which they model.

Replacement alternatives (for example isolated tissues, cell cultures and computer models) are high discrimination but, inevitably, low fidelity. They '*reproduce one particular property of the original, in which we happen to be interested*'. The *Limulus Amoebocyte Lysate* test (Levin & Bang 1964), used to detect the presence of Gram-negative endotoxins in a range of materials used in clinical practice, is an example of

a low-fidelity/high-discrimination model. It does not use mammalian tissue; does not rely on reproducing the pyrexia and other systemic adverse effects seen when Gram-negative endotoxins interact with mammalian systems; but instead reliably demonstrates the presence of Gram-negative endotoxins by a specific change in the haemolymph of horseshoe crabs.

### The Three Rs

The concepts of replacement, reduction and refinement in relation to the use of animals in science can be traced back to Victorian Britain (Richmond 2000). An 1839 London Medical Gazette editorial advised that live animals should not be used:

*... till it is sufficiently clear that the fact pursued neither is, nor can be proved by any other evidence which is within reach, nor by any more mode of enquiry.* (Anon. 1839)

The principles of humane experimental technique also feature in Marshall Hall's publications from the same period. In an 1847 Lancet article he wrote:

*We should never have recourse to experiment in cases which observation can afford us the information required; No experiment should be performed without a distinct and definite object and without the persuasion that the object will be attained and produce a real and uncomplicated result; We should not needlessly repeat experiments and cause the least possible suffering, using the lowest order of animals and avoiding the infliction of pain; We should try to secure due observation so as to avoid the necessity of repetition.* (Hall 1847)

Russell and Burch (1959) subsequently provided a conceptual framework where humane animal care and use was set in the context of the need, whilst safeguarding or enhancing the quality of the science undertaken. This framework requires the implementation of all reasonable and practical means available to replace sentient animals; the reduction to the necessary minimum of the numbers used; the refinement of their production, care and use to minimise the suffering caused; and the promotion of research relevant to replacement, reduction and refinement.

They referred to replacement, reduction and refinement as the principles of humane experimental technique, but not as 'alternative methods' or the '3 Rs'. The earliest reference to replacement, reduction and refinement as the 'Three Rs' is in David Smyth's book *Alternatives to Living Animals* (Smyth 1978).

Russell and Burch (1959) defined:

- replacement as '*any scientific method employing non-sentient material which may in the history of animal experimentation replace methods which use conscious living vertebrates*';
- reduction as means of minimising, other than by replacement, '*the number of animals used to obtain information of a given amount and precision*';
- refinement as measures leading to a '*decrease in the incidence or severity of inhumane procedures applied to those animals which have to be used*'.

Progress with the Three Rs is not solely, or even primarily, driven by a desire to improve animal welfare. Methodological improvements are required to overcome the limitations of existing animal models and open up new lines of scientific enquiry. In practice, 'alternative' methods are generally more technically 'advanced', cost effective, reliable, easily scalable and scientifically valid than those traditionally used.

Thus the case for the Three Rs can be made simultaneously on three grounds:

- better animal welfare;
- better science in terms of quality and rate of progress;
- logistics and economics.

### A holistic approach

A holistic, rather than sequential, approach to the Three Rs is required, particularly with respect to reduction and refinement where tensions can exist, balances may have to be struck and synergies exploited. In all cases decisions must be taken on a case-by-case basis in the context of the specific scientific objectives being pursued.

### Simple words: complex meanings

The commonly used definitions of replacement, reduction and refinement are deceptively simple, and the use of these everyday words conceals subtleties of meaning that must be carefully considered and fully understood in order to appreciate the power and relevance of the Three Rs. Even the term 'alternatives' can mislead by creating the false impression that only replacement is relevant; and that alternative methods simply substitute for, but retain the scope and limitations of, the original animal models.

Replacement methods are not just substitutes for animal models: they are often better science, more powerful and versatile and the tools of choice. For example the use of robotics and *in vitro* replacement systems for high-throughput screening of potential novel pharmaceuticals allows rates of progress not previously possible using animal models.

Reduction is best considered as minimisation or optimisation of animal numbers. The intention is to minimise the number of animals required to provide suitably robust data: using more is wasteful; using fewer at best requires that work is repeated and at worst results in misleading conclusions being drawn from the available data. There are occasions when the original estimates of the number of animals required prove on examination to be too few to meet the scientific objective, and on these occasions applying the principles of reduction will result in the intentional use of more animals than originally estimated.

The total number of animals used annually for experimental and other scientific purposes is determined by a range of factors, including the level of spending on science (which is increasing in real terms), strategic funding priorities (for

example better understanding of gene function and control), the availability of new technologies (such as the ability to produce genetically altered animals) and changes in regulations to protect man and the environment (for example the European Union REACH legislation). Because of such drivers, progress with replacement and reduction cannot be judged simply on the basis of the total number of animals used for experimental and other scientific purposes. However, there are specific classes of animal use where replacement and reduction have had a demonstrable impact; for example improved tissue culture systems have effectively ended the use of animals to produce monoclonal antibodies by the ascites method; and the use of the Limulus Amoebocyte Lysate test has reduced the use of rabbits for pyrogen testing.

In some cases, to minimise welfare costs, balances have to be struck between reduction and refinement. More aggressive protocols, the intensive re-use of animals and less refined endpoints may allow scientific objectives to be attained using fewer animals, but at a disproportionate welfare cost. On other occasions, there may be a choice to be made between the use of asymptomatic large-animal models which will not experience significant pain, suffering or distress; and symptomatic small-animal models which will. Experience and expert judgment may be required to determine which option is both scientifically satisfactory and minimises the overall likely suffering. In all cases, the correct and most humane principle that can be applied is to minimise the total suffering that might be caused, without compromising the scientific objective, and without imposing an unreasonable welfare cost on any experimental subject (Richmond 1999).

Despite the tremendous progress that has been made with refinement, as evidenced by numerous practical instances detailed elsewhere in this book, it has proved difficult to date to capture and publish definitive data, other than case studies, which objectively demonstrate the resulting aggregate welfare gains.

### Scientific validation and regulatory acceptance

The adoption of new and improved research technologies depends on the publication and acceptance of technical progress. However, in many cases little or no prominence is given to progress with the Three Rs in mainstream core-science journals, and, although there are specialist publications and websites dedicated to the Three Rs, this literature may be unfamiliar to many scientists.

Formal scientific validation of alternative methods with respect to their relevance and reliability for their stated purpose, is required if non-animal tests, and more refined animal tests, are to gain regulatory acceptance. Scientific validation addresses test optimisation and definition, within-laboratory variability, transferability between laboratories, between-laboratory variability, predictive capacity, applicability domain and minimum performance standards (Balls *et al.* 1995). Although these can be addressed in a sequential process, 'modular' approaches (Hartung *et al.* 2004) have been developed to take account the non-sequential development of alternatives; as have 'weight-of-evidence'

(Balls *et al.* 2006) and 'catch-up' schemes to cope more efficiently with variations on existing methods.

The scientific validation of replacement, reduction and refinement alternatives is fraught with problems.

Although the most appropriate means to assess the validity of any replacement or more refined method would seem to be a direct comparison of its performance against reliable human (or other target species) data, this is seldom possible. Where animal test data is available the inherent variability, indeed unreliability, of some existing animal models presents difficulties. Available animal data tends to be of variable quality, generated using test systems not themselves fully standardised or scientifically validated, and which imperfectly reproduce the human response. An improved alternative test that has greater specificity or sensitivity, although better science and more reliable, will therefore give different results to the established animal model. The inability to reproduce strictly the results obtained with imperfect but established test methods can delay the validation and acceptance of new and improved test systems. In addition there is still no efficient global mechanism for the rapid regulatory acceptance and use of newly validated test methods.

### Training and teamwork

The ability to review that which has already been reported and to make new connections, or offer new insights, is common to success in many walks of life. It should be regarded as a core competence of all of those involved in the care and use of animals for scientific purposes. A scientific training and continuing professional development should instil and maintain the knowledge, mindset and practices that place the Three Rs at the heart of animal-based research and testing. The objective is not only to equip individuals with factual knowledge and technical skills relating to their immediate area of scientific interest, but also to develop the other competencies required to plan, conduct, assess and report high-quality, humane research and to keep abreast of technical progress.

This includes awareness and acceptance that expert input from others is required, as it is no longer possible for any one person to have all of the necessary knowledge and skills; and even the largest research teams may at times have to seek expert advice. For example, with the relentless increase in information available in both peer-reviewed journals and the internet, accessing and assessing relevant information increasingly needs specialist training and skills, requiring either the training of scientists to do this better, or placing reliance on information specialists. In addition, it is no more reasonable to expect a short training course in statistics to turn a biological scientist into a competent statistician, than it would be to expect an equally short training in the biological sciences to turn a statistician into a competent biological scientist.

For these reasons many research organisations provide institutional-level expert support with elements of animal care and use, experimental design, laboratory animal science and veterinary medicine.

### Replacement

Although we do not currently have the means to replace all forms of animal use without slowing or halting scientific progress in many areas of research and testing, replacement is relevant to fundamental and applied biomedical research, regulatory testing and the use of animals for education and training. Replacement alternatives offer a range of benefits over the animal models they supersede, often allowing more rapid progress than was possible using animal models and in some cases providing scientific insights not possible using animal models.

Russell and Burch (1959) defined replacement as '*any scientific method employing non-sentient material which may in the history of animal experimentation replace methods which use conscious living vertebrates*', distinguishing between 'absolute' replacement, with no sentient animal use (for example computer models), and 'relative' replacement, using animals in non-painful procedures (for example humane killing to obtain tissue, or the use of immature forms incapable of experiencing pain, suffering or distress).

Replacement alternatives must be based on good science and produce responses that correlate with those of biological systems which they model. Their development requires an understanding of the underlying biological mechanisms and their responses; and is often dependent on the availability (or *de novo* generation) of reliable animal or human reference data, and appropriate non-animal technologies.

Progress with replacement models has, to date, been largely with single-stage processes involving biological effects mediated by clearly understood single-event mechanisms, and for which there is high-quality human or relevant animal data. Devising non-animal models of more dynamic and complex biological interactions is more difficult; although a 2007 NC3Rs workshop has indicated that even with processes as complex as emesis there are signs that non-sentient test systems are possible and perhaps even within reach.

The range of replacement options can be deceptively wide and may include:

- strategies avoiding the need to generate new animal-based data;
- systems allowing elements of evidence gathering, analysis or decision making to be undertaken without live animal use;
- methods and models providing the required insights without causing procedure-related pain, suffering or distress to sentient animals.

### Replacement strategies and systems

In some instances, scientific objectives can be achieved without the need for additional animal use. Examples include:

- Amending regulatory requirements and provisions to dispense with inessential tests: for example the Abnormal Toxicity Test (Schwanig *et al.* 1997) is no longer required for the evaluation of a range of products used in clinical practice.

- Harmonising international validation processes, regulatory testing requirements and decision making to eliminate the need to use animals in different protocols to inform multiple regulators about a single toxicological endpoint.
- Reformulating scientific objectives to allow relevant insights to be gained using existing data or new non-animal data.
- Reviewing published work to ensure that relevant existing data is not overlooked and animal experiments inadvertently replicated. There is, however, an important distinction to make between unnecessary duplication (the unintended repetition of studies that have already been completed and reported) and justified, intentional replication. This latter class of animal use may be necessary when introducing new model systems, evaluating procedural changes, restarting programmes of work after periods of inactivity or changing laboratories or key personnel.
- Data sharing where previous relevant findings have not been published – for example accessing data generated for in-house decision making or contained in regulatory submissions.

### Replacement methods and models

Where additional data are required, a wide range of replacement methods and models can be considered:

- The use of physico-chemical properties to predict biological effects to screen or fully evaluate test materials. Examples include the use of pH and buffer capacity to predict potential severe ocular irritation or corrosion; and the use of computer models, generally strictly limited in scope and heavily dependent on reliable *in vivo* data, allowing molecular structure to be correlated with specific biological activities.
- The use of non-sentient organisms. Examples include the use of bacteria to assess genotoxic potential (Ames *et al.* 1973).
- The use of immature forms of sentient species incapable of experiencing pain, suffering or distress; for example fish larvae to evaluate aquatic toxicity.
- The use of *ex vivo* and *in vitro* systems, of animal or human origin, at the level of the organ, tissue slice, cell culture/suspension or sub-cellular component. These may be absolute replacements (for example non-primary cell cultures that do not require to be maintained using foetal calf serum), or relative replacements (for example animal primary-cell cultures, or other cell culture systems requiring the use of foetal calf serum).
- Human studies, subject to appropriate ethical safeguards. Data may be gathered in the course of volunteer, clinical-trial, post-marketing surveillance or epidemiological studies. New technologies (for example improved methods of diagnostic imaging, and pre-clinical markers of biological effects) can offer new opportunities to work with human subjects.
- A wide range of replacement alternatives can be used in education and training to demonstrate biological phenomena, processes and interactions; train partici-

pants in manual skills; and develop problem-solving skills. These include models, films and videotapes of procedures, interactive software simulations, courseware on compact discs and interactive laser discs, and virtual reality systems. See, for example, the Interniche website<sup>1</sup>.

### Reduction

Russell and Burch (1959) defined reduction as '*reduction in the number of animals used to obtain information of a given amount and precision*' other than by replacement, stressing the imperative to use the right number rather than too many or too few.

Reduction can be considered to comprise any strategy or method which:

- other than by replacement reduces the need for animal studies; or
- minimises the number of animals required to achieve a defined scientific objective; or
- permits more data or product to be obtained from the animals that must still be used.

Reduction and refinement must always be considered simultaneously. Focusing purely on decreasing numbers can lead to solutions that reduce the numbers used, but produce a disproportionate increase in the pain and distress caused to the animals that are used (Richmond 1999).

Whilst statistical elements of experimental design such as sample size, power, variation, precision and the proper application of appropriate statistical methods are important means of determining the number of animals required and interpreting the data that is generated (Festing & Altman 2002), there are equally important non-statistical reduction considerations such as selection of suitable experimental subjects, husbandry and care systems, procedural details and other means of controlling and minimising unwanted stressors and unnecessary variables (see Chapters 3–16).

It is important to be aware of the full range of reduction options and opportunities.

- The sequence in which objectives are pursued and experiments are carried out are important considerations.
- One of the most effective means of minimising the numbers of animals required for a programme of work is to apply tiered and hierarchical approaches to enable the early identification and discarding of materials (and hypothesis) not destined for further development, thus obviating the need for inessential animal studies. Taking the assessment of the ocular safety of materials as an example (Gallegos Saliner & Worth 2007): considering physicochemical properties; considering *in vitro* test results; conducting dermal safety tests; and identifying strong skin irritants and corrosive materials, enable a reliable evaluation to be made of likely ocular safety without the need to undertake tests on live animals. When ocular safety tests on live animals are

<sup>1</sup><http://www.interniche.org/>

still required, testing first on a single animal can reduce the number of animals used as materials giving strong positives in a single animal do not require confirmatory testing using additional animals. These examples also link to refinement, dispensing with the need to use animals to test materials most likely to cause the greatest degrees of pain, suffering, distress and lasting harm. In other contexts, small proof-of-concept studies, if they fail to demonstrate the expected outcomes, obviate the need for failed large-scale definitive studies.

- Preliminary *in vitro* data can reduce the number of animals required for definitive studies.
- Although no single *in vitro* test, indeed no battery of such tests, has yet been scientifically validated as a full replacement for the live rabbit ocular safety test, a positive test result for some classes of test materials in some *in vitro* test systems can be accepted as evidence of ocular corrosive or severe irritant potential, requiring that only materials testing negative in the *in vitro* systems are further characterised using live animals (Gallegos Saliner & Worth 2007). This example again links to refinement.
- Preliminary cytotoxicity data is now used to reduce the number of animals used in acute toxicity studies by determining the appropriate doses of test materials to be used in the animal studies (ICCVAM 2001).
- Sometimes definitive studies can only be planned in detail once preliminary animal data are available:
  - Pilot experiments are small-scale preliminary studies to examine the logistics of proposed definitive studies (see Chapter 3). In many cases the results will not be published, but will be used to design improved definitive studies. Procedural improvements can include insights into: likely inter-individual variation and the number of animals required to obtain robust scientific results; the most appropriate dosing and sampling regimens; the nature, incidence, severity and timing of possible physiological, behavioural changes and adverse effects; and how they can best be avoided, elucidated or managed. Importantly, they may identify and remedy unexpected, extraneous experimental variables before larger-scale studies are undertaken.
- The number of animals required to meet the scientific objectives reflects the required degree of precision and certainty; thus the number of animals required should be no more than is necessary to meet the scientific objective:
  - There may be opportunities for reducing the number of animals required by taking account of prevalence of the outcome of interest (Hoffmann & Hartung 2006): it may require less data to identify candidate test materials with a common property, than with an uncommon property.
  - Where test materials are only to be assigned to general categories, requiring only an estimate of their biological properties, smaller numbers of animals may be sufficient rather than the larger numbers required to calculate the more precise or absolute values necessary to place test materials in rank order.
- Making appropriate use of control groups and data:
  - A negative control is known to give a negative result, acting as a means of demonstrating the baseline result obtained when a test was conducted, and confirming that the basic conditions of the test system were able to produce appropriate negative results even if the experiment does not produce a negative result.
  - A positive control is treated to produce a positive result under normal conditions, confirming that the basic conditions of the test system were able to produce appropriate positive results even if the experiment does not produce a positive result.
  - Control and other experimental groups are in all other respects exposed to identical conditions, observations and investigations.
  - Control groups can be used as standards for comparison, making conclusions about the relevance and significance of the results more robust by demonstrating that the test system is appropriately responsive; eliminating alternative explanations of experimental results (the possibility that the experimental subjects were prone to, or incapable of, giving appropriate positive or negative results); and taking account of other potential confounding variables within the test system (for example the chance that some unrecognised intercurrent problem influenced the responses observed).
  - In cases where the experiment causes substantial suffering it may be possible to reduce the numbers of animals in the treatment group but increase the numbers in the control group (by more than the numbers reduced in the treatment group). This technique results in the same statistical power, but fewer animals suffering in the treatment group. This example illustrates the need for taking informed decisions when refinement, in the sense of the total suffering that may be caused, must be balanced against outcomes requiring the use of larger numbers of animals.
  - When there is a need for control data, the number of animals might, in some circumstances, be minimised by the use of a single concurrent control to evaluate simultaneously a range of test materials for the same biological property, or by the use of historical controls. Both of these are relevant, for example, when animals are used to evaluate the skin sensitisation potential of test materials. In these studies a single control group may suffice when a number of test materials are tested in the same laboratory on the same day. Moreover, the routine use of concurrent positive controls, to demonstrate that the test method as applied in a laboratory can produce an appropriate positive response, is generally unnecessary if the routine testing programme itself regularly produces both positive and negative results.
- In some circumstances, a disproportionately large amount of additional information can be gained from

the use of small additional satellite groups to pursue more than one scientific objective within a single experiment. For example, toxicokinetic data can be gathered in the course of single-dose toxicity studies (ICH 1994).

- The degree of uniformity/lack of variability within and between experimental subjects is an important determinant of the number of experimental subjects required, and all reasonable efforts should be made to control relevant genetic and epigenetic factors and promote uniformity. In this context there are many synergies between reduction and refinement:
  - The use of purpose-bred animals permits varying degrees of control of genetic variability and microbiological status, and for many of the commonly used species the availability of inbred and isogenic strains allows the use of smaller group sizes than is possible with outbred or random-bred animals (see Chapter 4). In some instances the use of genetically identical animals allows scientific progress to be made that would otherwise be impossible (Festing & Fisher 2000).
  - Variability can be further reduced by providing a controlled and standardised environment, with the most uniform populations and results being produced when the environment is optimal for the animals' well-being (Chance 1957; Chance & Russell 1997). Variation (and therefore sample size) is reduced, not simply by ensuring a uniform environment, but by providing specific environmental conditions.
  - Stressed animals have different baseline behaviours, physiological findings and range of responses to experimental interventions, from unstressed animals. Therefore, all reasonable efforts should be made to identify and remove or minimise unnecessary stressors (Poole 1997).
- Even when the number of animals required for a given experiment cannot be reduced, there may be some scope to reduce the number of animals required for a programme of work by the responsible re-use of animals:
  - Re-use may be defined as the second or subsequent scientific use of an animal that has already completed a series of procedures for a defined scientific purpose when the use of a naïve, unused animal would have also been scientifically satisfactory.
  - Whilst re-use may reduce the total of number of animals required for programmes of work, it has to be balanced against the resulting increased, cumulative suffering experienced by the individual re-used animals.
  - Re-use should only be considered when the following conditions are met:
    1. The first use has not compromised the suitability of the animal for the second or subsequent use (for example animals which have been exposed to a pathogen or immunogen will not give a naïve response if subsequently re-exposed).

2. Animals experienced only minimal pain, suffering and distress, and no lasting harm, from their earlier use.
3. The animals have been shown on a case-by-case basis by a competent person, after completion of the first use, to have been restored to a normal state of well-being.

Examples include the re-use of rabbits which have given negative results in skin irritation tests for a single ocular safety study; the use of animals as blood donors; and, subject to suitable recovery periods, the re-use of dogs or non-human primates in pharmacokinetic studies.

- Matching the production of animals and the availability of animal tissues to known or likely demand avoids waste. Common examples include cryo-preservation of genetically altered animal lines (Glenister & Rall 2000) rather than maintaining 'tick-over' colonies, and through in-house tissue-sharing schemes finding scientific uses for tissue harvested when breeding stock are humanely killed.
- Retrospective analyses of results may show that the number of animals needed could in future be reduced without loss of precision. This has been found to be the case with some vaccine potency assays (Hendriksen & Steen 2000).

## Synergies and conflicts

It is clear from the above that reduction and refinement are interrelated and must be considered concurrently.

In addition there are technologies that involve initial surgical preparation but which then reduce the total number of animals required, minimise the stress animals subsequently experience and improve the quality of the findings. For example, there is a range of implantable telemetry devices (Kramer & Kinter 2003) that allow the remote capture of intermittent or continuous streams of 'physiological data' whilst animals undertake normal activities unstressed by disturbances to the social group, sedation, handling or restraint. These technologies may permit the numbers of animals per study to be reduced by the capture of serial data and the re-use of telemeterised animals.

In such cases there are trade-offs to be made between the welfare costs of the initial surgical preparation, the reduction in the number of animals required to give meaningful results, the procedural stresses that can be avoided after recovery from surgery and the improved nature and quality of the data that can be gathered (Brockway *et al.* 1993; Schnell & Gerber 1997), illustrating the interaction between the Three Rs, and the need to take a holistic rather than a sequential approach when putting humane experimental technique into practice.

## Refinement

Russell and Burch (1959) defined refinement as measures leading to a '*decrease in the incidence or severity of inhumane procedures applied to those animals which have to be used*'.

Refinement is not just a matter of minimising the incidence of adverse effects, or the number of animals used; it is minimising the total pain, suffering, distress and lasting harm that may be caused. A higher incidence of findings not indicative of a high welfare cost, such as reduced weight gain, may be preferable to a lower incidence of endpoints clearly indicative of higher levels of suffering.

### The significance of refinement

Refinement improves the quality of life of every animal bred, kept and used for experimental and other scientific purposes, and benefits every programme of work using live animals.

Consideration of refinement starts the moment there is an intention to breed or keep an animal for experimental or other scientific purposes; continues throughout the scientific use of the animal until it is humanely killed or otherwise disposed of; and does not end until the lessons learned are incorporated into future practice.

If research findings are to be considered meaningful then, before the scientific procedures are applied, the animals will ideally have physiological parameters and behaviours within the normal range. More refined systems of care and use, or rather the higher welfare state they produce, impact on experimental findings (Poole 1997; Bayne 2005). A key concept is that the impact of refinement on research findings must be seen as a stimulus rather than a barrier to developing and accepting more refined methods – as refinement, high standards of welfare, normal experimental subjects and good science go hand-in-hand. The possible limitations and inadequacies of data sets and conclusions obtained with less refined practices, rather than constituting a criticism of the scientific validity of data obtained by more refined methods, are an indictment of the reliability of the less refined methods. The fact that more refined methods might influence results is thus a powerful reason to accept, rather than resist, progress and change.

### Staff competencies and responsibilities

Animals in captivity are totally dependent on man for their well-being, and the attitudes and skills of those responsible for their care and use are the most important factors in achieving high welfare standards and conducting sound science. In addition to being technically competent, it is important that all staff develop and display an appropriate 'culture of care'.

The best and most refined use of animals in science requires a multidisciplinary, team approach. Laboratory animal veterinarians, laboratory animal scientists and animal care staff must play an active and expert part in refining animal care and use. Staff must be trained to recognise both normal behaviours and signs of pain and distress, both to improve all aspects of animal care and facilitate the recognition of experimental effects.

Those responsible for assessing animal welfare must be empowered to make the best provision for their housing, care and use; and to take prompt action when scientific and

welfare endpoints are approached or reached. They must be aware of contingency plans to deal with unexpected adverse effects.

### Assessing well-being

To make proper provision for animal welfare it is essential to understand and recognise what is '*meaningful to the animal*' and to do '*what is right for the animals*' (Russell & Burch 1959). Recognition of an abnormal state depends on an awareness of, and familiarity with, normality in the species and individual under observation. In the absence of evidence to the contrary, it is to be assumed that any stimulus, experience or pathology that produces pain and discomfort in man, also does so in sentient animals (Home Office 1965).

The behavioural and physiological responses of animals to adverse effects are not uniform between species, strains, individuals of the same species and strain, or even in the same individual at different times (Scharmann 1999). Thus assessment of welfare takes place at the level of the individual animal.

Welfare is assessed by taking into account behavioural, physiological, clinical and laboratory findings (see Chapter 6). Of these, behavioural findings and changes are often the earliest, most sensitive and most meaningful indicators.

Confidence in indices of welfare is best placed in findings which:

- occur in an appropriate context;
- progress with the nature and severity of the insult;
- are predictive of the ultimate welfare, clinical or pathological outcomes;
- can be controlled with appropriate specific, supportive or symptomatic measures or treatments.

For example, signs considered to be indicative of pain should occur in contexts where there is reason to believe pain may be present, and should abate with prompt, effective analgesic administration. However, it is important to recognise that:

- animals may be distressed, though not in pain, and therefore display signs which analgesics will not alleviate – this may be seen for example in animals with locomotor impairments due to neurological damage;
- analgesics can have direct pharmacological effects unrelated to pain relief producing behavioural changes and altering clinical findings (Roughan & Flecknell 2000);
- identifying and managing chronic pain and distress, where the signs can be insidious, pose particular difficulties (Flecknell & Roughan 2004).

As the judgement of animal well-being ultimately rests with humans a degree of critical anthropomorphism is perhaps inevitable. 'Critical' in this context implies empathy tempered with objective knowledge of the animal, its needs and normal behaviours; preceding events; and the significance of any signs which may be seen.

Expert judgement can be required to understand the scope, limitations, possible interpretations and significance

of even seemingly objective measures. Pitfalls to be borne in mind include:

- demonstrating behavioural or physiological differences contingent upon changes to an animal's environment. Otherwise, the procedures applied may not clearly indicate which represents the lesser welfare cost or higher welfare state;
- preference testing (Kirkden & Pajor 2006) may only identify the least objectionable rather than the optimum option, and short-term preferences may not be indicative of long-term preferences, needs and benefits;
- although technology is improving, measuring even basic physiological phenomena and behaviours sometimes requires additional interventions that add welfare costs or alter the parameters being measured.

### Severity scoring systems

A number of disturbance indices and severity scoring systems (see, for example, Hendriksen & Morton 1999) have been developed to assist with the assessment of the welfare of animals used for experimental purposes, to identify protocols with high welfare costs where work on replacement or refinement might most usefully be commissioned, and to evaluate the impact of potential refinement measures (see Chapter 6).

Such systems are based upon discrete and continuous indices of welfare, with continuous variables categorised to reflect what we understand to be meaningful differences in levels of significance and suffering. Combinations of signs tend to be more significant than the occurrence of any sign in isolation. Although they must be contextualised and adapted to reflect the research objectives, models and protocols, they are valid whether impaired welfare is due to the immediate or delayed, local or systemic, or primary, secondary or tertiary effects of the procedural interventions.

They encourage the use of standard documentation, and plain non-technical language with a limited range of keywords to identify, describe and record findings. These simplify staff training, provide a systematic approach to evaluating welfare and facilitate communication within and between research groups.

### Refinement: contingent and direct costs

The welfare costs to animals bred, kept and used for experimental and other scientific purposes have two distinct components (Russell & Burch 1959):

- 'contingent' welfare costs (harms), comprising the welfare-negative aspects of animal production and care whether caused by acts of commission or omission;
- 'direct' costs (harms) resulting from the experimental procedures applied.

### Refinement: contingent harms

Animal facilities and care practices must facilitate high standards of animal welfare and high-quality research by

eliminating, or controlling and minimising, unwanted variables whilst making the best possible, appropriate provision for the physiological, social and behavioural needs of the animals (see Chapters 9–12).

### The physical environment, husbandry, accommodation and care

Many elements of accommodation and care affect the welfare of animals and their response to experimental interventions (Poole 1997; Bayne 2005). These can affect both the validity and reproducibility of findings to an extent that experimental results may only be valid for, and reproducible within, the conditions under which they were obtained.

Ideally, standards of animal care and accommodation would be based on objective evidence of what is required to make best provision for animal welfare. At present much of the evidence required to derive and support such standards does not exist, with guidelines and regulations being based on a combination of the results of welfare research, field research, existing good practice and only making provision for the minimum expected or acceptable standards of care and accommodation (Council of Europe 2006).

### Pair- and group-housing

It has been shown in many species that housing with one or more socially compatible conspecific significantly reduces stress, and that being kept singly in isolation compromises both an animal's welfare and its suitability as an experimental subject (Poole 1997). Animals, other than those which are naturally solitary, should be socially housed in stable groups of compatible individuals. Nevertheless, care is required to ensure that pair- and group-housed animals are socially compatible, and it must be remembered that population density and group size influence the physiological and psychological state of the animal and affect experimental responses.

There will be some circumstances, for example the use of a single instrumented animal, when the companion animals will not be experimental subjects yet will be exposed to any contingent harms.

Animals should be singly housed only on veterinary or other welfare grounds, or justified scientific need; in which case animal care and veterinary staff should be involved, and appropriate additional resources targeted at animal welfare.

### Space: requirements and structure

The key considerations are the animals' physical and behavioural needs, and how provision for these is best made within the context of their production, care and use.

Basic physiological and ethological needs (such as freedom of movement, appropriate social contact and the ability to withdraw from social conflict; the performance of meaningful activities; and access to food and water) should never be restricted without good cause, and then only to the justifiable minima.

Animals should be provided with a sufficiently spacious and complex environment to facilitate a wide range of normal activities and behaviours, taking account of their physiological and ethological needs. The preferred systems will vary according to species, strain, age, physiological condition, stocking density and group size, and whether animals are kept as stock, for breeding or experiments.

### Environmental enrichment

Environmental enrichment (see Chapter 10) covers a wide range of provisions with which a captive animal can interact to promote its physical and psychological well-being. Enrichment can achieve this by allowing and maintaining the expression of normal species-appropriate (and in some cases strain-specific) social interactions, and physical, behavioural and mental activities; or preventing or reducing abnormal physical findings and behaviours.

The laboratory environment can never reproduce the complexity of an animal's natural environment, and the intention is generally to mimic critical natural environmental factors so that normal, strongly motivated behaviours can be expressed, reinforced and maintained (Blanchard & Blanchard 2003). Not all natural behaviours are appropriate in the laboratory setting (Fraser 1993): natural behaviours may represent what the animal needs or wants to, would not normally choose to do (for example, responding to or coping with environmental stressors), or will only choose to do when the opportunity or need arises.

Environmental enrichment options can be categorised as:

- **Social enrichment:** housing with compatible conspecifics complemented by space of sufficient volume and complexity to permit an appropriate range of species-specific interactions and interaction with man. In many circumstances, social enrichment is both more effective than inanimate physical enrichment, and a prerequisite for the effectiveness of physical enrichment. Appropriate early social experience can be essential for the development of a normal behavioural repertoire; thus conditions at breeding and rearing facilities play a large part in determining the subsequent suitability of animals as experimental subjects or future breeding stock.
- **Physical enrichment:** including the provision of an adequate amount of suitably structured space, materials to manipulate, sensory stimuli and a varied diet. To prevent or reduce stress-induced behaviours animals should be given a degree of control over their environment by encouraging species-appropriate physical exercise, foraging, manipulative and cognitive activities.

A creative and critical approach is required. Not all changes are beneficial; and if one form of enrichment is chosen others may have to be excluded.

It is important that appropriate options are identified and critically evaluated in terms of immediate and long-term impact on the animals' well-being and on the research objectives (Bayne 2005; Benefiel *et al.* 2005). Assessing the impact of potential environmental enrichments depends on the ability of staff to interpret and draw informed inferences

about the animal's state of mind and welfare state. Measures of success can include:

- normalisation of the frequency and duration of appropriate normal activities;
- greater control over the spatial, physical and social environment;
- reduced frequency of abnormal behaviours;
- increased, appropriate and purposeful use of the environment;
- increased ability to adapt to and cope with changes and challenges;
- more robust scientific results.

It cannot be overemphasised that the most important resources required to devise and evaluate environmental enrichment opportunities are competent and caring staff.

### Restraint

During the course of a variety of husbandry and scientific procedures, animals may be restrained to minimise the risk of injury to the subject and handler, and facilitate the performance of the procedures. Restraint can be stressful, producing changes in physiological parameters and behaviours depending on the nature, duration and degree of restraint, particularly when the restrained animal is also removed from its enclosure or social group. Appropriate restraint procedures will depend on the species and the nature and duration of the procedure for which the animal is being restrained, with the most refined method of restraint being that which causes the least stress to the animal and its social group.

Training to accept reasonable restraint procedures is possible in a range of species, and has been shown to reduce the resulting physiological and behavioural changes (Wolfensohn & Honess 2005). Consideration should always be given to the use of procedural training to encourage animals to allow the safe performance of routine procedures without the need for restraint (see Chapter 16).

### Marking and identification of animals

Individual animals bred, kept and used for experimental and other scientific purposes need to be identifiable. This is generally achieved by marking individual animals rather than identification based on natural physical characteristics. Faced with a choice of effective identification and marking methods, the preferred means is that which causes the least pain, suffering or distress to the animal.

### Transport of animals

The transport of animals, between or within establishments, indeed even within a room, can be stressful. All reasonable efforts must be made to avoid or minimise any stress that may be caused, and to ensure that animals are acclimatised to a new environment before being used for scientific purposes (see Chapter 13). Journey times should be minimised, the least stressful modes of transport used, and appropriate contingency plans should be in place.

The subsequent acclimatisation period will vary with the stresses imposed by transportation; the differences in the

housing and care systems; and the species, strain and the condition of individual animals. It may be necessary to take expert advice to determine the appropriate minimum period for recovery and acclimatisation, and to confirm that animals have recovered before being used for scientific purposes.

In some cases, welfare costs can be minimised by transporting ova or embryos rather than live animals – and this is also a means of disease control when acquiring animals from facilities of different or unknown microbiological status.

### Humane killing

The majority of animals produced and used for scientific purpose are humanely killed as part of, or at the end of, their scientific use – as are surplus stock.

Humane methods of killing (AVMA 2001; Close *et al.* 1996, 1997), when properly applied, typically ensure rapid loss of consciousness without producing signs of pain or distress, and result in the death of an animal with a minimum of physical and mental suffering. They should also be aesthetically acceptable, and must incorporate careful and compassionate animal handling routines that avoid or minimise the stress due to any necessary restraint or the need to remove the animal from its enclosure or social group (see Chapter 17). All require expertise which can only be developed by appropriate training, and the provision and maintenance of appropriate equipment.

After a humane killing method is applied, in all cases death should be confirmed before removing tissues or disposing of cadavers.

### Refinement: direct harms

A number of procedures applied to animals for experimental purposes impose welfare costs. The welfare costs tend to vary in proportion to:

- the degree of sentience and needs of the individual experimental subject;
- the nature, duration, intensity and frequency of the challenge;
- the biological systems and mechanisms involved;
- other factors which aggravate or ameliorate the suffering experienced by an individual experimental subject.

### Choice of experimental subjects

Animals produced and used for experimental and other scientific purposes should to all intents and purposes be normal, with any departure from their normal state being directly and intentionally attributable to the scientific procedures applied. Standardisation of experimental subjects requires an understanding and control of factors including the animal's genotype; environmental conditions; other elements of animal husbandry, accommodation and care; and microbiological status.

The choice of species is thus relevant to refinement. Some species:

- are afforded special legal protection;
- are believed to have a greater capacity to experience pain and distress (sometimes referred to as 'neuro-physiological sensitivity');
- have specific, complex husbandry requirements difficult to provide in the research context.

Choosing the species whose needs can best be catered for in the laboratory setting may constitute refinement.

In addition, where there is flexibility in the interpretation and implementation of regulatory testing requirements, selection of the 'lowest' appropriate species should be on scientific considerations, not custom and practice or availability.

Animal models of disease, animals expressing harmful natural genetic mutations and some lines of genetically altered animals (Wells *et al.* 2006) have specific problems and needs in addition to, or different from, those of normal animals. These special needs must be considered, identified and met when such animals are bred, kept or used for scientific purposes.

### Wild-caught animals

Such are the environmental, ethical, welfare and scientific benefits of using purpose-bred animals, that the use of non-purpose bred, and in particular wild-caught, animals requires special and specific justification. Where the use of wild-caught animals can be justified, capture should be by competent persons using humane methods, minimising the impact of capture both on the captured animals and the remaining wildlife and habitat (see Chapter 7). Animals in poor health should be examined promptly by a competent person, and appropriate action taken.

Proper provision must be made for the acclimatisation, quarantine, housing, transportation, husbandry and care of wild-caught animals, mindful that their behaviours and needs are likely to be different to those of animals bred in captivity. The eventual fate of wild-caught animals should be given due consideration before work begins.

### Experimental models

Always consider whether the scientific objective might be achieved by the use of animal models where pre-clinical endpoints can be set. The murine local lymph node assay for skin sensitisation (Kimber *et al.* 1990) is a case in point. It relies on subclinical changes caused by the induction phase of the sensitisation process; whereas the traditional guinea pig maximisation test relies on the clinical changes and gross pathology of the acute dermatitis seen as a result of the subsequent full-blown allergic response.

### Procedural training

Training using positive reinforcement (see Chapter 16) to encourage co-operation during procedures (from weighing animals, through common methods of dosing and sampling, to sophisticated behavioural testing), can be beneficial to the

animals, their handlers and the programme of work (Wolfensohn & Honess 2005) by:

- reducing the procedure-related stress;
- dispensing with the need for animals to be forcibly restrained;
- fostering human/animal socialisation;
- enabling those handling the animals to become familiar with individual animals' normal behaviours;
- reducing the time taken to perform the procedures.

### Reward vs punishment

Behavioural testing often requires that experimental subjects remain interested in performing prescribed tasks. Various means have been devised to better motivate experimental subjects to undertake such tasks on demand or for longer periods.

Methods of motivating test subjects may be based upon rewards/positive reinforcement (for example, access to a preferred food or drink as a reward for displaying the desired behaviours) or punishment/negative reinforcement (for example, exposure to an air-puff or mild electric shock to discourage other behaviours). In some cases, the reward may be made more desirable by a period of deprivation (for example, access to fluid after a period of enforced fluid deprivation).

The most refined and ethically justifiable paradigms are those that rely solely on reward/positive reinforcement systems without prior deprivations, with punishment/negative reinforcement regimens requiring specific justification.

### Dosing

Research protocols commonly require that animals are dosed with test materials, and detailed advice on limit volumes and practical issues is available elsewhere (Diehl *et al.* 2001). Refinement is relevant to consideration of:

- The dose or exposure:
  - if the intention is to mimic natural exposure, to attain or maintain a particular level at a target site, or to produce a specific effect (and not to produce unwanted effects) pilot studies may be required to identify the appropriate dose/exposure parameters.
- The route of administration:
  - With oral administration admixing the test material with food or water (providing palatability is not a problem) or administration in liquid, tablet or capsule form, may be more refined than gavage-dosing. When gavage-dosing is used staff must be sufficiently well trained and experienced to avoid misdosing or accidental injury; and the timing of the doses, and volumes administered, must neither compromise the animals' normal food and fluid intake, nor cause discomfort or other volume-related effects.
  - Test materials may be administered parenterally by injection or cannula. Other than administration directly into the circulation, this can lead to varying rates of uptake depending principally on the injection

site, the general condition of the animal and the volume and formulation used. Administration by intraperitoneal injection is a special case: it results in the test material being taken up simultaneously into the systemic circulation and hepatic portal circulation (where it may be metabolised by the liver before it enters the systemic circulation). How test materials partition between the portal and systemic circulations depends on the nature and volume of the test material, varies from subject to subject, and in the same subject from day to day.

- Topical application of test materials to skin or mucous membranes may require some form of restraint, or other measures, to ensure the test material remains in place and is not ingested by the animal or its cage mates.
- The frequency and duration of dosing:
  - These are generally determined by the properties of the test material (for example, its bioavailability and biological effects), its interaction with the experimental subject (for example, how it is metabolised, where it accumulates and how it is excreted) and the study objective.
- The equipment used:
  - For injection procedures the smallest bore needle capable of delivering the volume required in an acceptable time should be used.
  - The need for multiple injections, and the associated restraint procedures, may be dispensed with by the placement and use of cannulae to permit repeated (or continuous) administration. These potential *refinement* gains must be balanced against the welfare costs of the procedures to insert the cannulae, the restraint and other cannula-care procedures that may be required, and the possible cannula-related problems.
- The volumes to be administered:
  - For intravascular administration the volume and the time over which materials are administered should avoid unwanted volume-related effects, and should not produce any biological changes due to the nature and volume of the vehicle used. Advice on limit volumes (which should always be considered the justifiable maxima rather than the norm) can be found elsewhere (Diehl *et al.* 2001).
  - For injection into closed spaces (for example, intramuscular or intradermal injection) the volumes and rates of administration should avoid adverse effects due to pressure effects or over-stretching of tissues.
- The formulations to be administered:
  - The formulation and volume of test materials used are generally determined by the frequency of administration, the required accuracy of dosing, the nature and solubility of the test material, the required dose and preferred concentration.
  - In general, for parenteral administration the closer the osmolarity, pH, buffer capacity, viscosity and temperature of the test material to normal body fluids the greater the biocompatibility and the less discomfort and stress will be caused.

In many cases the most refined options to meet the scientific objective can only be determined by pilot studies.

### Blood sampling

Blood sampling is one of the most common procedures used in animal research, and advice on limit volumes (which should always be considered the justifiable maxima rather than the norm) and other practical issues is available elsewhere (Diehl *et al.* 2001).

Refinement is relevant to:

- The nature of the sample:
  - In many species venous blood can be obtained from superficial veins by venepuncture or venesection.
  - Arterial blood is generally obtained by direct arterial puncture or closed cardiac puncture (the insertion of a needle directly through the chest wall into the left ventricle of the heart under general anaesthesia). Cardiac puncture is best suited to sampling under general anaesthesia from which the animals are not allowed to recover.
  - Blood obtained by retro-orbital puncture is not a physiological fluid: such samples comprise admixed capillary and venous blood, contaminated with other tissue fluids, in which a variety of clotting factors have been activated. Its haematological and biochemical parameters are neither physiological nor representative of blood anywhere in the systemic circulation.
- The frequency of sampling and the volumes required:
  - The volumes, rates of withdrawal and frequency of sampling must be designed to prevent hypovolaemia and anaemia. Average blood volumes and limit sampling volumes are generally calculated on the basis of body weight (Joint Working Group on Refinement (JWGR) 1993; Wolfensohn & Lloyd 2003), but must be interpreted in the knowledge that the safe sampling limits are typically lower in animals with welfare problems.
  - If frequent samples are required, consider cannulation as a means of minimising the stress of sampling.

Up-to-date information and detailed advice on contemporary good practice can be found at the NC3Rs web site<sup>2</sup>.

### Non-invasive sampling

A range of biochemical parameters can be measured without the need to obtain blood samples. A number of hormones and metabolites can be measured in urine and faeces, allowing estimates to be made of recent circulating levels in unrestrained animals, mindful that there is a time lag between their production, release and excretion. Procedural training has been used to ensure animals deposit excreta in suitable receptacles without being restrained.

Although physiological responses to instantaneous stressors cannot be measured in urine or faeces, for some materi-

als determination of salivary levels can provide a minimally invasive means for measurement of short-term responses and for detecting and quantifying other metabolites and biomarkers (Chiappin *et al.* 2007).

### Anaesthesia and analgesia

A detailed review of current best practice in the use of anaesthetics and analgesics is beyond the scope of this chapter, and authoritative information can be found elsewhere (see, for example, Flecknell 2009; Flecknell & Waterman-Pearson 2000) and in the species-specific chapters, but there are a few general principles particularly relevant to refinement.

General anaesthetic agents affect many physiological parameters, and care must be taken to ensure this does not compromise experimental data or animal welfare. Appropriate steps should be taken to monitor and maintain the circulation, respiratory function and the body temperature of the anaesthetised subject within normal physiological limits throughout surgery and until the effects of general anaesthesia have worn off.

Recovery from general anaesthesia can be hazardous, and animals should not be left unattended until the effects of general anaesthesia have worn off, any necessary specific, symptomatic or supportive treatments have been given and their effectiveness determined. Consideration should be given to administering the first dose of analgesia before recovery from anaesthesia as total post-operative analgesic requirements are reduced when the initial dose of analgesic precedes the animal's ability to feel pain.

Post-operative analgesia should be the norm, and it should be administered as required to control pain and speed the restoration of normal behaviours, such as food and water intake, thus shortening the post-surgery catabolic phase. This requires appropriate observation schedules, and that the treatments given are based on the findings in, and needs of, individual animals.

### Surgery

Surgical procedures must only be carried out by competent persons; using the best available surgical and animal care techniques; and the anaesthetic and analgesic regimens best suited to the species, the nature and duration of the procedure and the scientific objective. Recovery surgery should be performed using aseptic technique in areas designed for and dedicated to this purpose.

The availability of trained, competent staff to take responsibility for the care of animals during the post-operative period must be determined before surgery is scheduled. To make best provision for post-operative care it is recommended that complex surgical procedures are carried out as early in the working week, and working day, as possible.

### Observation schedules

Arrangements must be made to check animals under study at appropriate times to gather data and safeguard their welfare. All animals should be checked at least once a day by a competent person capable of recognising and remedy-

<sup>2</sup><http://www.nc3rs.org.uk/bloodsamplingmicrosite/page.asp?id=426>

ing welfare problems. The frequency of checks should be intensified when problems are likely, or have occurred.

Good communication and teamwork are essential. Positive findings, the action taken and the animal's response should be recorded.

## Humane endpoints

Humane endpoints, minimising the direct welfare costs of justifiable animal-based research, are essential components of humane experimental technique, and a cornerstone of refinement (Richmond 1999). Humane endpoints incorporate all reasonable and practical steps that can be taken to minimise justifiable suffering by avoiding, or promptly recognising and remedying, unnecessary adverse effects arising during scientific procedures.

To some the term 'humane endpoint' merely represents '*the earliest indicator in an animal experiment of severe pain, severe distress, suffering, or impending death*' (OECD 2000). That is a dangerous misconception.

Contrary to the narrow OECD definition, humane endpoints are often particularly appropriate when levels of pain and distress being experienced are not high and death is not imminent. Indeed, early indicators are often the most meaningful with respect to welfare problems and scientific outcomes, and avoid unwanted later changes due to unnecessary secondary or tertiary effects.

## Humane endpoints in practice

Humane endpoints must be objective and evidence-based in order to:

- avoid the needless culling of animals whose welfare is less compromised than believed, or before the scientific objective has been achieved;
- prevent evidence indicative of significant suffering being missed;
- inform judgments about the severity of different procedures and models;
- evaluate potential refinements.

Although they must be contextualised to the project, the experiment and the experimental group, they are best thought of as being applied to the individual animal.

Humane endpoints take account of legal, ethical, welfare and scientific considerations, and must cater for a number of eventualities including:

- having achieved the experimental objective (or when it is recognised it cannot be achieved), even if there is no immediate welfare problem; indeed in some cases pre-clinical endpoints can be set and implemented;
- experimental subjects experiencing pain, suffering, distress or lasting harm beyond that which is required or can be justified; again such endpoints are often invoked at low levels of suffering – for example reduced weight gain can often be accepted as an early indication of overt toxicity;
- when intercurrent problems, for example a subclinical background infection, compromise the quality of the

data or product, even when they may not have compromised the well-being of the animals – for example mice known to be carrying the mouse hepatitis virus may have no overt welfare problem, but will have atypical immune responses.

When an endpoint is recognised, the action taken may take several forms including:

- the animal ceasing to be an experimental subject;
- adjusting the protocol to reduce or remove the immediate cause of the adverse effect to allow the animal to recover;
- the administration of specific, symptomatic or supportive treatments;
- humane killing.

Humane endpoints must be described in meaningful terms and be promptly recognised and acted on by those entrusted with the welfare of the animals. There should be no delay between their detection and appropriate action being taken.

## Planning of humane endpoints

Before animal use begins, humane endpoints should be defined; minimum observation schedules determined; and arrangements for the provision or withholding of specific, symptomatic and supportive treatments, and other remedial measures, established. This requires an understanding and consideration of likely adverse effects (immediate and delayed: primary, secondary and tertiary), and how they will be avoided, recognised and remedied. The critical periods, training needs and resource implications should be identified before work starts. Thought must also be given to how unforeseen outcomes will be identified, interpreted, reported and managed. Particular care may be required to recognise transient pharmacological effects not indicative of true welfare problems. Pilot studies can inform the timing of observations and how the adverse effects should be identified and managed, minimising the welfare costs of definitive studies.

An understanding of relevant biological mechanisms and likely clinical findings allows appropriate symptomatic and supportive therapies to be delivered, permitting the processes of interest to continue whilst minimising or eliminating unnecessary suffering. In practice, primary changes are often subtle in nature and, even when symptomatic and supportive treatments are given, are overshadowed by less specific secondary (for example anorexia) or tertiary (for example weight loss or dehydration) changes. Untreated secondary and tertiary effects compromise both science and welfare: therefore you do not need a reason to give supportive or symptomatic treatment, rather you need good reason not to do so.

In some cases scientific judgements can be made on the basis of what might otherwise have been assumed to be general, non-specific changes (eg, behaviour, appearance, body weight, food or water intake, or body temperature). Examples include the use of the HID50 (hypothermia-

induced dose 50) as an indicator of impending overwhelming infection as an alternative to the significant morbidity and mortality associated with traditional LD50 or PD50 studies to establish bacteriological virulence (Soothill *et al.* 1992).

Death should seldom, if ever, be set or accepted as a required scientific endpoint. As procedure-related death is often the result of secondary or tertiary changes, it may be that lethal endpoints are not consistent with good science and could be replaced by earlier humane killing and autopsy, or be avoided by improved observation schedules and supportive or symptomatic treatments.

The humane endpoints and associated actions must be communicated to, and understood and implemented, by the staff involved. The documentation and verbal descriptors should use plain language and be understood by the staff checking the animals; should read across to other studies involving the same research team and establishment; and be meaningful to those working elsewhere in the same field of research to allow comparison with similar work performed by others, to define best practice and further raise standards.

Staff must be properly trained to recognise, and empowered to promptly implement, the endpoints. Welfare is not protected by systems that necessitate that decisions and action require lengthy internal notifications or consultations.

## Recognition and implementation

All animals should be checked at least once a day by trained staff, and the schedules intensified as required to ensure the prompt recognition and alleviation of significant welfare problems. All instances where animals are killed *in extremis* or found dead should be reviewed and the endpoints and observational schedules revised as necessary. These events may indicate that opportunities for refinement have been missed, and require that additional animals are used.

Once work is underway and insights are being gained into the likely welfare costs and scientific outcomes of procedures, those involved should again ask whether the specific experimental objective and findings to date justify the levels of suffering being produced, and whether the objective and/or methods can be adjusted to provide equally useful data at a lower welfare cost.

## Review and lessons learned

Completed studies should be reviewed to determine whether all of the likely clinical manifestations of the pathologies produced were detected, and if the scientific objectives could have been achieved if earlier endpoints were applied. This information should be taken into account when future studies are planned.

Published work should describe how endpoints were determined and implemented and summarise the welfare problems encountered. Russell and Burch offered sound

advice in this area: the objective is not just to enable others to 'do what you did', but to allow them to 'see what you saw'.

## Responsibility for the Three Rs

The Three Rs of replacement, reduction and refinement are now accepted, sustained and implemented at international, national, institutional and individual level.

### International activity

International acceptance of the Three Rs plays an important part in ensuring that the principles of humane experimental technique are implemented. Examples of where only international collaboration is, and will remain, essential are discussed in the following paragraphs.

### Legislative provision

Both the European Union and the Council of Europe have made provision for the care and use of animals for experimental and other scientific purposes that reflect the Three Rs.

### Regulatory requirements

The development of new and revised international regulatory requirements increasingly reflects the Three Rs. Harmonisation of regulatory requirements can ensure that a single test is sufficient to satisfy international regulators about a single toxicological endpoint.

The mutual acceptance of data and data-sharing prevent unnecessary duplication of animal tests.

### Scientific validation

This is expensive and time consuming, and increasingly takes place at the international level in order to set agreed priorities, reduce the time required, pool available resources and ensure international acceptance of the outcomes. Organisations such as the European Centre for the Validation of Alternative Methods<sup>3</sup>, the USA's National Toxicology Program Interagency Center for the Evaluation of Alternative Toxicological Methods Interagency Coordination Committee on the Validation of Alternative Methods<sup>4</sup> and Japanese Centre for the Validation of Alternative Methods<sup>5</sup> not only support validation within their own geographical regions, but actively collaborate to make the best use of available resources to ensure that:

- as far as possible their validation processes are consistent;
- multiple centres from around the world contribute to validation studies;

<sup>3</sup><http://ecvam.jrc.it/>

<sup>4</sup><http://iccvam.niehs.nih.gov/>

<sup>5</sup><http://altweb.jhsph.edu/wc6/paper483.pdf>

- processes are in place to ensure that the validation studies of the other centres can be quickly reviewed and, if appropriate, endorsed by the others.

#### International meetings

Science is international, and international meetings focusing on the Three Rs such as the World Congresses on Alternatives and Animal Use in the Life Sciences, and societies such as the Middle European Society for Alternative Methods to Animal Testing<sup>6</sup>, and various international laboratory animal science associations provide opportunities to showcase progress with the Three Rs at the international level.

Nevertheless, much remains to be done at the international level:

- There are still significant differences between, and in some cases within, economic regions in the legislative provision made for the protection of animals used for experimental and other scientific purposes.
- Regulatory requirements are still imperfectly harmonised and can be slow to adopt technical progress.
- Scientific validation remains a time-consuming process and, despite the increasing co-operation between the validation centres, there is still the potential for different centres coming to different conclusions about the same data sets.
- The international meetings and societies are high quality and well attended, but tend to attract those already active in, and familiar with, the Three Rs.

#### National activity

Much can be, and is being, done at national level. Clearly national legislative provision for the protection of animals used for experimental and other scientific purposes is important to ensure that the Three Rs are given due consideration. National support for the Three Rs is also expressed in other significant ways:

- Government funding for work on the Three Rs. The amounts involved can be difficult to determine as funding primarily to improve methodologies is not necessarily premised on animal welfare considerations and may not be readily identifiable as direct support for the Three Rs.
- The establishment of national centres to champion the development and acceptance of alternative methods – for example the National Centre for the Three Rs in the UK, ZEBET in Germany, the Canadian Council for Animal Care in Canada, the Center for Alternatives to Animal Testing in the USA and the Norwegian Reference Centre for Laboratory Animal Science and Alternatives in Norway. These act as focal points for the discussion and dissemination of good practice.
- For a comprehensive listing of professional, industrial, academic and other non-governmental organisations specifically involved with developing and promoting alternative methods see the AltTox website<sup>7</sup>.

<sup>7</sup><http://www.alttox.org/trc/resources/organizations.html>

#### Institutional activity

There is a number of institutions that play an active part in the promotion and uptake of humane experimental technique.

#### Funding bodies

Funding bodies should ensure that the Three Rs are given due consideration before programmes of work are funded, and that progress with the Three Rs made in the course of funded work is published.

#### Research journals

Research journals should ensure that published work takes account of the Three Rs, and that progress with the Three Rs is published.

#### Animal users and breeders

Establishments that breed, keep and use animals for scientific purposes play a central role. Institutional support extends far beyond simply providing suitable physical facilities and typically includes the provision of:

- expert advice on accommodation and care, statistics and other elements of experimental design, veterinary care and laboratory animal science;
- animal facilities and standards of accommodation which meet or surpass published provisions and recommendations;
- systematic education, training and continued professional development to develop and maintain both the necessary technical competencies and the required culture of care;
- processes which encourage innovation and continuous improvement.

#### Individual activity

There is no doubt that the factors that are most important to promote the development and application of humane experimental technique and the Three Rs are the expertise and culture of those responsible for the production, care and use of animals – both their individual contributions and their ability recognise and capitalise on the expertise of others. Each individual involved must take responsibility for their own personal development and personal effectiveness, mindful that competence can be attained by experience, qualification and training. This requires ensuring that individuals:

- obtain appropriate training and continued professional development (including periodic revalidation of existing skills), keep abreast of good practice by involvement with appropriate professional societies and scientific bodies and seek opportunities to visit and benchmark against other establishments;
- make timely contributions to the planning and performance of animal production and use;

- confirm that others with responsibility for the animal welfare are both competent and effective;
- make sure that only high-quality science is undertaken;
- ensure that best practice is being followed;
- require that outcomes are reviewed, lessons learned incorporated into future practice and technical improvements communicated to others;
- network with others, both to share their own expertise and capitalise on the knowledge and experience of others.

## Concluding remarks

In addition to considering the principles set out above, and applying the practices set out in later chapters, it is hoped that readers will in due course be able to capitalise on, and communicate to others, their own new insights and practical examples of how the principles of replacement, reduction and refinement can further contribute to both animal welfare and high-quality science.

# 3 The design of animal experiments

Michael F.W. Festing

## Introduction

This chapter is aimed at anyone involved in research using laboratory animals including: research workers, animal house staff and members of ethical review committees. It covers the main principles of experimental design, but deliberately does not cover the statistical analysis of the results. To some this may be strange because the design and statistical analysis of experiments are intimately linked. No experiment should ever be designed without a clear understanding of how the results will be statistically analysed. However, there are many good textbooks covering methods of analysing data once it has been collected as well as numerous statistical packages which will do the actual calculations. In contrast, there are few publications which deal specifically with the design of animal experiments. If an experiment has been well designed there should be no difficulty in getting the results analysed. The chapter contains no mathematics, which should endear it to the widest possible audience.

Experiments need to be well designed. Those which are biased or lack power (the ability to detect a response to a treatment) because they are too small may give the wrong answer and be totally wasted. Experiments which are excessively large may give the right results but with a waste of animals, money, time and other scientific resources. Unfortunately, surveys of published papers suggest that there is substantial room for improvement both in the design of experiments and in their statistical analysis. In many cases fundamental principles, such as the need to control random variation, randomisation and blinding (where possible), are either ignored or not reported. All too often methods of determining sample size depend more on tradition than clear scientific principles (Festing *et al.* 2002). Well designed experiments are not only more ethical, but they can also save money, time and effort and improve the chances of achieving the scientific objectives of the study.

## Research strategy and the use of models in research

Most animal research is aimed directly or indirectly at curing or alleviating a specific human or animal disease. Careful thought needs to be given to developing a suitable

research strategy, which may involve many experiments ranging from *in vitro* studies, through experiments on animals, possibly to clinical trials.

*In vitro* and animal studies usually involve modelling some aspect of animal or human disease. The models need to be relevant and capable of answering specific questions. It is highly unlikely that they exactly replicate the human condition, but they may lead to a better understanding of the disease process (Sams-Dodd 2006). There seems to be relatively little literature on the theory of models in biomedical research. Russell and Burch (1959) recognised that models have at least two dimensions which determine their use. They used the term 'fidelity' to describe the overall similarity of the model to the target (say humans). Thus non-human primates would normally be considered a high-fidelity model because they resemble humans in many ways. In contrast, a cell line would be a low-fidelity model because it is very unlike a human. Intuitively, scientists feel that they would like to work with high-fidelity models, yet they do not all work on primates. This is justified by considering another dimension; that is the ability of the model to distinguish between experimental treatments. A cell culture system which could distinguish between chemicals which are carcinogens and those which are not would be a preferred model in toxicity testing even though it is of low fidelity. Other attributes of models are also important (Festing 2000). They must resemble the target in ways relevant to the specific study, but must also be different from the target in other ways. For example, the mouse is widely used because it resembles humans in many ways, but also because it is different from humans in being small, economical to maintain easy to manipulate genetically, and because experiments can be done using the mouse which could not be done in humans. But the first step in using any model in research is to ensure, as far as possible, that the model is relevant. The second is to design experiments that are capable of detecting responses in the model. Models are not little humans, and attempts to make them seem more like humans, such as by using genetically heterogeneous animals so as to resemble the genetically heterogeneous human population, are often misguided. Research is a multistep process. The model is chosen because it is thought to be relevant to humans, but the experiment can only determine the response of the model, not the response of humans.

## Steps in the design of an experiment

### Defining the purpose of the experiment

There are three main types of experiment:

- Pilot experiments are small studies used mainly to examine the logistics of a proposed larger study, and to gather preliminary information, such as whether dose levels seem to be appropriate. They may involve a single animal or small groups if the aim is to gain some idea of inter-individual variation. In most cases the results will not be published, but will be used to design more definitive studies. Investigators are advised to make good use of pilot studies, which can often lead to substantial improvements in the design of larger scale studies.
- Exploratory experiments are used to study the pattern of response to some intervention, without necessarily having a clearly defined hypothesis which is being tested. They often involve measuring many outcomes or traits, and are used to generate hypotheses for further investigation. If many outcomes are measured, there can be serious problems with false positive results, so the results of the statistical analysis need to be treated with some caution.
- Confirmatory experiments are used to study a relatively simple hypothesis often concerning a single outcome, which is formulated before the experiment is started. However, many outcomes may be measured and the results may suggest other hypotheses which may need to be tested in further confirmatory experiments. Thus confirmatory experiments often have a dual confirmatory/exploratory role in testing hypotheses and suggesting new hypotheses which need testing.

An experiment which aims to explore a dose–response relationship will need to be designed differently from one which is designed to study, say, the effect of three diets on body weight in both males and females. So the purpose of each experiment needs to be clearly stated. However, in all cases the aim should be to design experiments which give the maximum amount of information using the minimum number of animals and other resources. Determining relevance to humans or other animals and deciding future action given the different possible outcomes, as noted above, is an entirely separate, non-statistical step which should be considered *before* starting the experiment.

In many cases the aim of the experiment is to compare the means of two or more groups of subjects which have had different treatments. Optimum group size depends mainly on the size of the differences between the group means and on inter-individual variability. If individuals are very variable, large differences between the group means could occur by chance. Great care therefore needs to be taken to choose uniform animals or to reduce variability using randomised block or crossover designs, discussed later in this chapter. Covariance analysis can also be used if some character related to the outcome variable can be measured before the experiment is started. Methods of estimating sample size are also discussed later in this chapter.

There are other types of experiment. In an uncontrolled experiment a treatment may be given to a single group of individuals to see whether, for example, the treatment has some immediately obvious effect on them such as hyperactivity. A control group is not required because animals do not normally become hyperactive within a short period of time without any treatment. An LD<sub>50</sub> test is of this sort, but the outcome is so severe that for ethical reasons a more humane endpoint (Stokes 2000) should be used wherever possible. Experiments may also be done to estimate the mean or proportion of a group with some attribute such as a tumour, or to study the relationship between two variables such as time and growth rate. Occasionally an ‘experiment’ may either be successful or unsuccessful, such as in an attempt to develop a new strain of GM mice. This type of experiment is not considered here.

There is some confusion about what exactly constitutes an ‘experiment’. Biologists will sometimes define an ‘experiment’ as something which was done to one or a group of animals at a particular time, with the statistical analysis combining data from several such ‘experiments’. However, it is more appropriate to define an experiment as a planned strategy for collecting a set of data to answer a specific question. It is this whole set of data which is subject to the statistical analysis. Something which was done to the individual subject may more correctly be called a replicate or part of an experiment. A statistical analysis which combines the results of several independent experiments is called a meta-analysis. This is usually done by professional statisticians following well defined procedures. For example, in an attempt to determine how well animal experiments predict human responses, all papers which involved one of six different interventions in animals were combined using a meta-analysis to see whether they predicted known human responses to the same interventions (Perel *et al.* 2007). In three cases the conclusions of human and animal studies did not agree, although it was not clear whether this was because the animal model was not appropriate, or because the experiments were not sufficiently repeatable or because of methodological differences between the human and animal experiments. For example, some of the animal experiments may have been designed to study mechanisms rather than to predict the response in humans.

### Identification of the experimental unit

A fundamental principle in designing an experiment is that there should be independent replication of the observations. The response of one subject should not be correlated with that of any other subjects. The ‘experimental unit’ (EU) is the individual subject in the experiment. It is also the unit of statistical analysis. Any two experimental units must be capable of receiving a different treatment. Very often it will be an animal, with animals being assigned to the treatments at random. However, if there are several animals in each cage, and they all receive the same treatment, then the cage, not the individual animal, is the experimental unit. Each cage will be assigned at random to one of the treatments and the statistical analysis will normally be done on the mean of all animals in the cage for whatever outcome(s) were being

studied. In a teratology experiment a pregnant animal is treated with a test compound but measurements and counts of abnormalities are done on the foetuses. It is a common error to assume that each foetus is an experimental unit but in fact the mother is the experimental unit as it is the mother which was assigned to a treatment group. So in this case each mother will have a score based on the average number of abnormalities and measurements such as the mean weight of the pups in the litter. It may be necessary to take account of litter size in the statistical analysis as large litters will provide a better estimate of the susceptibility of the treated female than small litters, and females with large litters may respond differently from those with small ones.

Sometimes it is possible to do within-animal experiments. If the back of an animal can be shaved and treatments can be applied to individual patches of skin (eg, in testing for an allergic skin reaction), then the patch on the back of an animal is the experimental unit since any two patches can receive a different treatment. Similarly, if an animal can have a series of treatments done sequentially in random order, as is possible in an experiment to see if animals can taste certain solutions, and it can be assumed that each treatment does not alter the animal, then the animal for the period of treatment time will be the experimental unit.

Failure to identify the experimental unit correctly is not uncommon. One result is that 'n', the number of experimental subjects, is seriously over-estimated with the result that the statistical analysis and possibly the conclusions are incorrect.

## Dependent and independent variables

There are two sorts of variables in an experiment. The independent variables include those factors which are being studied, and are deliberately varied as part of the experiment. This will usually include a factor called 'treatment' or it may have other names such as 'diet', 'strain' or 'sex' if these are the factors being deliberately varied. An independent variable may have several levels which may be quantitative (eg, dose 0, 2, 4, 8mg/kg) or qualitative (diets A, B, C, D). If the aim is to study a dose-response relationship, there may be many dose levels. If two or more variables are deliberately being varied simultaneously in the same experiment, then this is known as a 'factorial' experimental design. The variables may be of equal interest, or some may be included mainly in order to increase the generality of the result. For example, an experiment which shows that both sexes respond in the same way to an intervention provides a more general result than one done using only males. Occasionally, a fixed effect can be taken into account statistically. For example, outbred animals may be genotyped at some locus thought to be related to the outcome. In comparing treatment means, variation at this locus could be taken into account using covariance analysis (not discussed here).

Characters such as the sex and strain of the animals which can not be assigned to an animal at random are known as classification variables. Extra care needs to be taken to ensure that when strains, for example, are being compared that the animals are comparable in other ways. If the strains

differ in age or the environment where they were bred, then these differences will be confounded with differences due to the strain and could be mistaken for such strain differences.

The independent variables can involve either fixed effects or random effects. A fixed effect is one over which the investigator has some control, and could include things like treatment, sex, strain, diet and housing conditions. Random effects are things like day-to-day variation, any remaining inter-individual variation, variation between rooms, cages (receiving the same treatment), or locations over which the investigator has little control. The strain of mouse is usually considered a fixed effect unless a group of strains used in an experiment is considered to be a random sample of all possible strains of mice and the aim of the experiment is to quantify the variation among strains. Thus in some cases whether a variable is considered fixed or random depends on the purpose of the experiment. Generally, random effects should be controlled as far as possible, and also taken account of by using an appropriate design. For example, a randomised block design will have one or more fixed effect factors such as treatment, and one random effect factor called 'block' which might be position in the animal house or a time variable. Uncontrolled variation either leads to more false-negative results, or sample size needs to be increased to average out the effect. This is discussed in more detail in the section on power analysis.

There are also many other factors which are not varied in the experiment, but which can still influence the outcome and need to be considered in interpreting the results. For example, if an experiment is done using only male animals on diet X using bedding type Y in plastic cages of size  $A \times B \times C$ , it is a matter of supposition as to whether similar results might have been obtained if the experiment had been done using females on diet A using bedding of type B in metal cages of size  $M \times N \times P$ . However, there is no way round this problem. All experiments are done under a particular set of conditions and it is never possible to be sure that they would be valid under a slightly different set of conditions.

The experimenter will usually measure one or more dependent variables which are used to measure the response to the treatments. Things like body and organ weights, haematology, clinical biochemistry, physiological variables such as heart rate and blood pressure, behaviour and measures of gene expression are examples of the sort of 'outcomes' or traits which may respond to the treatments, and which will be measured. Sometime there is a single outcome variable. At other times many variables may be measured. For example, in a microarray experiment there may be thousands of observations on each animal (or other experimental subject).

## The randomised controlled experiment

The randomised controlled, double-blinded clinical trial, is the gold standard for the design of nearly all experiments, although with animal experiments it is much easier to control the many variables which can influence the outcome. Randomisation is of fundamental importance as it ensures

that, provided it is maintained throughout the whole experiment, there will be no systematic difference between the treatment groups. Any differences must either be due to chance inter-individual variation or to the effect of the treatment. With proper randomisation the effect of the random variation can be estimated and taken into account in the statistical analysis. The aim of the statistical analysis is to quantify the part that chance may have played in determining group differences. If it is highly unlikely that the differences could be due to chance, then they are assumed to be due to the effect of the treatment. Of course, if the animals (it will be assumed from now on that the experimental subjects are animals, but they could equally well be cages of animals or tissue culture dishes) are very uniform, then chance differences between groups will be small and the experiment will have high probability of detecting any differences between treatments. So it is very important to control variation. This is discussed later in this chapter.

### Randomisation in practice

Physical randomisation is very easy. For example, if the aim is to assign animals to five treatments (say a control and four dose levels), with six animals per treatment group, the numbers 1, 2, 3, 4 and 5 would each be written six times on separate pieces of paper or card. These would then be physically shaken in a suitable receptacle. The first animal is then taken, and a piece of paper is withdrawn from the receptacle (and not replaced) to show which group it should be assigned to, and so on.

Some statistical packages will take a column of numbers and re-arrange them in random order, so in this case a method very similar to physical randomisation could be used. Commonly used computer spreadsheets may have a function such as RAND() which generates a random number greater than or equal to 0 and less than one, evenly distributed. In the above example, the numbers 1, 2, 3, 4, 5 could each be put in a column six times. A column of 30 random numbers could then be put in the next column and both columns could be sorted by the random number column. This will put the numbers 1–5 (each six times) into random order. This could be done in the office, with the results being printed out and taken to the animal house for use. Many statistical texts also have tables of random numbers which can be used according to instructions.

With a randomised block design (discussed later in this chapter) the randomisation is done separately within each block, so it may be necessary to do several separate randomisations. But this presents few problems either with physical randomisation or using the computer.

Randomisation must be maintained throughout the whole experiment, with the animals housed in random position in the animal house and with the outcomes measured in random order, otherwise bias could be introduced. If the experiment involves surgery, the surgeon may improve his/her technique with practice. If all the controls are done first in order to gain practice, this will also introduce bias as the treated group will benefit from better surgery.

### Blinding

Blinding or 'allocation concealment' is another important way of avoiding bias. Research workers are not unbiased observers of the results of their experiments. Very often they would like there to be a difference between the treatment groups. If there is any subjective element in assessing results, and the investigator knows the treatment group, then he/she may unconsciously bias the results by altering the scoring. This can be avoided by blinding. Of course, blinding is not always possible. There may be obvious differences between groups. Strains of mice being compared may differ in coat colour or groups may differ in body weight if diets are being compared. But if samples of tissue are taken from the animals, these should be coded so that any measurements can be done blind with respect to strain or treatment. Investigators should always mention whether or not they have used blinding in their experiments so that a reader will know whether the results are likely to be unbiased.

Any resulting publication should state whether randomisation and blinding were used, with the method of randomisation being stated. In one survey, animal experiments which were not blinded and/or randomised were significantly more likely to have a 'positive' outcome than those which were blinded and/or randomised (Bebarta *et al.* 2003), suggesting that these procedures really do reduce bias.

### Controlling variability

Other things being equal, uniform material leads to high powered experiments, so control of variation is extremely important. Controlling genetic variation using inbred strains, for example, may mean that fewer animals need to be used in the experiment than if outbred stocks are used. However, if a single strain (inbred or outbred) is used, then strictly the results will be valid only for that strain. Crossover (within subject) designs in which each animal (or other subject) receives different treatments in random sequential order are particularly powerful because they automatically control the genetic and much of the environmental variation. Unfortunately, such designs cannot be used for long-term experiments or any experiment in which the treatment alters the animal.

### Variation among the animals

Animals should, as far as possible, be the same weight, age and genotype and free of pathogens. Disease not only increases variability, it may also seriously interfere with the results. For example, diseased and disease-free animals may respond differently to a treatment. Most of the mice and rats supplied by reputable commercial breeders are now of SPF (specific pathogen free) quality and are routinely screened for the presence of pathogenic organisms. In-house bred animals should be similarly screened to ensure that they are pathogen-free.

Researchers using laboratory mice or rats should use isogenic (inbred or F1 hybrid) strains where all animals are

genetically identical unless they can make a compelling case for using outbred stocks (Festing 1999). More details of the origin, maintenance and characteristics of isogenic strains are given in Chapter 4. The response to a treatment may be strain or genotype-dependent. More than one strain can be used in a factorial design (see later in this chapter) to see whether this is the case, usually without increasing the total number of animals needed.

Some people suggest that an outbred stock should be used on the grounds that humans are genetically heterogeneous, but this is false logic. Humans also vary in weight and age, but this does not mean that the animals used in an experiment should also be uncontrolled for weight and age. Uncontrolled genetic heterogeneity increases the phenotypic variability and reduces the power of the experiment leading to more false-negative results. Experiments may also be less repeatable because nothing is known about the genotypes of the individuals, which can therefore not be repeated. Even the degree of genetic variability within an outbred stock is unclear as it depends on the previous history of the stock. Certainly it is unlike the variability within human populations.

There is some evidence that stressed animals are also more variable. For example mice, which are social animals, are more variable in body weight when housed singly than when housed in groups (Chvedoff *et al.* 1980). Frequent sympathetic handling will tend to reduce stress associated with any procedures, another important source of variation. However, the effects of environmental enrichment are still unclear (see Chapter 10). In some cases it seems to increase variability, possibly because some 'enrichments' may increase aggression, but well designed and validated enrichments should decrease variability (Garner 2005).

Position in the animal house may also be important. Animals on the top shelf generally get more light and possibly a warmer temperature than those on lower shelves. Ideally, the animals should either be housed in random order on the shelves or a randomised block design (see later in this chapter) should be used in which each shelf has equal numbers of treated and control animals and any differences between shelves can then be eliminated in the statistical analysis. Certainly a randomised block design should be used if the animals need to be split into more than one location or treated at different times. If a power analysis (see later in this chapter) suggests that the experiment needs to be quite large, then it may be difficult to obtain large numbers of uniform animals all of similar weights and ages. Again, in this case a randomised block design should be considered.

Cage effects can be an important source of variation which may be difficult to deal with. Cages of identically treated animals may differ as a result of social interactions, unevenly distributed sub-clinical infection, cage position or other unknown factors. Moreover, individually housed animals may differ in their responses from those which are group housed. Possible ways of taking these effects into account in the design of the experiment are discussed in the section on factorial experimental designs.

Where some variation cannot be fully controlled, it is often useful to obtain individual measurements before starting applying the treatments. These can then be used to

correct the observations using statistical methods such as the analysis of covariance. For example, final body or organ weights can be corrected for variation in initial body weight in this way. This does not obviate the need to choose animals of as uniform weight as possible and the use of randomised block designs, discussed later in this chapter, may be helpful.

### Measurement error and variability in the procedures

Some outcomes, such as measuring the activities of enzymes or gene expression, may involve multiple steps. Tissues may need to be removed, extracted in some solution and assayed in various types of apparatus. There may be variation in the calibration of the instruments, in the composition of the reagents, incubation temperatures, pipetting errors etc, leading to considerable measurement errors. In such situations it may be advantageous to split the sample as soon as it is taken and run duplicate or triplicate determinations which are then averaged for the statistical analysis. This is sometimes called 'technical replication' compared with the 'biological replication' associated with differences between individuals. Note that technical replication does not increase the number of experimental units but it does increase the precision with which each experimental unit is measured so therefore contributes to a reduction in sample size or increase in power. The variation associated with the technical replication should not be used in assessing differences between treatments.

Behavioural observations provide another example. The animals may be observed and different types of behaviour recorded for relatively brief periods. Although such observations may be adequate, they may not fully reflect the behaviour. Modern apparatus is now available to record a wide range of behaviours automatically, sometimes with several animals per cage (Roughan & Flecknell 2003). This is likely to be more accurate than observing animals for only brief periods of time, although any technical limitations of such apparatus need to be taken into account. Also human observers may be more likely to identify interesting or anomalous events. Although automated behavioural recording systems are expensive they may still be cost effective when considering the total cost of a research project.

Experimental procedures themselves may introduce a considerable source of variability which reduces the power of the experiment (or requires larger sample sizes). Intraperitoneal injections are widely used in animal research, but the failure rate may be as high as 10–20%. This may result in statistical outliers which, if not taken into account, could have a serious effect on the power of the experiment (Das & North 2007). Other routes of injection may also have high failure rates, though these can usually be substantially reduced by training. Biophotonic methods appear to have many advantages as a training aid (Wiles *et al.* 2007). Skill should also improve with practice. As far as possible staff should be fully trained before participating in an experiment.

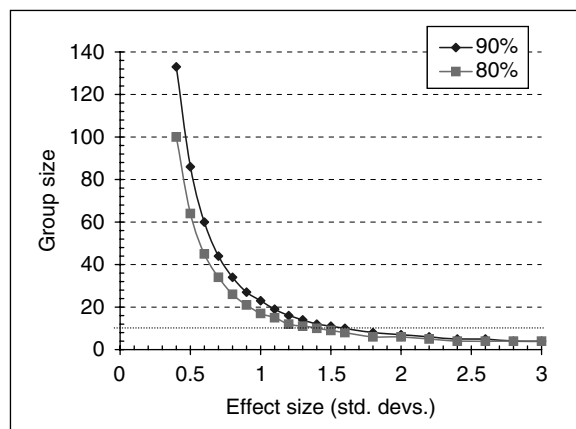

## Sample size determination

Many scientists use sample sizes determined by tradition. In some disciplines, group sizes of eight are almost universal and some referees may go so far as to reject a paper which deviates from this norm. But traditional designs can be very inefficient leading to serious waste of animals and scientific resources. If there are several groups then the sample size of each group can usually be reduced, thereby saving animals. There are two methods discussed here which can be used to give a better estimate of the required sample size: 'power analysis' and the 'resource equation' method. Both of these methods have weaknesses, but are still substantially better than traditional methods of having a fixed number in each group.

## Power analysis

This method depends on a mathematical relationship between sample size and a number of other variables specified by the scientist. It is the method of choice for clinical trials or any other large, expensive but relatively simple experiment. In the situation where the aim is to compare the means of two groups (say treated and control) it requires the following specification:

- The type of statistical test which is to be used. This depends on the nature of the data. Quantitative data can normally be analysed using Student's t-test, the analysis of variance (which is mathematically identical in the special case of just two groups), or a non-parametric test, while qualitative data may be analysed using a chi-squared test, Fisher's exact test or a normal approximation of a binomial. In the example (below), it is assumed that a quantitative variable is measured and the means are to be compared using a two-sample Student's t-test.
- An estimate of the standard deviation, in the case of a quantitative variable. This has to come from a previous study, or a pilot experiment as the experiment has not yet been done. Unfortunately, pilot studies are usually small, so any estimate of variation will be imprecise. This may result in an under- or over-estimate of the numbers needed. This, and the fact that it cannot be used when the outcome has never before been measured, or where there is no good estimate of variability, is a potential drawback.
- The effect size. This is the minimum difference between the means of the two groups which would be of clinical or biological significance. Clearly, a very small difference would not be of great interest whereas it would be important to be able to detect a large difference. The effect size is the cut-off between these two.
- The required power. Somewhat arbitrarily the power is usually set at 80–90%. A power of 80% implies that if there is an effect as large as that specified, then there will be an 80% chance of detecting it. The power should be set taking account of the implications of failing to detect an effect. If this could be serious, say in toxicity testing where it might mean that a toxic effect was

**Figure 3.1** Power analysis estimates of sample size per group as a function of the effect size in standard deviations, assuming a two-sample t-test with a 5% significance level and an 80% or 90% power.

missed, then a higher power should be specified. However, it is not possible to specify a power of 100% as that would require an infinitely large experiment.

- The significance level. This is the probability of a false-positive result (ie, of claiming a treatment effect when in fact it is purely due to chance). This is usually set at 0.05 or 5% although this is entirely arbitrary and other levels may sometimes be set.
- The sidedness of the test. A two-sided test is used when it is not clear whether the mean of the treated group will be less than or greater than that of the control group. However, if the hypothesis is that the mean will move in a particular direction then a one-sided test should be specified.
- The sample size. This is usually what is being estimated. However, in some situations the sample size is fixed by the availability of animals. In this case the calculations can be used to determine the power of the experiment or the effect size likely to be detectable.

The formulae connecting these variables are not easy to use, but fortunately most good statistical packages will do the calculations and there are a number of web sites (eg, Biomath<sup>1</sup>) where the data can be entered and the results calculated. It is often useful to express the effect size in standard deviation units by dividing it by the standard deviation, as this puts everything into the same units and the required sample size can be read from a graph such as Figure 3.1. When there is more than one outcome variable, separate calculations are needed for each variable and the estimated sample sizes will differ depending on the variable of interest. It may be necessary to decide which outcome is most important, and base sample size on that variable.

*Example:* The mean body weight of a group of F344 male rats in a growth trial was 259 g with a standard deviation of 11.0 g (real data). Suppose a diet experiment is to be set up using these male F344 rats such that the experiment is able to detect a difference in mean body weight between the two

<sup>1</sup><http://www.biomath.info>

diet groups of 10g or more, assuming that the treatment does not alter the standard deviation. How many F344 rats will be needed?

Assume a two-sided t-test, a power of 90%, a significance level of 0.05 and an standard deviation of 11, then the aim is to be able to detect  $10/11 = 0.91$  standard deviations. From Figure 3.1 this would require about 25–30 rats per group. A more accurate estimate using the Biomath website suggests 27 rats per group.

If the mean body weight of the rats is 259 and the standard deviation 11, then among a group of 100 rats body weight could range from about 230 to 290g. Suppose the rats were specified to range in weight from 250–270g, then applying this to the real data, the standard deviation was found to be reduced to about 5g. This would mean the experiment would only need to be able to detect an effect of  $10/5 = 2$  standard deviations, and from Figure 3.1 it would require only about 7–8 instead of 25–30 rats per group.

Some statistical packages also allow sample size calculations for qualitative (dead/alive, positive/negative) variables. In this case it is not necessary to specify the standard deviation as it is a function of the proportion affected. In general, many more animals are needed to compare two proportions than if a measurement variable can be used.

### The resource equation method (for quantitative variables)

This method, described somewhat informally by Mead (Mead 1988) is the method that was used by most applied statisticians before power analysis became a practical possibility. It depends on the law of diminishing returns. Adding one more animal to a small experiment gives good returns in terms of increased power. However, doing the same to a large experiment will hardly increase power at all. The critical thing in most experiments is to have a good estimate of the variation, against which any differences in means are assessed. The ‘error mean square’ in an analysis of variance of the proposed experiment is an estimate of the population variance, and this needs to be estimated reasonably well. It depends on the size of the whole experiment and the number of treatment groups, not the individual group sizes. Mead suggests that if the error degrees of freedom ( $E$ ) is between about 10 and 20, then the experiment will probably be of an appropriate size. However, these limits should not be applied too rigidly. A good case can be made for  $E$  being 25–30 or more to ensure equal group sizes, and it can go even higher when the experimental units are very cheap, such as when they are wells in a tissue culture dish. In a completely randomised design  $E$  is the total number of subjects minus the number of treatment groups.

$$E = \left( \begin{matrix} \text{total number} \\ \text{of animals} \end{matrix} \right) - \left( \begin{matrix} \text{number of treatment} \\ \text{combinations} \end{matrix} \right), \text{ and } 10 < E < 20$$

For example, if a factorial experiment is planned with both sexes and three dose levels then there will be six treatment groups. If it is proposed that there should be eight animals in each treatment group (as is common), there will be 48 animals in total and  $E = 48 - 6 = 42$ . This experiment is unnecessarily large. Redesigning it with four animals per

group,  $E = 24 - 6 = 18$ , which is within the suggested limits of 10–20. Using the example of body weight of F344 rats discussed under power analysis, two groups of 10 rats per group gives  $E = 18$ , which is within the specified range. This is slightly more than the 7–8 rats per group needed to detect the 10g or more treatment effect in the animals with a standard deviation of 5.0g using power analysis.

A power analysis should be used in preference to the resource equation method wherever possible. Unfortunately, power analysis is not so easy to use when there are more than two groups because it is more difficult (but not impossible) to specify the effect size of interest. This difficulty is even greater when there are many outcomes (characters) being measured as separate calculations are necessary for each one with some sort of compromise being applied, unless the most important one can be identified. The resource equation method is useful when there is no previous estimate of the standard deviation. It is particularly suited to complex factorial experiments, and it is much better than relying on tradition.

### Statistical analysis of planned experiments

Only a general description of the main methods used in the statistical analysis of experimental data is given here. Detailed accounts with numerical examples are given in many textbooks (Kvanli 1988; Altman 1991; Mead *et al.* 1993; Montgomery 1997; Petrie & Watson 1999; Festing *et al.* 2002). These days all the calculations will normally be done using a dedicated statistical package such as SPSS (SPSS Inc. 233 S. Wacker Drive, 11th floor, Chicago, Illinois 60606), MINITAB (Minitab Inc., Quality Plaza, 1829 Pine Hall Rd, State College PA 16801-3008, USA) or SAS (SAS UK, Wittington House, Henley Road, Medmenham, Marlow, Buckinghamshire, SL7 2EB). These are expensive commercial packages. The ‘R’ statistical software or ‘language’<sup>2</sup> is widely used by professional statisticians and is free of charge, but it is command driven so initially may be difficult to learn. Some textbooks on the use of this language are now becoming available (Dalgaard 2003; Verzani 2005). Some free statistical software can be found on the Free Statistics<sup>3</sup> and StatPages<sup>4</sup> websites. The author does not recommend the use of spreadsheets as they are more difficult to use for this sort of analysis than dedicated statistical packages and may give non-standard output.

A large majority of experiments result in quantitative measurement data rather than discrete (eg, binary) data. These experiments can usually be analysed using Student’s t-test or an analysis of variance (ANOVA), as long as the assumptions relevant to these tests are met (see next section). It may be necessary to transform a scale to reduce heterogeneity of variation and make the residuals (deviations from group means) have a more normal (bell-shaped) distribution. However, in cases where the data is very non-homogeneous so called ‘non-parametric’ methods may have

<sup>2</sup><http://www.r-project.org/>

<sup>3</sup><http://www.freeststatistics.altervista.org>

<sup>4</sup><http://www.statpages.org>

to be used. It is important to examine the data to get a feel for the type and distribution of the observations.

The first step should always be to screen the data for possible errors. This is usually best done graphically. Where outliers are detected the records should be traced back to ensure that they are not due to recording errors. Genuine outliers should not be discarded. A good way of dealing with them is to do the statistical analysis with and without them. If they make no difference to the conclusions, then they can be retained. However, if the aim is to obtain a good estimate of a mean or some other parameter such as the slope of a regression line, then there may be a case for deleting them provided that there are very few of them, there is a clear explanation as to why this is being done, and that analyses both with and without the outliers are presented (Das & North 2007).

### The analysis of variance and the t-test

The aim of the analysis of variance and the t-test is to compare the means of two (in the case of the t-test) or two or more (in the case of the ANOVA) groups. The hypothesis to be tested is that there are no differences among the means (ie, that they could all be random samples from the same population). Where there are three or more means, the ANOVA does not indicate which means differ, only that it is unlikely that they could have come from the same population. Further tests such as *post hoc* comparisons or planned comparisons, described in most textbooks, are needed to determine which means differ. A 'one-way' ANOVA is used to compare means from a completely randomised single-factor design (see below). In this case unequal group sizes present no particular problem, although in most cases it is preferable to have equal group sizes. Randomised block designs are analysed using a 'two-way ANOVA *without* interaction' and factorial designs are analysed using a multi-way ANOVA *with* interaction. However, unequal group sizes cause problems with two-way designs and it is usually necessary to resort to a 'general linear model' ANOVA in such cases. This is available in all good statistical packages. Thus the ANOVA will deal with quite complex situations. Roberts and Russo (Roberts & Russo 1999) give an excellent introduction to the analysis of variance. The analysis of covariance (ANCOVAR) can sometimes be used to correct for other variables in order to further increase statistical power. For example, some of the variation associated with the initial body weight of the animals might be removed using this technique.

ANOVA and t-tests are mathematically identical when there are just two groups. However, the ANOVA is more versatile as it can be used to analyse complex experimental designs. Both depend on three assumptions:

1. the residuals (deviation of each observation from its group mean) have a normal distribution (note it is the residuals, not the 'data' that should have a normal distribution); a 'normal distribution' is a bell-shaped distribution;
2. the variation is the same in each group;
3. the observations are independent; this depends on

correct identification of the experimental unit and appropriate randomisation.

The first two of these assumptions can be examined using graphical plots of the residuals, available in many good statistical software packages. For example, a normal probability plot of the residuals can be used to study assumption 1, above, and a plot of fits (group means) versus residuals can be used to investigate assumption 2, above. However, the ANOVA is said to be quite 'robust' to deviations from these assumptions. Only if they are seriously violated does the ANOVA give the wrong answer. Unfortunately, it is not easy to give clear guidance on exactly when parametric methods should be abandoned in favour of non-parametric methods. Robustness is a matter of degree. If the normality assumption is seriously violated, then the type I error (false positive) rate may be 0.1 rather than a nominal 0.05, but this would be an extreme case. Lack of homogeneity of variance should not be a serious problem if group sizes are equal with at least five subjects per group. However, with unequal group sizes serious errors in type I error rates may occur. Both parametric and non-parametric methods depend on the assumption of observations being independent. This depends on correct experimental design (Maxwell & Delaney 1989).

Where the assumptions are seriously violated, transformation to a different scale rather than the use of non-parametric methods may be the best approach as the power of non-parametric methods (see later in this chapter) is usually low. For example, biological data often have a log-normal distribution (ie, the logarithms of the actual values have a normal distribution). This is particularly the case when measuring the concentration of some substance in body fluids. It is not possible to have a concentration of less than zero, low concentrations may be common, but there may be a few very high values. Taking the logarithms of the observations will usually result in the residuals having a normal distribution. So in this case all the analyses will be done on the log-transformed data. Results can either be presented on this scale, or back-transformed to the original scale (although the standard deviation cannot be back-transformed).

### The chi-squared and Fisher's exact tests for discrete data (counts)

Experiments which involve discrete (often binary) data which is summarised as the proportion or percentage of animals (say) having a particular attribute (eg, a tumour) in each group can usually be analysed using a chi-squared test. Note that all calculations are done using the actual numbers not the percentages. The null hypothesis is that there is no difference in the proportions in the two (or more) groups. All good statistical packages should be able to analyse such data. The main limitation of this test is that the expected numbers in all cells of the table should exceed five. If this is not the case, then it is necessary to use Fisher's exact test. There are numerous web sites which will do the calculations when there are just two groups (a web search on 'Fisher's exact test' will find them). For three or more groups more specialised software may be necessary.

## Non-parametric methods

These methods are used when the data are very heterogeneous and no scale transformation can be found which would make it possible to use parametric methods. The methods tend to lack statistical power, so should not be used routinely. The main methods are the Mann-Whitney (also known as the two-sample rank sum, or the Wilcoxon two sample rank sum) test, the non-parametric equivalent of the t-test, which is used to compare the medians of two groups, the Kruskal-Wallis test, the non-parametric equivalent of the one-way ANOVA used to compare several medians, and the Friedman's test, which is the non-parametric equivalent of the two-way ANOVA without interaction, and can be used for randomised block designs (see later in this chapter). These tests are used to compare locations (eg, medians) of the groups, but problems may arise if the distributions are very different. Most textbooks include sections on these methods, they are available in all good statistical software packages, and there is a number of specialist textbooks explaining the methods (Sprent 1993).

## Some experimental designs

### The completely randomised (between subjects) design

This is the simplest design with a single factor, the treatment. There can be any number of levels and numbers of subjects on each treatment do not need to be equal, although it is usually most powerful if they are. One of the groups may be considered a 'control', or the aim may be to compare a set of qualitatively or quantitatively different treatments. The statistical analysis is relatively simple.

This design may be difficult to use for large-scale experiments as the larger the number of animals needed the more difficult it is to get a homogeneous group of animals all at the same time. The need to break the experiment down in time or space into more manageable bits also increases (this can be done with a randomised block design). Animals are assigned to treatment groups strictly at random, as shown in the example in Figure 3.2, and the positions within the animal house and the order in which the treatments are

C	C	A	B	B	D	D	A	A	D	D	B	C	B	C	A
---	---	---	---	---	---	---	---	---	---	---	---	---	---	---	---

**Figure 3.2** Example of the layout of a completely randomised design with four treatments (A, B, C, D) each with four animals. These are shown in random order. This could be maintained throughout the experiment or at least the recording of the observations should be in a re-randomised order. Thus, the first and second animals will be assigned to treatment C, the third to A etc. These should be housed on one shelf or split into two or more shelves in this random order, and all measurements of the outcome should be made in the same order. Note that using the Resource Equation method of sample size determination  $E = 16 - 4$ , which is 12, so the experiment is probably of an adequate size. Note also that the shelf level could be a source of variation which could be controlled not by randomisation, but by using a randomised block experimental design.

given and the outcome is measured should also be in random order. Wherever possible, the staff measuring the outcome should be blinded with respect to the treatment group as noted above.

As with all the designs discussed here, there may be multiple outcomes. For example, a haematologist will look at the counts of a large number of blood cell types. In this case the statistical analysis either analyses each outcome separately, or some sort of 'multivariate' analysis is done which combines the different characters into a single composite character. However, this probably requires the advice of somebody with experience of these techniques. In some cases a character may be measured sequentially over a period of time. These samples will not be independent because if the animal has a high count on day 1 it is also likely to have a high count on day 2. Methods of analysing such data depend on individual circumstances. Suggested approaches include analysing the mean of the measurements, the slope of the line connecting them, the area under the curve or the time to reach a certain value. This should not be confused with a repeated measures design, discussed later in the chapter, where a single animal receives a series of different treatments.

### The randomised block design

This design can be used to maximise statistical power in several situations. It is an extremely useful design widely used in agricultural research and it could be more widely used in research with laboratory animals. It involves splitting the experiment up into a number of 'mini-experiments', the results of which are then re-combined in the statistical analysis. Some of the reasons for using it include:

- If the animals are quite variable for weight or age or in some other identifiable characteristic such as batch or source. In this situation, animals which are similar should be grouped in a 'block' and then assigned at random to the treatments. Typically, a block will be the same size as the number of treatments. So if there are three treatments, then a block will consist of three animals as similar as possible which will be assigned at random to the three treatments. However, a block could consist of six animals with two assigned to each treatment although it is important that equal numbers are assigned to each treatment within each block.
- If sufficient animals of the required specification are not all available at the same time. In this case the experiment can be started with the first batch as block 1, then other blocks can be added as the animals become available.
- If there is some heterogeneity in the environment which may affect the outcome. For example, if the experiment needs to be split into two or more locations, or if account needs to be taken of a range of environments within a room. The top shelf in an animal house has a different environment from the bottom shelf, so each shelf might house a different block.
- To ensure that the results are repeatable over time. This is common with *in vitro* studies which are often repeated

two or more times on different days. The investigator often considers these to be separate 'experiments', and often is not clear how they can be combined. But if they are pre-planned, then they represent a single experiment split over a number of time periods and can be analysed as a randomised block experiment using a two-way ANOVA without interaction. Note that the animals assigned to a block should be as similar as possible, but there can be multiple differences between blocks. Thus block 1 might be uniformly heavy animals on the top shelf treated in week 1, with block 2 being light animals on a lower shelf treated in week 2 etc.

Randomisation is done separately within each block in this type of design, as shown diagrammatically in Figure 3.3. Note that a 'matched pairs' design is a randomised block with a block size of two, as is a study involving monozygous twins.

### The repeated measures (within subject) and crossover design

In these designs the experimental unit is an animal (or cage of animals etc) for a period of time (the 'subject'). For example, if the aim is to compare the effects of four anaesthetics on blood pressure in, say, dogs, then the anaesthetics might be assigned to each dog sequentially in random order with blood pressure being monitored each time. It is assumed that the treatments make no permanent changes to the subjects, which will normally be rested between treatments. Where necessary this assumption can be tested by applying the same treatment a second time and comparing first versus second application. The experiment will usually involve several such subjects, depending on the required sample size, each receiving their four anaesthetics in random order. This is virtually the same design as the randomised block design with each dog being considered a 'block'. So, for example, Block 1 in Figure 3.3 might consist of a

B	C	A	D	Block 1
D	A	B	C	Block 2
A	B	D	C	Block 3
A	C	B	D	Block 4
D	C	B	A	Block 5

**Figure 3.3** Diagram of a randomised block design with four treatments (A, B, C, D) and five blocks. Note that animals are chosen for each block which are as similar as possible, and are then assigned to one of the four treatments at random. Blocks can be separated in time so, for example, block 1 can be started this week, block 2 next week etc. Blocks can also be separated in space, such as being on different shelves or in different rooms. The results should be measured in the same random order for each block. The results, assuming a quantitative outcome variable, are analysed using a two-way ANOVA without interaction.

single animal given anaesthetics B, C, A, D in that random order.

Usually such a design will be extremely powerful because the variation within an animal over a period of time is much less than the variation between animals which may have both genetic and environmental components. The experiment is also analysed using a two-way ANOVA without interaction. Differences between subjects are assumed to be a random effect (like a block), with the treatments being a fixed effect.

A special case of the within animal experiment is a 'before and after' experiment where an animal is used as its own control. Thus, some outcome is measured in the untreated animal, then a treatment is applied and the same outcome is again measured to assess the effect of the treatment. While this is a useful design in many cases it suffers from the technical disadvantage that there is no randomisation. It is not possible to have an 'after' before the 'before'. The results therefore have to be interpreted with extra care.

Note that there can be some confusion in the name of the design because experiments where some outcome is measured several times following a treatment is *not* a repeated measures design because time is not a 'treatment'. It is a design with multiple outcomes. Methods of analysis of this type of data were discussed earlier in this chapter.

### The Latin square design

This design was developed for agricultural research where crop experiments are frequently laid out in fields and there may be a gradation in fertility from left to right (columns) and top to bottom (rows). It is rare in animal research. The design removes the rows and columns effects in order to increase statistical power. The number of treatments must be the same as the number of rows and the number of columns, hence it is 'square'. In animal research 'rows' might, for example, be represented by the shelf in a rack of cages and columns by position from left to right. Whether this would be worthwhile depends, of course, on whether there are important environmental effects of cage location. In Figure 3.4 every row and every column has all three of the treatments A, B and C. Thus the experiment is balanced in such a way that it is possible to remove the differences between both rows and columns so that the effects of the treatments can be assessed more accurately. The Latin

A	B	C
C	A	B
B	C	A

**Figure 3.4** A 3 × 3 Latin square design. There are three treatments A, B and C, three rows and three columns. Every row and column has exactly one of each of the treatments. However, a 3 × 3 Latin square is too small for practical use. It can, however, be replicated with separate squares being combined in the statistical analysis.

square in Figure 3.4 was written with the three treatments A, B and C in this order in the first row, then displaced one column to the right in the second column etc. Randomisation is achieved by randomising whole rows and then whole columns.

With the  $3 \times 3$  Latin square there will only be two degrees of freedom for the error term, which is far too few. In practice Latin squares are best with between five and seven different treatments involving 25–49 subjects in total. Any smaller and they will lack power, any larger and they become difficult to manage. However, it is possible to replicate small squares in order to increase their power.

The statistical analysis of a Latin square using a three-way ANOVA poses no problems. Data will normally be presented in the computer in four columns. The first will indicate the treatment, the second the row, the third the column and the fourth the observation or measurement. A three-way ANOVA will then be invoked with the column and row being random effects and the treatment being a fixed effect. However, complications will arise if there are missing values. Generally complex designs of this sort should not be used if missing values are likely to be common. A numerical example can be found in many statistical text books.

### Factorial experimental designs

A factorial design is one in which two or more factors are varied in a single experiment. For example ‘treatment’ could be a factor with levels low, medium and high and strain may be another factor with levels C57BL/6, BALB/c. A factorial design based on these two factors would have all six combinations of treatment and strain. Where drugs or toxic agents are being studied one factor could be drug A (say at several dose levels) and another factor being drug B at several levels. The results will show whether the drugs potentiate or interact with each other. Similarly, it is often desirable to find out whether the response to some treatment depends on gender, strain, diet or any other factor which might influence the outcome.

Suppose an experiment is designed to compare a group of 12 C57BL/6 mice treated with a test chemical with 12 control C57BL/6 mice receiving the vehicle, but it would be desirable to know whether the response is the same in males and females. One way of doing this would be to do the experiment in males and then repeat it in females. This is known as the ‘one variable at a time’ approach, but it would mean using a further 24 mice and, because these are separate experiments, there is no way of testing whether males and females were responding in the same way. The alternative would be to use a factorial design with six male and six female mice receiving the test chemical and six male and six female mice receiving the vehicle control. This is a  $2 \times 2$  factorial, with four treatments and would only involve 24 rather than 48 mice. It has the added advantage that it is possible to test whether the two sexes respond in the same way. Using the resource equation method of determining group size,  $E = 24 - 4 = 20$ , so the experiment seems to be of an appropriate size.

How should these animals be housed? This is not an easy question to answer.

- Housing one mouse per cage would ensure that each animal was independent, but mice are social animals and individual housing is stressful. It may be acceptable for a short period, but not for a long-term study.
- Housing them in four groups (by treatment and sex, six mice per cage) would be bad because the individuals would not be independent. Environmental or social effects may differ among cages. For example, males may fight in one cage but not in another one or one cage may get more light or be warmer than another.
- If the mice are individually treated, then it would be possible to house a treated and control mouse in each cage. This might be a problem if the treated mice become temporarily sick and get bullied by the control mice, or if the treated mice produce faeces or urine which affects the control mice. Assuming that these factors are not a problem, then this design is actually a split plot (discussed in the next section) rather than a factorial design. The comparison between the treated and control animals is more precise (because it is a within-cage comparison) than that between males and females (a between-cage comparison).
- The mice might be housed two per cage so that there were three cages of male treated, three of male control and the same for the females, giving a total of 12 cages. In this case the experimental unit is a cage with two mice. However, the statistical analysis could detect whether there are statistically significant cage effects. If not, then it might be acceptable to consider the individual mouse as the experimental unit.
- Another strategy would be to make the experimental unit a cage with two mice in it, but that would double the number of mice. Ethically, it is sometimes better to use more animals each of which suffers less, but each case needs to be considered on its merits.
- Another similar strategy would be to house the experimental animals one mouse per cage, and give each one a companion which is not part of the experiment and on which no observations are made.

Assuming that the individual mouse is the experimental unit (say it is housed with a companion) and the outcome variable is a quantitative measurement such as body weight or red blood cell count, the statistical analysis of this experiment will involve a two-way analysis of variance *with interaction*. This would indicate whether there was a statistically significant difference between the treated and control means averaged across the two sexes (known as the ‘main effect’ of the treatment), whether there was a significant difference between males and females averaged across the treatments (the main effect of gender), and whether the response in the males was the same as in the females (the interaction between treatment and gender). Of course, if the interaction is significant it implies that males and females respond differently. In this case it does not usually make sense to average across the sexes when looking at the response to the treatment. The four groups will need to be averaged separately.

Factorial designs can have any number of factors and any number of levels of each factor, although as complexity increases, the interpretation may become more difficult. In the above example it would be possible to have a third

**Table 3.1** Layout of a 2 (treatments)  $\times$  2 (gender)  $\times$  2 (strain) factorial design with three mice in each treatment group. For discussion see text.

Strain	Treated		Control	
	Male	Female	Male	Female
C57BL/6	3	3	3	3
BALB/c	3	3	3	3

factor, strain, as shown in Table 3.1. This would make it a  $2 \times 2 \times 2$ , or  $2^3$  factorial design with eight treatment groups and would show whether the response to the treatment depended on both gender and strain. In this case E would be  $24 - 8 = 16$ , which is still of an adequate size.

Some scientists express concern about sample size in factorial experiments. In the above  $2^3$  example there will only be three mice in each of the eight treatment combinations, whereas in some fields of research there is a tradition of having eight animals per group. However, in this example when comparing the treated versus control mice there will be 12 animals in each group, as there will be for comparing males and females and the two strains. The concept of group size needs to be modified with this type of design. Moreover, in experiments of this type it is necessary to estimate the mean of a group, which can be done with quite small numbers, but it is also necessary to estimate the standard deviation which needs larger numbers. In the factorial design the sub-group means are estimated from three mice (in this example) which is perfectly adequate because the standard deviation is estimated from the whole experiment, and is based on 16 degrees of freedom. Statisticians sometimes call this 'hidden replication', and it accounts for the great efficiency of factorial designs.

Factorial designs provide extra information, when compared with a single factor design, at no extra cost in terms of animals and scientific resources. The value of factorial designs has been recognised by statisticians for many years. According to R.A. Fisher:

*If the investigator ... confines his attention to any single factor we may infer either that he is the unfortunate victim of a doctrinaire theory as to how experimentation should proceed, or that the time, material or equipment at his disposal is too limited to allow him to give attention to more than one aspect of his problem. ... Indeed in a wide class of cases (by using factorial designs) an experimental investigation, at the same time as it is made more comprehensive, may also be made more efficient if by more efficient we mean that more knowledge and a higher degree of precision are obtainable by the same number of observations. (Fisher 1960)*

However, it is important for investigators to understand both the statistical analysis and interpretation of such experiments. One important limitation is that these designs should not be used where many missing numbers are expected, and group sizes should be equal otherwise the statistical analysis and interpretation is more complicated although still possible with good software.

As noted, factorial designs can have any number of factors and any number of levels of each factor. However, the  $2^n$

series is of particular interest as it can be used to explore the relationships between many factors, each at two levels, without using excessive numbers of experimental units. Special methods are available for dealing with ten or more factors simultaneously. These depend on the assumption that high-level interactions are usually zero, so these interactions can be combined to give an estimate of error. This makes it possible to use as few as one animal per group in high-dimensional designs. More details are given by Montgomery (Montgomery 1997) and other specialised texts. These designs are common in industrial research when optimising output (say) from a chemical reaction which may involve many variables. In biomedical research they could play a useful role in optimising a screening programme for drug development (Shaw *et al.* 2002), and their more widespread use in toxicity testing using rats or mice of several inbred strains rather than an outbred stock has been advocated for many years (Russell & Burch 1959; Festing 1979, 1980, 1995).

### The split-plot design

The split-plot design is somewhat similar to a factorial design although it is more complicated. Again it was developed from agricultural research involving field experiments on crops, but is often applicable to animal research. It is easiest to describe by an example.

Suppose several cages containing, say, two animals are assigned either as controls or to a treatment in the food or water. Within each cage it would be possible for some animals, chosen at random, to receive, say, a vitamin supplement by injection and the other one to receive a placebo. This design has two sorts of experimental units. So far as the treatments are concerned, the cage is the experimental unit, as it is the cage of animals which is assigned to one of the treatment groups. But so far as the vitamin supplement is concerned, the individual animal within a cage is the experimental unit since animals within a cage can have different vitamin treatments (or be of a different strain).

The split-plot design provides a relatively poor estimation of the main effect of treatments, depending on the number of cages, but a good estimate of the within-cage effect, eg, the effect of the vitamin supplement and also the interaction between vitamin supplement and treatment. The statistical analysis is done using a 'nested' ANOVA (the vitamin treatment is said to be nested within the cage) and probably requires expert statistical advice.

### Other designs

There is a range of other experimental designs which can be used in particular circumstances. For example, incomplete block designs are used when there is a natural structure to the experimental units but the number of treatments is greater than the natural block size. This might occur, for example, if the aim is to compare the effects of, say, six micro-organisms on mice but only four isolators are available. These will need to be re-used in such a way as to ensure that each micro-organism is compared with every other one

in a fair way. Sequential designs can be used in situations where a small number of units may be compared quickly, and the numbers can be extended if necessary in order to achieve a given level of statistical power. These can be useful designs to minimise animal use but, except in very simple cases, the statistical analysis can be complicated.

## Concluding remarks

There are five criteria for a good experiment.

1. It should be unbiased with all treatment groups having the same environment unless environment is the subject of the study. This is achieved by ensuring that the animals (or other subjects) are randomised both in the allocation to a treatment, but also throughout the whole experiment. The investigator should also do the experiment blind with respect to the treatment groups so that no bias is introduced by inadvertently favouring one particular group.
2. All experiments should have adequate power so that if there is a scientifically or clinically important treatment effect there will be a high chance of detecting it and it will not be drowned out by 'noise' or random variation. The latter is achieved through two measures: First by controlling the variation. As far as possible animals should be the same age, weight, sex, health status, be housed in a controlled environment and have similar prior experience. Where there is detectable heterogeneity or where there is some natural structure to the experimental material, then a randomised block design may be appropriate. Similarly a within-subject crossover design is often very powerful because the variability within an animal is usually less than the variability between animals. Second, when the variability has been controlled, sample size can be determined using a power analysis or the resource equation methods. Although both have limitations, they are far better than traditional methods of having a fixed number per group in all experiments.
3. If it is important to know whether the results depend on the strain, sex, diet or other factor (and this is often the case) then a factorial design should be used in order to increase the range of applicability. Factorial designs should be used wherever possible, with the exception of studies where very unequal numbers in each group are unavoidable, because they provide extra information at no additional cost apart from a slight increase in the complexity of the statistical analysis. Using such designs it is possible to include both sexes or more than one strain in addition to a treatment without increasing the total number of animals which are used. However, if these designs are used it is essential to use the correct statistical analysis otherwise all the advantages are lost.
4. Experiments should be simple so that the chance of making a mistake is minimised. The experiment should always be pre-planned and additional treatment groups should not be added at a later date as randomisation will not be possible. The method of statistical analysis

should be considered at the design stage, and not be left until after the experiment is finished.

5. Finally, the experiment should be amenable to statistical analysis. The most important criterion in this case is that there should be independent replication of the observations. This requires correct identification of the experimental unit, which may, for example, be a cage of animals if the treatment is given in the food or water, or a single animal if animals were individually treated.

# 4 Introduction to laboratory animal genetics

Michael F.W. Festing and Cathleen Lutz

## Introduction

The aim of this chapter is to give an introduction to laboratory animal genetics both for the research worker wishing to use these animals and for the staff who will be required to breed and/or maintain them. Inevitably, most of the examples involve mice or rats. However the principles of genetics are universal, and one striking finding of recent years is the extent to which many genes and even genetic linkages have been conserved through evolution.

Research workers are now faced with a wide array of different species, stocks, inbred strains, mutants and transgenic strains from which to choose suitable experimental animals, assuming that the research cannot be done with some non-sentient alternative. However, only in mice is the full array of types available and even in the mouse there are no genetic 'models' for all diseases of interest. In rats there are many inbred strains, some mutants and a few transgenic strains, and in zebra fish there are many mutants, defined strains and transgenic strains but targeted mutagenesis is not yet possible. For larger and/or less widely used species, such as primates, cats, dogs, pigs and even rabbits and guinea pigs, the research worker usually has to be satisfied with the product of breeding colonies for which there is relatively little genetic information. However, knowledge of the genetic basis of susceptibility to disease and environmental agents is increasing exponentially at present so the demand for genetically defined animals of all species is likely to rise in the future. It is particularly important that people using rodents should make an informed choice of the type of animal for their particular project. Failure to do so could result in a waste of scientific resources and the unethical use of excessive numbers of animals.

## Modes of inheritance

The characteristics of an individual, whether human, mouse or dog, are determined both by the composition and nature of the hereditary material that it receives from its parents, and by the environmental influences that it encounters during its growth and development.

The hereditary material consists of DNA (deoxyribonucleic acid) in the classical double-stranded helix made up of a sugar backbone and four bases: adenine (A), thymine (T), guanine (G) and cytosine (C). It is the sequence of these four bases which make up the genetic code which in turn deter-

mines the polypeptide synthesised by the gene. Genes are located on chromosomes (and some, in the mitochondria, not discussed here), one set of which is passed to an individual from each parent. Thus a mouse will normally have 40 chromosomes (20 pairs) 20 of which will have come from each parent. One pair of chromosomes varies between the sexes, with female mammals having a pair of X chromosomes of similar size and shape, while males are 'heterogametic' and have only one X chromosome and a smaller Y chromosome. In birds the females are heterogametic.

By April 2007 there were 22 188 known genes in the mouse which code for proteins and a further 3014 which code for RNA (ribonucleic acid)<sup>1</sup>, but the genes in mammals constitute only about 2–3% of the total DNA, the rest consisting of various classes of repetitive sequences, non-functional genes (known as pseudogenes) and small amounts of DNA introduced by viruses. Each gene is situated at a particular position or 'locus' on the chromosome and usually consists of separated tracts that together code for polypeptides, known as 'exons' and non-coding sequences between the exons, known as 'introns'. There are also DNA sequences outside the gene known as the 'promoter' and 'enhancer' sequences that control the time and place in which it is expressed. The introns are eliminated and the set of exons that form a single gene are brought together during the complicated process of gene transcription and splicing to form messenger RNA which in turn codes for a specific polypeptide. Discussion of the genetic code and mechanism of gene transcription leading to the synthesis of polypeptides is beyond the scope of this chapter.

## Mutations and polymorphisms

Sometimes a *mutation* occurs in a gene or larger segment of a chromosome either spontaneously or induced by radiation or a chemical. This can lead to a defective or abnormal gene product. It may also lead to a clearly visible abnormality in an animal such as albinism, obesity or hairlessness or it may have no obvious effect if, for example, it codes for resistance to a disease-causing organism which is not present in the colony. The mutant gene is known as an *allele* of the normal or so called *wild type* gene locus at which it occurs. Some of these mutations can occur in genes controlling biochemical pathways, and they may have a very slight effect on the

<sup>1</sup><http://www.ensembl.org>

phenotype. These often continue to segregate within a population as *polymorphisms*.

Mammals are diploid, meaning that at each locus there are two copies of a gene, one from each parent. If these alleles are identical, then the animal is said to be homozygous at that locus. If they are different, then the animal is heterozygous at that locus. If a mutation is expressed only when the animal is homozygous for the mutation, then the mutation is said to be recessive. If it is expressed in the heterozygote it is said to be dominant or semi-dominant if it is intermediate between the homozygote and heterozygote.

Microscopic observation of the chromosomes has shown that a number of different chromosomal abnormalities may occur. Total loss or gain of one or more whole chromosomes (aneuploidy) is rare and is usually fatal at an early stage of development. However other types of abnormality are more common. These 'cytogenetic abnormalities' include the fusion of two chromosomes so that the total number of chromosomes is reduced, but one chromosome is much larger than normal. These are known as Robertsonian translocations, and they have been found in wild mice. Another type of translocation occurs when parts of two chromosomes break and join with one another. These 'reciprocal translocations' do not result in a reduction in the total number of chromosomes, but they may alter their relative sizes. Individuals carrying these are usually perfectly viable, though males may be sterile. There are also several other cytogenetic differences such as small deletions and inversions (where a bit of chromosome has broken in two places and re-joined the wrong way round) which can usually only be seen microscopically using stains which give a banding pattern to the chromosomes, or by using special breeding techniques.

Finally, certain characters may have a non-chromosomal mode of inheritance caused by the 'vertical' transmission of certain characteristics from parent to offspring via the cytoplasm, placenta, or the milk. The best known example of this is the vertical transmission of the Bittner mammary tumour virus which is passed from mother to offspring through the milk in certain susceptible strains of mice. Normally, the young will receive the virus, and this results in the development of mammary tumours in females of that strain. However, if the young are fostered to another strain which does not carry the virus, then the cycle will be disrupted and the young will not develop mammary tumours in subsequent generations. There are numerous other viruses which can be vertically transmitted from parents to offspring, though in most cases it is not possible to eliminate them by cross-fostering.

### Nomenclature of simple mutants

The genetic nomenclature of mice and rats is controlled by the *International Committee on Standardised Genetic Nomenclature of the Mouse* and *The Rat Genome and Nomenclature Committee*<sup>2</sup>. The main purpose of standardised genetic nomenclature is to give each genetic locus and allele a unique name so that information about it can be accumulated in databases ranging from those involved with DNA sequences

<sup>2</sup><http://www.informatics.jax.org/mgihome/nomen/index.shtml>

up to those which record the phenotypic consequences of the mutation. Clearly it would soon become chaotic if each investigator used a different name for the same gene or a name that has already been taken by a different gene.

There are detailed rules for different types of genes including spontaneous and induced mutations and various types of genetically modified animals as well as for inbred strains. However, only the nomenclature of gene mutations is discussed here. Nomenclature of inbred strains and genetically modified organisms is considered later.

When a mutation occurs, and it is shown to be inherited it is given a name which is usually descriptive such as 'obese'. In the case of a recessive gene this starts with a lower case letter and a gene symbol in italics (in this case '*ob*'). The normal unmutated allele is designated by a plus sign +, or as a superscript to the gene symbol *ob*<sup>+</sup> if the context makes it necessary to indicate the locus. However, research on the obese locus has since shown that it codes for a protein which has been named leptin, so the name of the locus was changed to the leptin locus with the gene symbol *Lep*, and the allele is now indicated by a superscript *Lep*<sup>ob</sup>. Note that the gene symbol now starts with an upper case letter as it is the allele not the locus which is recessive.

At a time of rapid research progress it is very common for gene names to change as more is known about them. Attempts are also made to use the same locus name and symbol across species. For example, the nude mutation in the mouse was found to be a homologue of a gene in *Drosophila* called forkhead 11 (a so-called homeobox gene which helps to determine body pattern, and a mutation of which causes a forked head in *Drosophila*) so the gene name is now forkhead box N1 with the gene symbol *Foxn1*. The nude mutation is therefore now designated *Foxn1*<sup>nu</sup>. Human gene symbols are all given in upper case letters, which serves to indicate that a transgene (see later) is of human origin if shown in upper case letters. A complete list of previous names is maintained, at least for the mouse, and is available on the Jackson Laboratory website<sup>3</sup>.

Table 4.1 lists some examples of relatively old mutations which are of biomedical interest. Note that in most cases the original name has been changed because the locus and DNA sequence are known.

### Mendelian inheritance

The rules of Mendelian inheritance may be illustrated by reference to the albino locus which is about half way along chromosome 7 in the mouse. Alleles at this locus affect the activity of the enzyme tyrosinase, with the albino mutation now being designated *Tyr*<sup>c</sup> (the c standing for colour). There are several different mutations or 'alleles' at this locus, including the chinchilla and Himalayan mutations, though there can only be two in an individual animal.

### The monohybrid cross

Crosses involving mutants at a single locus (ie, a monohybrid cross) can be designated using the above symbols.

<sup>3</sup><http://www.informatics.jax.org>

**Table 4.1** Example of some old mutants of interest in biomedical research. Note that most mutants are now listed as alleles of a renamed locus (eg. *nu* is now an allele of the *Foxn1* locus), but the function of the locus of others (eg. *qk*) has yet to be determined.

Gene symbol	Locus (allele name)	Brief description
<i>A<sup>y</sup></i>	Yellow	Yellow coat colour, obese, increased tumours
<i>Atp7a<sup>Mo-br</sup></i>	ATPase, Cu <sup>++</sup> transporting, alpha polypeptide (brindled)	Sex-linked semi-dominant lethal, abnormal copper metabolism
<i>Dh</i>	Dominant hemimelia	Asplenic, skeletal abnormalities
<i>Eda<sup>Ta</sup></i>	Ectodysplasin-A (tabby)	Sex-linked, abnormalities of pelage
<i>Foxn1<sup>nu</sup></i>	Forkhead box N1 (nude)	Hairless, athymic, immunodeficient
<i>Hr<sup>hr</sup></i>	Hairless (hairless)	Hair loss, mild immunodeficiency
<i>Kit<sup>W</sup></i>	Kit oncogene (dominant spotting)	Anaemia, defective haematopoietic stem cells
<i>Kit<sup>Sl</sup></i>	Kit ligand (steel)	Anaemia, deficiency of mast cells
<i>Lama2<sup>dy</sup></i>	Laminin, alpha 2 (Dystrophia muscularis)	Muscular dystrophy
<i>Lep<sup>ob</sup></i>	Leptin (obese)	Type II diabetes
<i>Lep<sup>rd</sup></i>	Leptin receptor (Diabetes)	Non-insulin dependent diabetes on a C57BL/Ks background, phenotype virtually identical to obese when on a C57BL/6 background
<i>Lyst<sup>bg-j</sup></i>	Lysosomal tracking regulator (Beige)	Dilute colour, lacks natural killer cells, immunodeficient
<i>Prkdc<sup>scid</sup></i>	Protein kinase, DNA activated, catalytic polypeptide (severe combined immune deficiency)	Immunoglobulin deficiency, severe immunological defects
<i>Ptpn6<sup>me</sup></i>	Protein tyrosine phosphatase non-receptor type 6 (motheaten)	Severe autoimmune disease
<i>Qk</i>	Quaking	Myelin deficiency, neurological abnormalities
<i>T</i>	Brachyury (brachyury)	Tailless, embryonic lethal, interesting genetics

Thus, crossing a mouse which is wild type at the albino locus and therefore is *Tyr<sup>+</sup>/Tyr<sup>+</sup>* with one which is albino (*Tyr<sup>c</sup>/Tyr<sup>c</sup>*) is designated:

$$Tyr^{+}/Tyr^{+} \times Tyr^{c}/Tyr^{c}$$

The resulting 'F1' offspring will get one allele from each parent, so will have the genotype *Tyr<sup>+</sup>/Tyr<sup>c</sup>*. The appearance of an animal is referred to as its phenotype (in this case wild type), whereas its genetic make up is referred to as its genotype (in this case *Tyr<sup>+</sup>/Tyr<sup>c</sup>*).

If two of these F1 animals are crossed to produce an F2 generation:

$$Tyr^{+}/Tyr^{c} \times Tyr^{+}/Tyr^{c}$$

then each parent will produce gametes which are either *Tyr<sup>c</sup>* or *Tyr<sup>+</sup>* and these will recombine at random to give the following types of mice in the statistical ratios 1:2:1:

$$Tyr^{+}/Tyr^{+} \quad Tyr^{+}/Tyr^{c} \quad Tyr^{c}/Tyr^{c}$$

This results in a 3:1 ratio of animals with the wild-type phenotype and the albino phenotype. The phenotypically wild-type animals will either be homozygous for wild type or heterozygous.

The crossing of animals which differ at two loci is not considered here although in practice it is important as it is used to test whether the two loci are linked on the same chromosome, and if so how close they are to each other in terms of how frequently they re-combine. This is discussed briefly later in this chapter.

### Sex linkage

Genes carried on the sex chromosomes are said to be sex linked, as their expression, and the frequencies of the different phenotypes differ between the sexes. The 'tabby' gene in the mouse has a sex-linked mode of inheritance. This dominant mutation was first designated *Ta* in 1953, but is now known to be an allele of a locus called ectodysplasin-A with the gene symbol *Eda<sup>Ta</sup>*. In studying the mode of inheritance of such characters, the Y chromosome may be considered to be inert and devoid of hereditary material (though it does in fact carry some genes such as a Y-linked alloantigen and a sex-determining locus). Thus in the male with an X and a Y chromosome, all the genes on the X chromosome will be expressed (ie, will act as though they are dominant). Such a male is said to be *hemizygous* for the gene. So in the case of the *Eda* locus, the male will have the genotype *X<sup>Eda-Ta</sup>/Y* which is described as having a 'greasy coat' phenotype, while the female heterozygote has the genotype *X<sup>Eda-Ta</sup>/X<sup>Eda+</sup>* and is said to have a tabby phenotype (a bit like a tabby cat). A cross between these two mice results in 25% greasy coat and 25% wild type males and 25% greasy coat and 25% tabby females. The female has two X chromosomes. However, one of these X chromosomes becomes inactive at an early stage of embryonic development. Either the maternally or the paternally derived chromosomes may be inactivated, and the choice seems to be random in any given cell. Once a chromosome has become inactive, in an embryonic cell, clones derived from that cell will have the genetic characteristics associated with the active X chromosome. If the female is

heterozygous for a sex-linked gene such as tabby, the result is that the female becomes a mosaic of cells expressing the tabby gene (*Eda<sup>Tn</sup>*) and those expressing the wild-type gene (+). Tabby mice in fact have stripes which consist of patches of fur with the greasy-coat phenotype seen in males carrying tabby, and normal fur, hence their tabby appearance.

### Linkage and linkage maps

Two loci will be linked (ie, they will not segregate independently) if they are close together on the same chromosome. Linkage will not be absolute, however, because during meiosis (the process of forming the gametes) the chromosomes twist together and often break, and rejoin. This leads to 'crossing over' or recombination, which will only be observable if both genetic loci are polymorphic. For example, one chromosome may carry the alleles designated by capital letters A and B while the other chromosome carries those designated by lower case letters a and b. After genetic recombination one chromosome will now carry A and b and the other a and B at these two loci. The frequency of such recombination will depend on how close the gene loci are on the chromosome. Linkage analysis measures this recombination involving at least three loci in order to obtain a 'linkage map' by observing the types of offspring from appropriate crosses. This has become increasingly easy in the last decade due to the development of large numbers of DNA-based genetic markers such as microsatellites (short stretches of repetitive DNA sequence, with the number of repetitions varying) and single nucleotide polymorphisms (a difference in the base at a particular locus in different animals).

Extensive linkage maps of the mouse and rat are now available. These may be used both for fundamental genetic studies such as in the identification and cloning of genes and also in a number of practical ways. It has been found that quite large parts of mouse chromosome have orthologous parts in humans, so if two mouse genes are linked, there is a good chance that the same genes will be linked in humans. As genetic mapping in the mouse is much easier than in humans, this is a substantial advantage. Physical maps showing the actual DNA sequences and the locations of individual genes and their components are also available now that rapid DNA sequencing methods have been developed.

### Genes in populations of animals and the Hardy–Weinberg equilibrium

The examples of Mendelian inheritance given so far have been considered in relation to the mating of individuals of a designated genotype. Many research workers use outbred stocks of rats, mice, guinea pigs etc; stocks which are usually closed colonies, and still contain a considerable amount of genetic variation. The laws derived by Hardy and Weinberg independently in 1908 describe the distribution of genetic variants in such populations. The Hardy–Weinberg laws refer to a theoretically 'ideal' population which is infinitely large, which is maintained by random mating and which is closed to the introduction of new stock. The laws also assume

that no selection of the offspring occurs, and that the gene locus has no effect on viability or reproductive performance. In practice, none of these conditions would hold with a real group of animals, but real populations may behave approximately as stated by the Hardy–Weinberg laws.

In the ideal population which is segregating at a locus with alleles *a* and *A* it would theoretically be possible to count or estimate the frequency of the *a* and *A* genes. For example, a sample of 500 animals (therefore having a total 1000 genes at each locus counting all animals) could be taken and the number of animals which were *AA*, *Aa* and *aa* determined. Suppose that it turned out that there were 405, 90 and 5 animals of each type respectively. Therefore, the frequency of the *a* allele is  $(2 \times 5 + 90)/1000 = 0.10$ , and the frequency of the *A* allele is  $(2 \times 405 + 90)/1000 = 0.9$ . The Hardy–Weinberg laws state that:

1. in the ideal population, gene frequency will remain constant, with no tendency to change from generation to generation;
2. the frequency of animals of genotypes *AA*, *Aa* and *aa* is determined solely by the gene frequencies and follows the binomial  $(p + q)^2$  where *p* is the frequency of one allele and *q* ( $= 1 - p$ ) is the frequency of the other one.

The practical consequences of the Hardy–Weinberg laws are most commonly noticed in the maintenance of a coloured strain of animals such as hooded rats which carry wild-type at the albino locus although they are homozygous for the hooded gene *h* (ie, they are *hhCC* or *hhCc*). In one case, approximately 1% of all the rats produced in a hooded rat colony were albino. Such large numbers cannot arise as a result of new albino mutations, but are easily explained by references to the Hardy–Weinberg equilibrium.

If 1% of the animals are albino, the frequency of the albino allele, *q*, can be calculated as the square root of 0.01 which is 0.1, so *p* is 0.9 and the frequency of heterozygotes is  $2pq = 2 \times 0.9 \times 0.1 = 0.18$  or 18%.

Although the effects of selection to eliminate a gene such as albinism in a hooded rat colony will not be considered in detail here, it is clear from the above that most of the albino genes are maintained in the heterozygous state, so that in the case of a recessive gene such as this one, culling of the 1% of albino animals will have relatively little effect on the future frequency of albino animals produced. The only practical way to eliminate a gene of this sort in an outbred population is to progeny test each breeding animal by crossing it to a homozygous recessive animal to see if any mutant offspring are observed. If not, and if sample size was reasonably large (say eight to ten offspring), then it is unlikely that the animal being tested carries the recessive mutation. This is a laborious process which has to be done on a large scale in order to reconstitute the outbred stock without the recessive mutation.

### Directional selection

Selective breeding has been used to develop several rat models of spontaneous hypertension, a number of rat strains differing in behaviour and strains of mice which differ in

their response to sheep red blood cell antigens, carcinogens and alcohol, to give just a few examples.

The usual method, known as 'mass selection by truncation', involves measuring the trait of interest in all animals. Only those animals which exceed a certain value (the point of truncation) are used for breeding. If the heritability of the character (briefly the extent to which any variation is inherited, as opposed to being due to environmental influences, usually designated  $h^2$ ) is known, then the progress from this type of selection can be calculated from:

$$\text{Progress/generation} = h^2 \times \text{selection differential.}$$

The selection differential is the difference between the mean of the whole population, and the mean of the selected individuals. Thus, the greater the selection differential, the greater the progress.

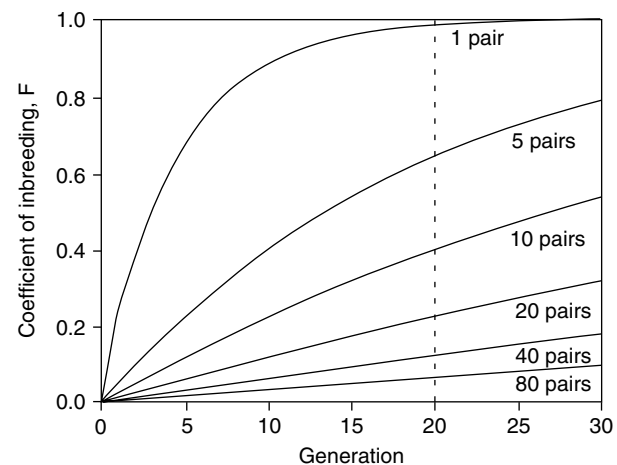

Very small animals are often regarded as 'runts' and are not used for breeding in case they are genetically abnormal. As a result there has been mild selection over a long period for increased body weight in mice and rats. The 10-week body weight of the three outbred stocks of mice supplied by one commercial breeder all exceed the 10-week body weight of the 17 inbred strains supplied by the same breeder. Similar selection is practised with inbred strains, but as there is no genetic variation within an inbred strain the heritability is zero, and there has been no response to such selection. Breeders wishing to maintain the characteristics of their outbred stocks so that they do not become heavier over time should ensure that there is no selection for larger body weight.

## Inbreeding

Inbreeding is the mating of related individuals. The more closely that they are related, the greater the degree of inbreeding. Thus the most intense inbreeding is self-fertilisation (in species where this is possible) as the closest possible relationship is that of an animal with itself. Next comes brother  $\times$  sister and parent  $\times$  offspring mating (which are of equal intensity), half-brother  $\times$  sister mating and so on. At the other extreme, in large populations of animals maintained by random mating the average relationship between any two individuals will be slight, so the rate of inbreeding will be low (Figure 4.1). Inbreeding is measured in terms of the 'coefficient of inbreeding', which is usually given the symbol 'F' (not to be confused with F1, F2 etc. which indicates filial generations from a given cross). Theoretically, F can range from 0.00 (ie, no inbreeding) to 1.00 (complete inbreeding).

The coefficient of inbreeding is a measure of the probability that two alleles at any given locus (one of which comes from each parent) are identical by descent (ie, that they are both copies of the identical piece of DNA in some ancestor). If the two genes are identical by descent the parents must have been related and the animal will, of course, be homozygous at that locus. Thus high levels of inbreeding are associated with high levels of homozygosity.

The calculation of the exact degree of inbreeding for any given animal will involve a study of the pedigree of the colony (if it is available) and will always be quoted relative to an arbitrary starting point at which the level of inbreeding

**Figure 4.1** Coefficient of inbreeding as a function of the generation in colonies of various sizes. Note, it is assumed that at the start the coefficient of inbreeding is zero.

is assumed to be zero. The calculations also assume that at the locus in question heterozygotes do not survive any better than homozygotes.

Inbreeding usually leads to 'inbreeding depression', which is a general decline in reproductive performance, vigour and ability to survive. This is largely due to the 'uncovering' of mildly deleterious recessive genes as they become homozygous. Such depression will be most severe in the early stages of inbreeding because this is when the homozygosity is increasing rapidly (Figure 4.1). If a strain is already highly inbred further inbreeding will not significantly increase homozygosity, hence it should not result in further inbreeding depression.

Inbreeding also has the effect of increasing the total genetic variation provided all individuals are maintained, while at the same time decreasing the genetic variation within any one family. An 'inbred strain', as discussed later, consists of a single branch of a colony inbred by brother  $\times$  sister mating. However, if the full set of all sub-lines has been retained (ie, a full set of independently inbred strains from the same initial colony), it would be found that the variation between these branches or strains would be very much greater than the variation present in the original colony. This means that, in general, a set of inbred strains will be more extreme in their phenotypic characteristics than would be found among individuals of an outbred stock. This point is of some importance in designing experiments based on a wide range of phenotypes, as it means that a collection of individuals of different inbred strains will cover a much wider range of phenotypes than will a collection of outbred individuals. A more detailed account of much of the material given so far is given by Green (1981) and Falconer (1981).

## Effects of genetic background: variation in the expression of genes

The 'genetic background' is the rest of the genome apart from a specified gene or genes. The expression of many genes depends on this genetic background as well as on

environmental influences. Chance effects during embryonic development may also play a part. In extreme cases, modifiers and environmental influences may prevent a gene from being expressed at all. Some genes may be lethal on some genetic backgrounds but perfectly viable on others. The viable yellow allele at the agouti locus in the mouse is one of the best examples of variable expression which is due both to environmental and genetic influences. Animals of the  $A^{vy}/a$  genotype can vary from pure yellow through a mottled yellow and agouti colour to a pseudo-agouti colour which closely resembles pure agouti. This variation occurs even when the genetic background is constant (ie, when the allele is in an inbred strain), showing that it is determined by unknown non-genetic or chance environmental influences. The frequency of the pseudo-agouti animals also varies according to the inbred strain in which the allele is maintained, showing that the variation is also dependent to some extent on genetic modifiers.

There is a powerful case for maintaining mutants and transgenes etc. on a standard inbred genetic background where the within-strain expression will be more uniform. Thus, in developing genetically modified animals it may be necessary to make crosses between strains largely because inbred strains do not always breed very well, but when studying the effects of the genetic modification it is good practice first to transfer the gene to an inbred background by backcrossing to produce a congenic strain (see below).

### Polygenic characters and quantitative trait loci

Many characters such as body and organ weights, growth rate, litter size, behaviour, cancer incidence, metabolic rate, response to chemicals and certain immune responses have a polygenic mode of inheritance which depends on the simultaneous action of many genes. Many of these characters have a continuous distribution so that it is not possible to designate distinct classes and assign animals unambiguously to them. In other cases, there may be clearly distinct classes (eg, animals which develop a spontaneous tumour and those that do not) but when these animals are bred, it is not possible to show that the offspring are of the types and in the numbers that would be expected from Mendel's laws. Each quantitative trait locus (known as a QTL) has a Mendelian mode of inheritance but this is obscured by the simultaneous segregation of genes at many other loci and by environmental effects.

The development of substantial numbers of genetic markers such as microsatellites and single nucleotide polymorphisms (SNPs) has made it possible to map and in some cases identify individual QTLs. Typically, two inbred strains which differ in susceptibility to a disease or toxic agent are crossed to produce first an F1 hybrid and then either an F2 or a backcross generation. These will be genetically segregating for the susceptibility genes. Each individual is then phenotyped (ie, characterised) for susceptibility and genotyped at a large number of marker loci distributed across all chromosomes. Any association between susceptibility and one or more of the genetic markers implies linkage between the two.

## Strains and stocks of laboratory animals

### Outbred stocks

An outbred stock is a colony of genetically heterogeneous laboratory animals usually maintained as a closed colony. Such animals are available in all species. The most common outbred stocks are CD-1 and Swiss mice (Chia *et al.* 2005) and Sprague-Dawley and Wistar rats. The individuals are said to be 'genetically undefined' because the genotype of an animal at any given locus is usually unknown unless the animal is individually typed. Most outbred stocks of mice and rats are albino, some stocks of rats are hooded (white with a coloured head and front legs) and many breeds (ie, outbred stocks) of rabbits have a defined coat colour. Some colonies of dogs, primates and pigs may be typed at the major histocompatibility complex (MHC) or other loci of particular interest in a particular research project.

The characteristics of a particular stock can change as a result of directional selection, inbreeding and random genetic drift, resulting in departures from the ideal Hardy-Weinberg population. Daughter colonies in other locations will only have a sample of the genes present in the parental colony, depending on the size of the founding group of animals, hence even if colonies have the same name and come from the same stock, they will be genetically different. Commercial breeders overcome this problem to some extent by circulating stock among different breeding colonies, but this poses a health hazard because there is a danger that one of the colonies has become infected but this has not yet been recognised.

A high level of heterozygosity is usually associated with good reproductive performance. This usually also means that the animals are relatively cheap to buy. However, the cost of the animal is usually only a small fraction of the total cost of the experiment. Increased phenotypic variability means that either sample sizes will need to be increased or statistical power will be decreased in controlled experiments when compared with the use of inbred strains (see Chapter 3). Taking into account the many other advantages of inbred strains such as long-term stability, known genotype at many loci, easy genetic quality control and international distribution, the investigator needs to give serious consideration as to whether the use of outbred stocks can be justified in a particular research project. Basically, the default position should be to use inbred strains except in circumstances when the use of outbred stocks can be specifically justified.

### Nomenclature

The International Committee on Laboratory Animals (now the International Council on Laboratory Animal Science, ICLAS) formulated rules for the nomenclature of outbred stocks in 1972<sup>4</sup>. Very briefly, to qualify for designation, an outbred stock should have been bred as a closed colony for at least four generations, and it should be maintained in such a way as to give less than 1% inbreeding per generation

<sup>4</sup><http://www.informatics.jax.org>

(see next section). The stock code name should consist of two to four capital letters, eg, NMRI. A laboratory code for the breeder, consisting of a capital and one to four lower case letters should precede the stock name, and be separated by a colon, thus: Tif:NMRI. In alphabetised lists the prefix may be left off so that all stocks with the same name are listed together. It is the prefixed code and the colon which serve to distinguish between an outbred stock and inbred strain. Further rules are given for the designation of mutant-bearing stocks and crosses between stocks. An appendix of the report also gives details of suitable breeding methods, discussed in the next section. There is no organisation which takes a particular interest in outbred stocks but a review of the origins and uses of outbred stocks of mice is given by Chia *et al.* (2005).

### Maintenance of outbred stocks

The objective of maintaining an outbred stock is usually to minimise the rate of change over a period of time. Change can occur as a result of selection (either natural selection as a response to a changing environment or artificial selection imposed by those who control the colony), inbreeding, random drift, mutation and genetic contamination. Wherever possible deliberate selection should be avoided, except that abnormal or unhealthy animals should be culled. Inbreeding and random genetic drift can be controlled by maintaining as large a population as possible, and by careful choice of an appropriate breeding system. In a closed colony maintained by random mating, the rate of inbreeding per generation  $\Delta F$  is:

$$\Delta F = 1/8N_m + 1/8N_f$$

where  $N_m$  and  $N_f$  are the numbers of breeding males and females, respectively. Note that the rate of inbreeding depends on the number of the least numerous sex. For example, if a colony is maintained with only four males the inbreeding will be at least 1/32 or 3.1% per generation however many females there are. Hence inbreeding is minimised by keeping equal numbers of each sex. This can be uneconomical with dogs and some other large species, where more males have to be kept than are really required to maintain the colony.

Inbreeding reduces heterozygosity by a certain percent each generation, so as heterozygosity decreases after each generation of inbreeding, it becomes less effective. The formula for calculating the inbreeding at generation  $t$ , designated  $F_t$  is

$$F_t = \Delta F + (1 - \Delta F)F_{t-1}$$

where  $F_{t-1}$  is the inbreeding from the previous generation. It is always assumed that the starting point is zero (ie, that the base population is not inbred). Table 4.2 shows the rate of inbreeding in random-mated groups of various sizes, according to these formulae. Random-mated colonies of 25 or more breeding pairs must be maintained in order to give less than 1% inbreeding per generation, which is the maximum recommended in the nomenclature rules.

A maximum avoidance of inbreeding system can halve the rate of inbreeding. Several such systems are available. The one shown in Table 4.3 is convenient as the mating

**Table 4.2** Inbreeding per generation for outbred colonies maintained with various numbers of males and females and random mating. Note that with random mating a minimum of 25 breeding pairs is needed to keep the inbreeding down to 1% per generation. Note also that the rate of inbreeding is halved with a maximum avoidance of inbreeding system if the numbers of the two sexes are equal.

Number of male breeders	Number of female breeders	Inbreeding per generation
4	4	6.3
4	40	3.4
13	13	1.9
10	20	1.9
25	25	1.0
80	80	0.3

**Table 4.3** A maximum avoidance of inbreeding system for 12 breeding pairs. Note that such a system can be used for any number of breeding pairs, and it remains the same in each generation. This system with 12 pairs would result in approximately 1% inbreeding per generation. See text for further details.

New pair number	Male from old pair number	Female from old pair number
1	1	2
2	3	4
3	5	6
4	7	8
5	9	10
6	11	12
7	2	1
8	4	3
9	6	5
10	8	7
11	10	9
12	12	11

schedule is the same each generation. Note that avoiding mating of close relatives does not reduce the overall rate because a high rate of inbreeding in one generation will be cancelled out in the next one. Where regular systems of this sort are not practicable, every attempt should be made to ensure that each breeding male contributes one male and each breeding female contributes one female to the next breeding generation.

Inbreeding and random genetic drift may be a problem in the maintenance of transgenic populations which are often maintained in small numbers. One result is that the expression of the transgene may change over a period of a few generations. Problems with inbreeding may also arise when maintaining some of the larger and more expensive animals such as primates where large breeding colonies may be extremely expensive to maintain and may produce more animals than are needed in research, but reducing population size may lead to inbreeding. Freezing of sperm and embryos may offer one possible solution to these problems.

Genetic contamination should be avoided by maintaining stocks with the same coat colour in different animal rooms where possible. Genetic monitoring methods may be used

to ensure that rapid genetic change as a result of contamination or other cause does not occur. However, the genetic monitoring of outbred colonies is expensive and time consuming, and is rarely done. It is necessary to find some genetic markers which are segregating within the population, and then screen quite large numbers of animals to see if the gene frequency changes. These are statistical calculations rather than the all/nothing results obtained with inbred strains. In one case the gene frequency of a biochemical marker which was segregating within an outbred mouse colony, changed quite dramatically over a period of 2 or 3 years, suggesting genetic contamination (Papaioannou & Festing 1980). Methods of genetic quality control are discussed in more detail later.

Outbred stocks are sometimes found to be carrying deleterious recessive genes. These can usually only be eliminated by progeny testing each future breeder by mating it to an animal homozygous for the gene. If no mutant animals are produced among the first 10 offspring, the animal is probably not a carrier (Green 1981).

#### Research uses of outbred stocks

The use of outbred stocks of mice relative to inbred strains is declining because of their obvious limitations, though outbred rats are still widely used in some disciplines such as toxicology. They are rather a blunt research tool, but are still of value in some types of research, particularly when a good breeding performance is important. Thus their use may be justified in reproductive physiology, embryology and teratology. Being cheap, they may also be used when the cost of the animal is a significant proportion of the total cost of the experiment, such as in some types of biological assay. It may be necessary to use more outbred than inbred animals, but this may still work out more economical (though ethically less desirable) in some studies. Outbred stocks may also be used during the development of new techniques, in cases where the type of animal used is likely to be of little significance, and in teaching, where the uniformity and genetic stability found in inbred strains may have little value. Finally, outbred stocks will have to be used in cases where inbred strains are not available. This is usually the case for the larger species of laboratory mammals such as rabbits, dogs and primates.

There is a number of 'genetically heterogeneous' stocks which have been developed for genetic research. In the hands of genetically aware scientists such stocks are valuable for specific types of research. Chia *et al.* (2005) concluded that:

*... outbred stocks (of mice) are a genetically ill-defined set of laboratory animals that are often erroneously used in toxicology, pharmacology and basic research. There is no system of genetic quality control for these stocks and even their names provide little help as to their genetic or phenotypic characteristics. These stocks should not be used in situations where smaller numbers of animals from a range of inbred strains would give optimal results, in terms of sensitivities to substances, for example, or for examining physiological parameters.*

They go on to say:

*However, outbred stocks, especially the experimentally designed and carefully monitored heterogeneous stocks, are helpful in positional cloning of QTLs and as a phenotype and genotype pool from which to select specific traits of interest. Nevertheless we believe the vast majority of papers currently published that refer to the use of outbred stocks should in fact be using inbred lines, and any experimental plans, including grant applications and papers, using outbred stocks need to be fully justified to avoid the current waste of animals and funding.*

#### Inbred strains

An inbred strain is produced by 20 or more consecutive generations of brother × sister mating (younger parent × offspring mating is also permitted), with all individuals tracing back to a common ancestor in the 20th or a subsequent generation. This second requirement eliminates parallel branches which will differ genetically. The result is that the animals should be homozygous for at least 98.6% of loci (Figure 4.1). The animals should also be isogenic, that is, all animals should be genetically identical at every locus, although 100% homozygosity is never achieved.

The first inbred strain of mice was DBA, developed by C.C. Little in 1909, with the first inbred strains of rats and guinea pigs being developed at about the same time by Drs. Helen King and Sewell Wright, respectively (Festing 1979). Most of the strains used today can be traced back to the 1920s and 1930s, though some new strains continue to be developed. Over 450 independent inbred strains of mice have been described including many 'old' strains derived from laboratory and pet or fancy mice (Beck *et al.* 2000) as well as a few strains developed from wild mice and sub-species such as *Mus spretus*. The relationship between 102 inbred strains and major substrains based on 1636 informative SNP markers is shown in Figure 4.2 (Petkov *et al.* 2004). Strains could be classified into seven groups according to their genetic similarity. A later study involving 673 SNPs quantified the genetic distances between 55 common mouse strains (Tsang *et al.* 2005). Such data can be useful in the selection of strains of known genetic similarity for future studies. All the 'classical' inbred strains of mice have some admixture of genes from the mouse sub-species. For example, C57BL/6 has about 92% of genes from *Mus musculus domesticus*, 7% from *M. m musculus* and 1% from *M. castaneus* (Yang *et al.* 2007). There are also many 'derived' inbred strains of mice such as the congenic, coisogenic, recombinant inbred and chromosome substituted strains discussed in the next section.

Over 200 inbred strains of rats have also been described (Festing 1979), although some of these have subsequently died out. A list of rats strains with their history and information on their published characteristics is available at the Mouse Genome Informatics website<sup>5</sup>. There are also a few inbred strains of hamster, guinea pigs, rabbits and some other species (Festing 1979). Tables 4.4 and 4.5 show the inbred strains of mice and rats most commonly cited in

<sup>5</sup><http://www.informatics.jax.org>

**Figure 4.2** Mouse family tree. The 102 strains tested are organized into seven groups. Group 1, Bagg albino derivatives; Group 2, Swiss mice; Group 3, Japanese and New Zealand inbred strains; Group 4, C57/58 strains; Group 5, Castle's mice; Group 6, C.C. Little's DBA and related strains; Group 7, wild-derived strains. The length and angle of the branches have been optimised for printing and do not reflect the actual evolutionary distances between strains. Petko M. Petkov *et al.*, *Genome Research* 2004, **14**, 1806–1811, reprinted with permission.

PubMed over a 5-year period. Note that 66% of the mouse citations are for BALB/c and two sublines of C57BL and that the three most popular rat strains accounted for 69% of citations. These strains are probably being used largely because being inbred they represent standard, repeatable, experimental material and not for any particular characteristics that they may possess. Strain C57BL/6 is frequently used as a genetic background for genetic modifications.

The use of inbred strains is highly variable between disciplines. Virtually all critical experiments in immunology which use rodents now involve inbred strains. In contrast, those disciplines with a chemical orientation such as pharmacology and toxicology have not yet fully realised the potential value of such animals.

#### Nomenclature of inbred strains

Inbred strains are designated by a capital letter or letters or, less preferably, by a combination of letters and numbers, starting with a letter (eg, CBA, C57BL). Exceptions to this rule include strains, such as 129, which were already well established at the time the rules were formulated. Where it is necessary to indicate the level of inbreeding, this is given by an 'F' and the number of generations of brother × sister

mating, eg, F100 indicates 100 generations of brother × sister mating. Care should be taken to ensure that the same strain designation is not used for both rat and mouse strains. Details of nomenclature are given at the Mouse Genome Informatics website.

Substrains are formed when a strain is split into two or more branches, and genetic differences between the branches are discovered or thought to be probable. Two branches of the same strain which have been separated between generations F20 and F40, or which have been separated after F40, but have been maintained separately for more than 20 generations should also be regarded as separate substrains, as in these circumstances it is highly probable that they will be genetically different at some loci. Substrains are indicated by a slash, followed by letters, which are laboratory codes, and/or numbers (eg, C57BL/6 and C57BL/10 are substrains 6 and 10 of strain C57BL which are known to differ at some loci). Substrain symbols may be accumulated (eg, C57BL/6J is a substrain of C57BL/6 developed at the Jackson Laboratory).

F1 hybrids between two inbred strains are indicated usually using abbreviated upper case strain names appending 'F1', for example B6D2F1, the F1 hybrid between strains C57BL/6 and DBA/2.

**Table 4.4** Inbred strains of mice and frequency of citations in the PubMed bibliographic database, 2001–2005.

### Characteristics of inbred strains

An inbred strain is like an immortal clone of genetically identical individuals. Such strains have many useful characteristics, outlined below, but care should be taken in generalising results obtained with a single strain to the species as a whole. A more general result can usually be obtained by using more than one strain. This can usually be done without increasing the total number of animals using a 'factorial' experimental design (see Chapter 3). F1 hybrids, the first-generation cross between two inbred strains, have most of the useful features of inbred strains except that they are not homozygous so when mated the offspring will be genetically segregating for all those loci at which the parental strains differed. They are not, therefore, immortal. However, they tend to be much more vigorous than inbred strains so are more suitable for some research projects. The main disadvantage of inbred strains is that they do not usually breed as well as outbred stocks or F1 hybrids. Where this is critical, as in the development of genetically modified animals, research workers are often forced to use a genetically heterogeneous stock. However, once developed it is usually better to backcross the transgene to an inbred strain (see later in this chapter) in order to stabilise the strain/mutant characteristics.

Inbred strains have made a substantial contribution to biomedical research. More than 20 Nobel prizes have been awarded for work which would have been either impossible

**Table 4.5** Inbred strains of rats in order of the number of citations in PubMed 2001–2005 (data from [www.isogenic.info](http://www.isogenic.info)).

or much more difficult were such strains not available (Festing & Fisher 2000).

The main properties of inbred strains can be considered under the following headings.

#### *Isogenicity*

The individuals of an inbred strain are isogenic (all animals are identical at more than 99% of the genetic loci which were segregating in the original foundation colony). One consequence is that a single individual can be genotyped, and this will serve to genotype all animals of that strain. In fact the DNA of 16 inbred strains of mice has now been fully sequenced<sup>6</sup>. Two individuals of a strain will be histocompatible (ie, they will not reject skin grafts or other tissue from another member of the same inbred strain). F1 hybrids, the first-generation cross between two inbred strains, are also isogenic and will accept skin and tissue grafts from each other and from both parental strains without immunological rejection.

#### *Homozygosity*

Each inbred animal is homozygous at more than 99% of the loci which were segregating in the original population. They do not carry any hidden recessive genes (except for recent mutations) and will breed true. This is what makes the strains immortal as new generations of identical animals can be produced at will. When mutations do occur they will segregate briefly in the strain until they are fixed (with  $\frac{1}{4}$  probability) or eliminated (with  $\frac{3}{4}$  probability) by further inbreeding.

#### *Long-term stability*

An inbred strain will stay genetically constant for long periods of time. It cannot change as a result of selection, inbreeding, or random drift of polymorphic gene loci (the

<sup>6</sup><http://www.niehs.nih.gov/news/releases/2006/snp2.cfm>

factors which cause change in outbred stocks). The only change that can occur is as a result of new, sometimes unnoticed, mutations becoming fixed. 'Quiet' mutations of this sort can sometimes remain undetected in a colony for many years (Stevens *et al.* 2007). Genetic drift occurs much more slowly than in an outbred stock because virtually all loci are homozygous so genetic drift can only occur as a result of new mutations, while in an outbred stock drift is a result of changes in gene frequency at many loci as well as being due to mutation at a few loci. It can also be prevented by maintaining banks of frozen embryos of inbred strains, which can be resuscitated periodically to replace colonies which may have fixed new undetected mutations. Investigators maintaining their own breeding colonies are advised to go back to the original source periodically (say every 20 generations) so as to minimise subline drift between the two colonies.

#### *Phenotypic uniformity*

The elimination of genetic variation generally leads to greater uniformity of most characteristics within an inbred strain. This is most obvious with a single polymorphic locus such as the major histocompatibility complex. However, it is also true for many polygenic characters, particularly those with a high heritability. Increased uniformity means that fewer inbred animals are needed relative to outbred animals to achieve a given level of statistical precision (Festing *et al.* 2002).

#### *Individuality*

Each inbred strain is a unique combination of alleles at approximately 25000 loci, and therefore differs from every other strain. These differences can be of great interest in themselves. A study of why one strain develops a particular type of tumour, or a particular pattern of behaviour, while another strain does not, may throw considerable light on the development of tumours or behaviour patterns respectively.

Some examples of strain characteristics which are of biomedical interest in inbred strains are given in Table 4.6. Most mouse genes have human homologues so identification of the mouse genes associated with human disease can be an efficient and economical way of identifying human genetic disease susceptibility.

#### *Identifiability*

Once an inbred strain has been developed, and some of the polymorphic loci such as microsatellites and SNPs have been characterised to provide a 'genetic profile', the strain may then be identified by this genetic profile. Scientists using inbred strains would be advised to keep a sample of tissue or DNA so that if they obtain unexpected results the authenticity and integrity of the strains can be determined. There are commercial companies which will carry out the appropriate tests, given a sample of DNA or tissue.

#### *Sensitivity*

There is some evidence that inbred strains are more sensitive to environmental influences than are outbred stocks. This is an advantage to the extent that they may be more sensitive to an experimental treatment, but is a disadvantage in other respects. For example, a breeding colony may stop breeding

**Table 4.6** Examples of inbred mouse strains with characteristics of interest in biomedical research. Note that these conditions do not necessarily preclude the use of the strains in general research.

Strain	Characters of interest
129P1	One of several major substrains of the original strain 129. Pink-eyed chinchilla coat colour. Develops testicular teratomas. Used in the development of ES cells which are used in the production of targeted mutations ('knockouts')
A/J	Susceptible to the development of lung adenomas. High incidence of congenital cleft palate
AKR	High incidence of lymphatic leukaemia and short lifespan
BALB/c	Possibly the most widely used strain. Develops myelomas when treated with a carcinogen. Used in the development of monoclonal antibodies. Useful general purpose albino strain, but males may fight
C3H/HeJ	Unfostered strains (now rare) develop a high incidence of mammary tumours. General purpose strain. High incidence of hepatomas. Substrain resistant to bacterial lipopolysaccharide due to spontaneous mutation previously designated <i>Lps<sup>d</sup></i> , now <i>Tlr4<sup>lps-d</sup></i>
CBA/Ca	General purpose strain with a high incidence of hepatomas
C57BL/6	Most widely used strain. Used as genetic background for many mutants and congenic strains. High preference for alcohol. Some microphthalmia and fur chewing on back
DBA/1	Susceptible to collagen-induced arthritis
DBA/2	Oldest strain. Susceptible to induction of audiogenic seizures
DDK	Semi-sterile when mated with C57BL males due to a defect of the F1 embryos
FVB	Relatively new strain. Breeds well. Large male pronucleus helpful in producing transgenic strains by microinjection
HRS	Carries hairless gene. Homozygotes for hr develop high incidence of leukaemia
I	Sex-linked phosphorylase kinase deficiency leading to 3–4-fold elevation of muscle glycogen
NOD	Developes insulin-dependent diabetes mellitus and associated pathology
NON	Obesity without diabetes
NZB	Develops autoimmune haemolytic anaemia
SJL	Develops reticulum-cell sarcoma (Hodgkin's disease). Males very aggressive
SWR	Polydipsia and polyurea on aging

as a result of some unknown environmental factor which may hardly influence an outbred stock. Their production and use requires more attention to details of husbandry and diet than is the case for outbred stocks. However, the actual breeding plan is much simpler. Very small populations can

be maintained, as an inbred strain will no longer be subject to further inbreeding depression, whereas the maintenance of outbred stocks requires large sample sizes and careful attention to methods of avoiding directional selection and genetic drift due to inbreeding.

#### *International distribution*

Inbred strains have an international distribution, so that work in the UK, USA, Germany and Australia, for example, can be carried out using virtually identical inbred mice or rats. This is possible due to the long-term stability of inbred strains, the fact that daughter colonies are genetically identical with the original colony and because genetic quality control is so much easier with inbred strains than with outbred stocks. Sublines separated for long periods will differ to some extent as a result of new mutations. This may affect the expression of mutations and transgenes. For example, the expression of the obese (*Lep<sup>ob</sup>*) and diabetic (*Lep<sup>db</sup>*) mutations in mice differs between the sublines C57BL/6J and C57BL/6KsJ (Hummel *et al.* 1972). Such effects need to be taken into account in designing and interpreting such studies. Colonies may also differ as a result of environmental differences. There have been several examples of strain characteristics being seriously altered as a result of an infection, such as Tyzzer's disease or ectoparasites.

#### *Background data*

Inbred strains stay genetically constant for long periods so it is possible to build up reliable data on their phenotypic and genetic characteristics. The names of many of the most commonly used strains are included as key words in electronic bibliographical data bases, so it is possible to retrieve all papers in which a particular inbred strain was used provided authors have used correct nomenclature. The Mouse Phenome database<sup>7</sup> provides a substantial body of information on the comparative phenotypic characteristics of many strains. This gives tables and graphical displays of comparative strain characteristics for a wide range of phenotypes including appearance, behaviour, blood characteristics, reproductive performance, response to pathogens and many more characteristics. The Rat Phenome database<sup>8</sup>, although less detailed, also provides a considerable amount of information about inbred strains and mutants of the rat.

#### **Maintenance of inbred strains**

Ideally, an inbred strain would remain genetically constant for an indefinite period. It should also be maintained as economically and efficiently as possible. Usually it is best to maintain a 'foundation stock' or 'stem-line' colony and a separate production colony as outlined in the next sections. Once a strain has been brother × sister mated for 20 or more generations, the main sources of change are from genetic contamination or as a result of the occurrence and fixation of new mutations, though some drift may occur due to 'residual heterozygosity', the small amount of heterozygosity remaining after 20 generations of inbreeding.

<sup>7</sup><http://www.informatics.jax.org>

<sup>8</sup><http://rgd.mcw.edu/>

The chance of genetic contamination can be minimised by keeping each strain physically separated as far as is practicable. If several strains must be kept in one room they should, ideally, have different coat colours. The cages should have clear colour labels, and the staff should be rigorously trained so as to be on their guard against genetic contamination. Staff should be assured that if a contamination occurs they will not get blamed otherwise they will tend to cover up any unusual behaviour in the colony. With mice and rats a monogamous breeding system with each pair staying together for the whole of their breeding life should be adopted, as this will minimise the chance of a mismating.

The best way of preventing genetic change due to new mutations would be to maintain a bank of frozen embryos of each strain, and thaw out samples to renew the colony at infrequent intervals (Hedrich & Reetz 1988).

#### **Stem-line or foundation stock colony**

This should be a small self-perpetuating colony of up to about 30 permanently mated monogamous pairs. Detailed pedigree and production records should be kept and care should be taken to ensure that no genetic contamination occurs. Ideally, this colony will be kept physically separate from all other colonies. Genetic quality control methods (see later in this chapter) should be used periodically to check genetic authenticity. Offspring from this colony will be used first to perpetuate the stem-line colony, and second as breeding stock for the production colony. All animals should trace back to a common ancestor about six to ten generations back. Sublines which breed poorly should be culled to try to eliminate quiet mutations which reduce breeding performance.

#### **Production colony**

Where large numbers of animals are to be bred (eg, by a commercial supplier) colonies of 100–1000 or more cages, possibly with several subdivisions such as an expansion colony (which may be pedigreed) and one or more generations of production stock, may be required. The production colony does not contribute to the long-term survival of the strain so animals may be mated as pairs or trios, or using some other system. Animals may be mated at random, rather than brother × sister, and detailed records of pedigrees need not be kept although they may be useful if problems arise. All animals in the production colony should trace back to stem-line ancestors within about four to six generations. In other words, up to about six generations may be used to multiply up the stem-line stock in the production colonies. Only in exceptional circumstances (eg, if the colony would otherwise be lost) should the random-mated production stock be used to perpetuate the inbred strain.

#### **Research uses of inbred strains**

Inbred strains may be used in many ways in research. The simplest case is when an inbred strain is chosen in preference to an outbred stock on the grounds that it is more uniform, genetically more stable, and better defined than the

outbred stock even though either type could be used. There is a strong case for using, say, C57BL/6 or BALB/c mice and F344 rats as the universal standard in experiments where there is no *a priori* reason for choosing a particular strain. Such standard strains are widely used as a genetic background for mutants and transgenes, discussed later in this chapter.

An inbred strain may also be chosen because the experiment would otherwise be impossible. For example, a study may require the transfer of cells, tissues, or tumours from one animal to another without immunological rejection. This is only possible if the host is isogenic with the donor unless animals with a defective immune system are used. A considerable number of experiments in immunology and cancer research fall into this class.

An inbred strain may be chosen for a particular project because it develops a spontaneous disease or condition which is of intrinsic interest or may be considered to be a model of human disease. Many strains develop specific types of neoplasia either spontaneously or after the application of a carcinogen. These are often of value in research. For example, the myelomas which may be induced in BALB/c mice by mineral oil, were vital in developing monoclonal antibodies.

In some cases the research worker wishes to do experiments on a wide range of phenotypes within the species so as to be reasonably confident that the results are general and do not depend on some quirk of an individual strain. It is a fallacy to assume that testing on an outbred stock will achieve this objective. If the outbred stock is truly variable, then this will result on a considerable amount of background 'noise' which may obscure treatment effects. The use of several inbred strains using a 'multi-strain' experimental design without using excessive numbers of animals should, however, provide a wide range of phenotypes on which to test the treatment without any associated problems of experimental noise (Russell & Burch 1959; Heston 1968; Festing, 1995). Very often it is the unusual strain which is of greatest interest.

Several strains may also be used to explore the relationships between different characters. For example, if some response to a treatment is quantified in several strains, grouping the strains by their *H2* haplotype (using data taken from published literature) may show whether the response is *H2* related. Quantitative relationships between variables may also be explored in this way, to show, for example, the relationship between certain types of biochemical activity in the brain, and some types of behaviour (Gaitonde & Festing 1976). It is, of course, essential to use more than two strains in such experiments. Indeed, the use of several inbred strains in this way offers one of the most powerful methods of analysing the response to a treatment effect. The ultimate tool for research workers interested in this approach is a full set of recombinant inbred strains, discussed later in this chapter.

### Derived inbred strains

Large numbers of new inbred strains have been developed from existing strains. The most common are the congenic

strains where a mutation or genetic modification has been backcrossed to an inbred strain. However, there are many other types, discussed in the following paragraphs.

### Coisogenic and segregating inbred strains

If a mutation (eg, for coat colour or other visible effect) occurs in an inbred strain, and is then bred separately, then it will differ from the inbred strain only at a single genetic locus, namely, the mutant locus. Two inbred strains which are genetically identical except at a single locus as a result of a mutation within the strain and subsequent separation of sublines are said to be *coisogenic*. A transgenic strain developed by micro-injection of DNA into a fertilised egg of an inbred strain will also be coisogenic with the parent strain. Targeted mutations developed within an inbred strain are also coisogenic with the background strain. Segregating inbred strains are developed by inbreeding with forced heterozygosity at a specific locus.

#### *Nomenclature of coisogenic strains*

Coisogenic and segregating inbred strains should be designated by the name of the inbred strain followed by a hyphen and the gene symbol so, C3H/N-*Kit*<sup>W-v</sup> is the N substrain of strain C3H carrying a mutation of the *Kit* oncogene with the allele designation *W-v* (viable dominant spotting, previously designated *W<sup>v</sup>*) as a result of a mutation within the strain. 129-*Alox5*<sup>tm1Fun</sup> is a targeted mutation (the tm1 superscript shows it is the first one developed by 'Fun', a laboratory code) of the arachidonate 5-lipoxygenase locus coisogenic with strain 129. When a mutation is maintained in a heterozygous state, this may be indicated by including a + sign in the symbol (eg, C3H/N-*Kit*<sup>W-v/+</sup>).

In the case of segregating inbred strains developed by inbreeding with forced heterozygosity, indication of the mutant locus is optional (eg, DW-+/*Pou1f1*<sup>dw</sup> an inbred strain DW carrying a dwarf mutation at the *Pou1f1* locus developed by inbreeding with forced segregation, could be designated simply as DW).

#### *Maintenance of coisogenic and segregating inbred strains*

Coisogenic strains are inbred strains and should be maintained in the same way as any other inbred strain. However, segregating inbred strains need to be maintained with continued segregation at the locus of interest. This usually involves mating animals with the mutant phenotype with those with a wild-type phenotype.

### Congenic strains

These strains are an approximation of coisogenicity produced by backcrossing an allele from another strain or outbred stock into a specific inbred strain for 10 or more generations. The result is a pair of strains (the inbred partner and the congenic strain) which should be genetically identical at virtually all loci not linked to the differential locus. On average, the differential locus is accompanied by about 20 centiMorgans of associated chromosome which will contain some contaminating genes. In most cases these are of little importance, and can be ignored, though the possibility that they may interfere with research results should not be for-

gotten. The nomenclature also recognises partially congenic strains following five generations of backcrossing.

Congenic strains are developed when an investigator wants to determine the characteristics of a mutation or QTL on a different genetic background or to maintain it on a standard inbred background such as C57BL/6. For example, many targeted mutations (see later in this chapter) have been developed on one of the 129-background strains, but for comparative purposes it is convenient to have them on a C57BL/6 background, hence they are backcrossed to that strain.

Backcrossing for 10 generations takes a considerable time. It can be speeded up using marker-assisted or 'speed' backcrossing by simultaneously selecting for genetic markers on other chromosomes which differ between the donor and background strains, but resemble the background strain (Markel *et al.* 1997). This should approximately halve the time required.

Congenic strains were first developed systematically by Dr. George Snell at the Jackson Laboratory (for which he received the Nobel Prize in 1980) as a means of separating out the loci responsible for rejection of transplanted tumours. The strains which he developed were called 'congenic resistant' strains because they resisted a strain-specific transplantable tumour which would grow in the background strain. The resulting strains were mostly found to differ at the major histocompatibility locus.

#### *Nomenclature of congenic strains*

Congenic strains are designated by a full or abbreviated name of the background strain, followed by a period (full-stop) and the abbreviated name of the donor strain, followed by a hyphen and a gene symbol (eg, B10.129-*H12<sup>b</sup>*). Thus B10 (abbreviation for C57BL/10) is the background strain, 129 is the donor strain and *H12<sup>b</sup>* is the allele of interest. When several strains are developed from the same donor strain they may be distinguished by a number and/or letter in parentheses (eg, B10.129(12M)-*H12<sup>b</sup>*). Partially congenic strains have the same nomenclature except they have a semi-colon between the two strain designations, eg, B6;129S-*Inhba*<sup>tm1Zuk</sup>, a partially congenic strain developed by backcrossing the first targeted mutation at the inhibin-beta-A locus developed by 'Zuk' (a laboratory code).

In other cases the full designation given above is not appropriate because the donor strain is not inbred, or because the congenic strain is already widely known. In such cases, a less complete symbol may be used (eg, A.SW, B10.D2/n, the n in this case stands for 'new', C3H.SW+).

#### *Maintenance*

Congenic strains are inbred strains in their own right, and are maintained as such.

#### *Research uses*

The value of congenic, coisogenic and segregating inbred strains is that the differential locus and its effects may be studied on a chosen inbred genetic background, free of the noise associated with genetically determined variation in expression and penetrance found in a heterogeneous stock. For this reason many mutant genes such as obese (*Lep<sup>ob</sup>*), dwarf (*Pou1f1<sup>dw</sup>*), nude (*Foxn1<sup>nu</sup>*) and yellow (*A<sup>y</sup>*) have

been placed on an inbred genetic background (usually C57BL/6).

Many congenic strains have also been developed which differ at the major histocompatibility complex (the *H2* complex in mice). A parasitologist or microbiologist may be interested in discovering whether the response to a parasite or bacterium depends on the *H2* genotype. All that is necessary in the first instance is to obtain, say, C57BL/10 (mice which are *H2<sup>b</sup>*) and some strains congenic with this, but differing at the *H2* locus such as B10.D2 (which is *H2<sup>d</sup>*), and B10.BR (which is *H2<sup>k</sup>*). The course of the infection would then be studied in the strains, and if they were found to differ, this would suggest that *H2* has some influence. Such a study does not depend on the research worker developing the highly specialised skills of tissue typing individual animals. The research worker would, however, be well advised to confirm his/her results using other pairs of congenic strains in order to rule out the possibility that the observed difference has some other cause (such as genetic contamination or mutation of one of the congenic lines).

#### **Recombinant inbred (RI) strains**

A set of recombinant inbred strains is developed by crossing two standard inbred strains followed by brother × sister inbreeding for 20 generations as a set of parallel strains (Bailey 1971). Ideally, at least 10–20 new inbred strains should be produced, though the more strains that are produced, the more useful the set will be. Each RI strain is an inbred strain in its own right, but its genotype will be composed of a recombination of the parental strain genes – hence the name recombinant inbred strain.

More recently a large collaborative study is developing a panel of 1000 RI strains from a cross involving eight diverse inbred mouse strains. Genetic analysis will involve comparisons of strains and crosses between them (Churchill *et al.* 2004).

#### *Nomenclature*

A set of recombinant inbred strains is designated by an abbreviation of the parental strain names separated by an X, with no intervening spaces. Thus CXB would be the designation of a set produced by crossing BALB/c (abbreviated C) with C57BL (abbreviated B). Different strains of the same series should be designated by a number or letter. Optionally, these may be separated by a hyphen thus: AXB5 or AXB-5. An exception is made in the case of strains already known by another designation. Thus Bailey's original seven strains are designated CXBD–CXBK (with CXBF missing).

#### *Maintenance*

Each recombinant inbred strain is an inbred strain in its own right, and should be maintained in exactly the same way as any other inbred strain.

#### *Research uses*

Recombinant inbred strains may be used for investigating the mode of inheritance of any character in which the parental strains differ. They are particularly valuable for studying characters requiring the destruction of the animal before it reaches breeding age, or discrete characters such as tumour

incidence in which a good estimate of the phenotype of a strain can only be obtained by averaging across several individuals. They can also be useful in the analysis of polygenic characters and the identification of QTLs (Plomin *et al.* 1991). These strains have great potential for the study of genetic variation in response to toxic or pharmacologically active chemicals such as those which cause lung tumours in mice (Malkinson *et al.* 1985).

The characteristics of the parental strains to the treatment should be examined first. If these differ, then the response of the full set of recombinant inbred strains should be characterised, and the 'strain distribution pattern' (SDP) should be studied. If the recombinant inbred strains fall into two distinct groups with about half of them resembling one parent and the other half the other parent, then this is presumptive evidence that the response is governed by a single Mendelian locus. If some genetic marker agrees closely with the separation into two groups, then that is evidence for linkage between a gene near the marker and the phenotype. The development of microsatellite and other markers has made it possible to characterise some sets of RI strains at several hundred loci on all chromosomes. This makes it virtually certain that an approximate chromosomal location of a well behaved Mendelian gene could be identified just from the strain distribution pattern, provided a reasonably large set of RI strains was available.

However, if the strains grade continuously between the two parental strains, then this would be evidence that the response is controlled by more than one locus and/or environmental factors. When the thousand or so strains from the collaborative cross being developed by the Complex Trait Consortium<sup>9</sup> are available, they will be particularly useful for identifying and mapping QTLs.

### Recombinant congenic strains

These strains have been developed largely for the study of complex traits. Two inbred strains are crossed and the offspring are backcrossed to one of the parental strains (the 'background' strain) usually for two (or sometimes more) generations before further generations of brother × sister mating to produce a set of 'recombinant congenic' or RC strains. They are regarded as fully inbred when the coefficient of inbreeding is the same as that used for inbred strains. With two backcrosses a further 14 generations of brother × sister mating are necessary. In use, the strains are individually phenotyped for a character of interest. Most of the RC strains will resemble the parental strain but some strains may carry a part of a chromosome from the donor strain carrying an allele which influences the trait of interest. Crosses between this strain and the parental strain can then be used to isolate and identify the gene responsible for the difference.

The set of strains is designated by BACKGROUND-STRAINcDONOR STRAIN-n, where n is a strain number. For example strain NONcNZO-1 is the first strain of a set of RC strains with strain NON being the background strain and NZO the donor strain.

### Chromosome substitution (CSS) or 'consomic' strains

These strains are produced by substituting a chromosome from one strain into a background strain by backcrossing with selection for the whole donor chromosome. This provides a very powerful tool for finding out what QTLs there are on a given chromosome which are associated with strain differences between the two strains because segregation on all other chromosomes has been eliminated. In a study of 53 traits in the full set of 22 A/J into C57BL/6J mouse strains a total of 150 QTLs affecting levels of serum components, diet-induced obesity and anxiety were identified (Singer *et al.* 2004). Once a QTL has been identified on a whole chromosome it can be mapped by intercrossing the substituted strain with the background strain and looking for any association between the phenotype and a set of markers on that chromosome. Backcrossing can also be used to develop congenic strains for the QTL. Thus, once a set of CSS has been developed, it provides a powerful tool for complex trait analysis.

#### Nomenclature of CSS

The designation of these strains is HOST STRAIN-Chr #<sup>DONOR STRAIN</sup> where # is the chromosome number. So a consomic strain with a C57BL/6 genetic background with chromosome 1 from strain A/J is designated C57BL/6-Chr1<sup>A/J</sup>.

### Genetic quality control

Genetic contamination of inbred strains is not uncommon (Festing 1982), and can cause substantial disruption to the research programmes. Animals should only be obtained from a reliable source and, if they are to be bred on site, their authenticity should be checked as soon as possible. Breeding colonies of inbred strains should be kept physically separated as far as possible. If several strains must be kept in the same room, then they need clear labelling. Staff need to be well trained and alert to any changes in the colony. Changes in coat colour and/or breeding performance should certainly be investigated, but monitoring these is not sufficient to ensure authenticity.

In the past, use has been made of biochemical and immunological markers and bone morphology but modern methods depend on examination of microsatellite and SNP DNA markers.

### Breeding performance

Inbred strains usually have a relatively poor breeding performance. F1 hybrids, in contrast, breed well due to hybrid vigour. Breeding performance is normally monitored routinely in order to detect any environmental influences which adversely affect output. However any breeding pair or group of related animals which breed exceptionally well should be regarded with some suspicion. It might be advisable either not to breed from such animals or to get them genetically typed using microsatellite or SNP markers.

<sup>9</sup><http://www.complextait.org>

### Microsatellite and single nucleotide polymorphic markers

Microsatellites are short repetitive DNA sequences such as the dinucleotide sequence CA, commonly 50–200 bases in length, with unique sequence flanking DNA. There are several thousand microsatellites in vertebrate DNA and they are often highly polymorphic in the number of repeats. The microsatellite profile of a test animal is compared with the published microsatellite profile of the particular strain.

More recently, genome scanning using SNP markers has become both cheap and powerful. There are literally millions of SNPs in the mouse genome, where individuals or inbred strains differ. Individuals to be tested can be typed and compared with the known SNP profile of authentic strains. Where they differ, this can be quantified. This technique can also be used to examine the success of backcrossing in the development of congenic strains by getting both the congenic strain and the inbred partner scanned and compared. These techniques require expensive apparatus, but are commercially available. Samples of tissue or DNA can be sent by mail so there is no need to send live animals. Results might be available in 2–4 weeks.

### Ovary transplants and embryo manipulation

A number of techniques which have been developed for studies of various aspects of reproductive biology and embryology have now assumed some importance in applied genetics.

#### Ovarian transplants

A technique for transplanting the ovaries between histocompatible hosts was developed some years ago, and has been used routinely to assist in the maintenance of some mutants which are difficult to breed, usually because the female dies young or is infertile.

Ovaries may be taken from donor females as young as 16 days of age. The ovaries may then be cut in half, with half being transplanted into each recipient. Thus a single mutant female provides sufficient material for four recipients.

The recipients must be histocompatible with the donor. Usually the donor is inbred and the recipient is an F1 hybrid (to obtain maximum breeding performance) in which the donor strain is one of the parents. For example, C57BL/6-*Lep<sup>ob</sup>/Lep<sup>ob</sup>* (obese) female mice are infertile, but their ovaries could be transplanted to B6D2F1 hybrid females without immunological rejection.

Once a phenotypically normal female has been given homozygous mutant (*m/m*) type ovaries, it can be mated with a normal *+/+* male of the same strain to produce known heterozygotes, or with *m/+* or *m/m* males to produce 50% or 100% homozygous mutant offspring, respectively.

#### Embryo transfers

The technique of embryo transfer may be used to study the effect of the material genotype on offspring characteristics,

as an alternative to hysterectomy as a method of eliminating disease-causing organisms from a strain, provided suitable disease-free foster mothers are available, or to implant thawed frozen embryos.

Donor mice are (optionally) superovulated using an appropriate hormone regimen (eg, an injection of 2–10 IU of pregnant mare's serum gonadotrophin, PMSG, followed 44–48 h later with 2–10 IU of human chorionic gonadotrophin, hCG) and mated overnight. Vaginal plugs indicate successful mating. After about 3 days (depending exactly on the aims of the study), the mice are killed and the embryos flushed out of the oviduct and uterus. These embryos may be transferred directly to the oviduct or uterus of a pseudopregnant foster mother (ie, one that has been mated with a sterile male, usually 1 day after the donor females were mated), or they can be cultured *in vitro* for 24 h. The foster mother, which need not be histocompatible with the strain of the embryos, is anaesthetised and the embryos are transferred directly to the uterus via a dorsal abdominal incision. If sterile techniques are used, and the foster mother is pathogen-free, then this provides a method of eliminating pathogens from genetically valuable strains and stocks. Practical details are given by Papaioannou and Johnson (1993).

#### Freeze preservation of mouse embryos and sperm

Mouse embryos obtained as described above may also be frozen and maintained virtually indefinitely in liquid nitrogen before being thawed and placed in a foster mother. Various techniques and cryoprotectives are used. One of the most common methods is to use eight-cell embryos, which are flushed from the mother on day 3 of gestation. They are placed in vials or straws in a medium containing dimethyl-sulphoxide (DMSO) as a cryoprotective agent, and are frozen under carefully controlled conditions, using a slow cooling rate. Eventually, the vials are placed in liquid nitrogen. When the embryos are wanted, they are thawed in a controlled manner, and are usually cultured for 24h before being transferred to a foster mother. This makes a viability check possible, as the embryos should undergo some degree of development during this period. They are then transferred to pseudopregnant foster mothers as described above.

The main advantages of maintaining banks of frozen embryos are:

1. freeze preservation of embryos from inbred strains should prevent genetic drift due to new mutations;
2. it provides an economical method of maintaining strains and mutants which are not currently being used;
3. it provides an insurance against loss of valuable stocks and allows such stocks to be maintained in smaller, more economical numbers;
4. in some cases, frozen embryos may be transported more conveniently than live animals.

The freeze preservation of mouse sperm is relatively easy, compared with embryos (Nakagata 2000) and is now used in ENU mutagenesis programs (see below). Sperm may even be repeatedly frozen and thawed, and still be capable of producing viable offspring (Aoto *et al.* 2007, Ostermeier *et al.* 2008).

## Genetically modified (transgenic and mutant) strains

Genetically modified strains of mice, and to a lesser extent other species, are now widely used in research. Initially, transgenic strains were developed by direct injection of DNA into early embryos. However, mutagenesis using ethyl-nitroso-urea (ENU), techniques for 'gene trapping', gene targeting using homologous recombination to produce 'knockout' and 'knockin' mice, the use of transposon-mediated mutagenesis and the use of RNAi (see later in this chapter) have transformed many areas of research. These techniques are described briefly in the following paragraphs.

### Direct injection of DNA

Transgenic strains were first developed in the 1980s by direct injection of foreign DNA into the pro-nucleus of an early embryo in such a way that it became incorporated permanently into the host DNA. The transgene is incorporated at random (or at least in an unpredictable location) and very often consists of a tandem array of many genes end-to-end. Occasionally, if it gets incorporated into an existing gene it may cause an insertional mutation. The transgene needs a promoter and enhancer region as well as the coding region to allow it to be expressed. A dramatic demonstration of the method involved the transgenic insertion of the human growth hormone gene with a metallothionein promoter region into mice. When these mice were subsequently treated with zinc sulphate, which induced a high level of growth hormone, the mice grew extremely large (Palmiter *et al.* 1982). Unfortunately, the mice also developed a range of defects and had a short lifespan. Mouse strain inbred FVB is now widely used in the production of this type of transgenic strain because it breeds well and has a large male pro-nucleus into which it is relatively easy to inject the transgene (Takeito *et al.* 1991).

Hundreds of transgenic strains have now been produced using these techniques, and are listed in various electronic databases. Most have been developed to answer highly specific research questions, but a few have been produced for more general research purposes. For example, the 'immortomouse' was developed as an aid to the establishment of cell lines from different mouse tissues. It was developed by injecting a DNA construct containing a thermolabile version of the simian virus 40 (SV40) large T antigen fused with an H2 (major histocompatibility complex) promoter region. *In vivo*, this transgene has little or no effect. However, when cells from these mice are grown *in vitro* at 33°C (but not at 37°C) in the presence of interferon (which induces SV40 T activity), they become immortal, due to the action of the SV40 T gene. Using this technique, it has been possible reliably to develop immortal cell lines from a range of tissues which have proved difficult to culture in the past (Jat *et al.* 1991).

'BigBlue' mice and rats and the 'Mutamouse' have also been developed as a means of assessing whether chemicals are mutagenic, and therefore potentially carcinogenic, *in vivo* (Gehlmann 1993). The animals carry a transgene in the

form of a 'shuttle vector' with a reporter gene *lac Z* (and its suppressor locus *lac I* in the case of BigBlue), which codes for bacterial beta-galactosidase. The reporter gene causes no ill effects in the animals. Animals are treated with the test chemical. If it is mutagenic, it will mutate some of the transgenes. The shuttle vector is then extracted from a target tissue such as the liver and the number of mutations is assessed and compared with a control.

Transgenic strains have also been developed with reporter genes such as the green fluorescent protein (GFP) and beta-galactosidase controlled by specific promoters as an aid to understanding in which tissues or at which times a gene becomes active. For example damage to the adult neural cortex leads to loss of motor function. In a mouse model grafts of embryonic mouse cortical cells expressing GFP were grafted into the damaged area and it was observed that host and transplanted neurones formed synaptic contacts with the re-establishment of cortical circuitry suggesting that there is potential to use neural transplants in the reconstruction of brain injury (Gaillard *et al.* 2007).

### Nomenclature of transgenic strains

Transgenic strains are designated by the background strain or background status followed by a hyphen then Tg(YYY)#Zzz, where YYY is the inserted gene, # is the serial number of the insert and Zzz is the laboratory code. For example STOCK Tg(GFPU)5Nagy is an outbred stock with a transgenic green fluorescent protein incorporated by microinjection into an early embryo. It is the fifth line that was developed by Nagy, a laboratory code. If the transgene should become inserted into a gene, then it will become an allele of that gene with the Tg(YYY)#Zzz being shown as a superscript of the gene designation. More details are given on the Jackson Laboratory website<sup>10</sup>.

### Chemical mutagenesis

One of the best ways of studying the function of a gene is to mutate it and see what happens. Chemical mutagenesis is now done almost exclusively using ENU because it gives a good yield of mutants and usually causes point mutations rather than deletions (Barbaric *et al.* 2007). Point mutations may not inactivate a gene, but may alter its function depending on exactly where in a given gene the mutation occurs. This is an advantage as a complete inactivation may be lethal and therefore more difficult to study. Chemical mutagenesis is a random process, so it is not normally possible to mutate a specified gene. Male mice are injected with ENU and after about 6 weeks, to allow the mutated sperm to develop and the males to become fertile again, are mated with normal females. The offspring are screened for abnormalities which might be caused by a dominant mutation. Techniques of screening have developed enormously in the last few years, with the EUMORPHIA Consortium developing many standardised methods<sup>11</sup> with clear standard oper-

<sup>10</sup><http://www.informatics.jax.org>

<sup>11</sup><http://empress.har.mrc.ac.uk>

ating procedures (Brown *et al.* 2005). Recessive mutations are detected with a further round of brother × sister breeding followed by further phenotypic testing. These screens involve the breeding of many mice, so care needs to be taken in optimising methods (Cordes 2005; Barbaric & Dear 2007).

With the automation of DNA sequencing techniques it is now also possible to screen samples of DNA from the offspring of mutagenised males for mutations in genes of specific interest (Michaud *et al.* 2005). Where phenotype can only be determined after killing the animal, such as those involving histology of internal organs, samples of sperm can be frozen before killing male mice. If a mutation is found, then it can be recovered from the frozen sperm.

Once an abnormal animal is detected further breeding is necessary to confirm that it is an inherited mutation and to map and identify the genetic locus. This can be time consuming as large numbers of mice may need to be bred and phenotypically typed.

### Embryonic stem cells

Embryonic stem (ES) cells are cell lines derived from early embryos, which are said to be totipotent, being able to form any cell type in the body. ES cells are derived by culturing pre-implantation embryos in suitable culture medium which allows them to multiply but not to differentiate (Evans & Kaufman 1981). The cells can be manipulated and mutated *in vitro* using gene trapping or gene targeting (see later paragraph) and can then be injected into the blastocyst of an embryo where they are incorporated, so that the resulting mouse is a chimera. If cells from the ES cell line colonise the gonads of the chimeric mice then offspring of the ES cell genotype will be produced. Usually strains of different coat colour are used in making the chimeras so that mutant offspring can be easily recognised. The majority of ES cells used so far come from the 129 inbred mouse strain, substrains of which differ in many ways including coat colour (Simpson *et al.* 1997). When making targeted mutants (see below) it is important that the DNA in the targeting vector is from the same substrain as the ES cells. It has proved to be difficult to produce ES cells from other strains and it has so far been impossible to produce ES cell in the rat. More recently suitable media have been developed which allow the development of ES cells from other mouse strains such as C57BL/6, although some substrains seem to be more amenable than others. Some reports suggest, for example, that it is easier to establish ES cells from C57BL/6N than from C57BL/6J.

### Mutagenesis using gene trapping

Gene trapping is used to randomly mutate genes which are expressed in ES cells. A DNA construct or vector is used which has a reporter gene such as green fluorescent protein or beta-galactosidase and a selectable marker such as *neo* (neomycin resistance) but no promoter region. ES cells are cultured with the DNA constructs, which are incorporated into the cells by electroporation (ie, subjecting the culture to an electric current) or by a modified virus. The DNA constructs are then randomly incorporated into the nuclear

DNA. If one lands near or within an active ES cell gene then the reporter gene will become activated by the ES cell promoter. It will usually (but not always) also deactivate or mutate the ES cell gene. In order to obtain live mice the mutated ES cells are then injected into mouse blastocysts. The result is a chimeric mouse which, when bred, may produce mutant offspring. DNA surrounding the gene trap construct can be sequenced to map and identify the mutant gene.

The gene trap DNA construct can be made to include sequences such as *loxP* (see below) which allow it to be deleted in certain tissues and/or at certain times.

The advantage of gene trapping is that it can be done in ES cells in a standardised way on a large scale using the most appropriate constructs, but live mice do not need to be derived until such a time as there are facilities available to study them. The disadvantage is that it is a random process, so to begin with many of the mutated genes will be 'new', but eventually more mutations will occur in genes which have already been mutated. Thus diminishing returns will eventually make the process less efficient. International projects to knock out every mouse gene will eventually need to use gene targeting to knock out the remaining genes.

### Transposon-mediated mutagenesis

Transposons or 'jumping genes' are sections of DNA which can move around in host DNA, sometimes causing insertional mutagenesis. They can also be used to insert genes into a host so may be of value in gene therapy. 'Sleeping Beauty' was a transposon found in fish which had been inactivated at least 10 million years ago, but was re-activated by genetic engineering (Wadman *et al.* 2005). It has been used for insertional and conditional gene trap mutagenesis in mice (Geurts *et al.* 2006) and also for the insertional mutagenesis of cancer genes where it can be made specific to particular tissues (Dupuy *et al.* 2006). It appears to be a promising new way of causing mutations in the mouse and possibly other species.

### Gene targeting and the production of 'knockout' mice

Gene targeting is used to mutate a specific gene in ES cells whose sequence is already known (Mansour *et al.* 1988). The targeting vector consists of several thousand bases of DNA sequences identical to those of the gene of interest, a positive selectable marker such as a *neo* (neomycin resistance) gene complete with promoter sequences inserted into an exon and a negative selectable marker such as *tk* (thymidine kinase), again with promoter sequences, at one end. It may also include sequences such as *loxP* sites (see later in this chapter) which can be used to delete the construct in certain tissues or at certain times chosen by the investigator. The targeting vector is incorporated into ES cells, usually by electroporation or within a virus. Because the sequences exactly match the DNA sequences of the gene of interest, in a very small fraction of cells homologous recombination will occur and the targeting vector, excluding the *tk* gene (which does not match the sequence so is left out), will become incorporated

into the DNA of the ES cell gene. Medium containing neomycin will ensure that cells where no targeting vector is incorporated do not survive and the inclusion of gancyclovir ensures that those cells which incorporate the targeting vector in a random location and still retain the *tk* gene do not survive, thereby enriching the culture in cells where homologous recombination has occurred. The *neo* disrupts the gene, thereby 'knocking' it out. Live 'knockout' mice are retrieved from chimeras formed by injecting the ES cells containing the construct into blastocysts of a normal mouse strain. Many targeted mutants are now available and two large international consortia, KOMP and EUCOMM, are using gene targeting as well as gene trapping to knock out each of the mouse genes in order to find out their function.

### Nomenclature

Targeted mutations result in new allele at the targeted locus. This is indicated by the gene symbol with a superscript tm#Lab code. For example B6;129-*Fshb*<sup>tm1Zuk</sup> is the first targeted mutation of the follicle-stimulating hormone beta produced by Zuk (a laboratory code). It was produced on a 129 genetic background and has been partially backcrossed (between 5 and 10 generations) to strains B6 (an abbreviation for C57BL/6).

### Gene targeting: 'knockin' mice

Knockin mice are being used to overcome some of the defects of transgenic strains produced by direct injection of DNA into early embryos. A non-critical gene is targeted with an insert consisting of the gene of interest flanked by DNA from the non-critical region. Homologous recombination is then used to insert the gene of interest into the site of the non-critical gene. In this way the investigator has complete control of the site of integration and avoids the problem of multiple copies being integrated. This ensures that the targeting construct is not interfering with an existing critical gene, so giving more reliable results. Nomenclature rules are given on the Jackson Laboratory website.

### Conditional mutations

Techniques are now available to produce conditional knockouts either in a particular tissue or at a particular time. This is necessary because many genes are essential for development so that knocking them out altogether results in a lethal phenotype which is difficult to study. Cre and FLP are 'recombinases' or enzymes which recognise 34 base pair DNA sequences designated loxP in the case of Cre and FRT in the case of FLP. Cre acts to delete any DNA flanked by two loxP sites. Basically, two loxP sites are placed on either side of the essential functional gene of interest using homologous recombination techniques. These cause no problems, so the gene continues to be expressed. Many transgenic strains have been developed carrying the Cre recombinase under the control of tissue specific or inducible promoters. In the absence of loxP sites, this rarely has an effect on the mice. However, when the mouse strain carrying the loxP sites is crossed with a strain carrying the Cre recombinase the target

gene of interest will be deleted in those tissues in which the Cre recombinase is being expressed. The use of both FLP/FRT and Cre/loxP gives even more flexibility to the system.

### RNAi RNA interference

RNAi offers an additional way of studying the function of a gene by knocking it 'down' so that effectively it is not expressed. This can be done in a tissue- or time-specific manner using transgenic or gene targeting methods. So called small or short interfering RNA (siRNA) interferes with gene translation by interacting with messenger RNA (mRNA) from the targeted gene in a sequence-specific manner. A similar process occurs naturally when microRNA is produced both to control gene expression and to fight off a viral attack.

Very briefly, a construct containing a sequence that codes for a short hairpin RNA (shRNA) with a sequence specific for the gene of interest, is introduced either by direct injection into the male pro-nucleus of a one cell embryo, by viral transduction or using gene targeting with appropriate selectable markers to a specific non-critical locus. When the sequence is transcribed it forms a short hairpin RNA (shRNA) which is then cleaved by an enzyme called 'dicer' to produce siRNA. This is transported from the cell nucleus and interferes with mRNA of the gene of interest. By using the Cre-lox technique the gene of interest can be knocked down in a time- or tissue-specific manner (Gao & Zhang 2007; Kumar & Clarke 2007).

### Concluding remarks

Mammalian genetics is developing rapidly at present as a result of new technology which, among other things, has made it possible to sequence the whole genomes of several species, including humans, the rat, mouse, dog and some species of non-human primate. Classical genetic techniques such as full-sib mating, backcrossing and selection have led to the development of many inbred, coisogenic, congenic and recombinant inbred strains of mice and rats and some other laboratory species. These have made a substantial contribution to biomedical research with several Nobel Prizes being awarded for work which would have been impossible without them. Mutations occurring spontaneously or as a result of irradiation of chemical mutagenesis have also been widely used in research. Some, such as the immune deficient nude and scid (severe combined immune deficiency) mutants, have not just been of interest in their own right but have also been used to grow grafts of tissue and tumours from humans and other species, making it possible to study aspects of biology which could not otherwise be studied. ENU mutagenesis is providing a steady stream of new mutants for further investigation.

The development of DNA-based techniques such as the polymerase chain reaction (PCR) resulted initially in the development of numerous genetic markers such as mini and microsatellites and single nucleotide polymorphisms. Linkage analysis, initially using phenotypic markers, but more recently using microsatellite and other DNA markers has led to the development of detailed genetic maps of most laboratory species. It is now possible to map quantitative

trait loci and methods of identifying these loci are improving rapidly. Mutagenesis using gene trapping, and the development of embryonic stem cells followed by gene targeting using homologous recombination now makes it possible to knock out any gene and observe the consequences. The amount of data being generated is enormous, and the science of informatics has grown from almost nothing to assuming major importance in the last two decades. Powerful computers and the World Wide Web are also fundamental to these developments, enabling information to be shared immediately in a way which would be impossible with a paper-based science. Scientists need to understand the fundamentals of laboratory animal genetics if they are to use animals efficiently and humanely in the future.

### Useful websites and collaborative genetics projects

#### The NIH Rat Genomics and Genetics Web site

<http://www.nih.gov/science/models/rat/>

This has pages on rat genomic and genetic resources, courses and meetings, funding opportunities, reports and publications, major resources and contacts.

#### RatMap

<http://www.ratmap.org>

RatMap is focused on presenting rat genes, DNA-markers and QTLs which are localised to chromosomes as well as rat gene nomenclature. It is maintained by the Department for Cell and Molecular Biology, Göteborg University, Sweden.

#### RGD (Rat Genotype Database)

<http://rgd.mcw.edu>

The aim of the RGD is the '*..establishment of a Rat Genome Database, to collect, consolidate, and integrate data generated from ongoing rat genetic and genomic research efforts and make these data widely available to the scientific community. A secondary, but critical goal is to provide curation of mapped positions for quantitative trait loci, known mutations and other phenotypic data.*

#### The Complex Trait Consortium

<http://www.complextait.org>

*'Quantitative genetics and QTL mapping have undergone a revolution in the last decade. Progress in the next decade promises to be even more rapid, and prospects for exploring the complex interplay between gene variants, disease, and the environment will be radically improved.'* The CTC organises meetings, publishes abstracts or full papers resulting from these meetings, provides some software for QTL research and generally keeps its members up to date with progress in complex trait analysis.

#### The International Mouse Strain Resource

<http://www.findmice.org>

The IMSR is a searchable online database of mouse strains and stocks available worldwide. It includes inbred, mutant, and genetically engineered mice. Note that the data found in the IMSR is as supplied by data provider sites.

#### International Gene Trap Consortium

<http://www.genetrap.org>

*Gene trapping is a high-throughput approach that is used to introduce insertional mutations across the genome in mouse embryonic stem (ES) cells. In addition to generating standard loss-of-function alleles, newer gene trap vectors offer a variety of post-insertional modification strategies for the generation of other experimental alleles.*

*The International Gene Trap Consortium (IGTC) represents all publicly available gene trap cell lines, which are available on a non-collaborative basis for nominal handling fees. Researchers can search and browse the IGTC database for cell lines of interest using accession numbers or IDs, keywords, sequence data, tissue expression profiles and biological pathways.*

It has four main components: Information, data access, tutorials and requests for the approximately 120000 cell lines which are available.

#### EUCOMM (European Conditional Mouse Mutagenesis Program)

<http://www.eucomm.org/>

This is a collaborative project set up under the European Union Framework 6 programme to develop a collection of 20000 conditional mouse mutations by gene trapping and homologous recombination on a C57BL/6 genetic background. The resulting mutants, made in a standardised way, will be made available to investigators world-wide. It includes participating laboratories in Germany, Italy, France and the UK. The gene trapping and the gene targeting vectors include both loxP and FRT sites, making future control and manipulation of the resulting mutants easier. It includes funds for training and databases. In addition it aims at the '*synergistic integration of EMMA, EUMODIC, EURExpress, FLPFLEX, EMAGE, FunGenES, PRIME and others and will collaborate with the Canadian NorCOMM, KOMP and members of the International Knockout Mouse Consortium (IKMC).*'

#### EUMODIC (The European Mouse Disease Clinic)

<http://www.eumodic.org>

This facility will undertake the primary phenotypic assessment of up to 650 lines of mice developed from ES cells produced by EUCOMM. Lines of particular interest will then be studied in more detail. It will make use of a sub-set of the comprehensive phenotyping protocols (EMPreSS) developed in the EUMORPHIA project.

#### EUMORPHIA

<http://www.eumorphia.org>

This was a project funded by the European Commission under FP5 from October 2002 until March 2006. The work created EMPReSS, a database of standard operating procedures (SOPs) for phenotyping mice, a database of mouse phenotyping information EUMODIC.

#### EMMA (The European Mouse Mutant Archive)

<http://www.emmanet.org>

This is a non-profit collaborative repository for mouse mutants and strains and for the cryopreservation of mouse mutants. The current membership includes the CNR Istituto di Biologia Cellulare in Monterotondo, Italy (core structure), the CNRS Centre de Distribution, de Typage et d'Archivage animal in Orleans, France, the MRC Mammalian Genetics Unit in Harwell, UK, the KI Karolinska Institutet in Stockholm, Sweden, the FCG Instituto Gulbenkian de Ciência in Oeiras, Portugal, the GSF Institute of Experimental Genetics in Munich, Germany and the EMBL European Bioinformatics Institute in Hinxton, UK. The EMMA network is directed by Professor Martin Hrabé de Angelis who also heads the GSF/IEG in Munich.

#### KOMP (The Knockout Mouse Project)

<http://www.nih.gov/science/models/mouse/knockout/>

This is an NIH-funded collaborative project, costing approximately \$42 million, to produce a set of ES cells carrying null mutations with reporters at about 10000 loci, using gene targeting methods. A C57BL/6 genetic background is considered preferable and the programme includes grants for the further development of robust C57BL/6 ES cells. The programme will support a repository to house the collection and a 'repatriation' of about 1000 of existing knockouts and a centre to coordinate the data which will be generated. It is intended to be complementary with other projects around the world such as the EUCOMM, and all the resources generated will be made freely available to investigators. It is recognised that data on gene expression and phenotypic characterisation would increase the value of the project, but it would also substantially increase the costs, so are not included as part of the main project. It is noted that '*a complete catalog of mouse knockouts will totally alter the sociology of the mouse research community landscape*' which may be disruptive and will create the need for extensive education and re-training.

#### Mouse Genome Informatics at the Jackson Laboratory

<http://www.informatics.jax.org>

This is a comprehensive database of mouse genetics including lists of genes and markers, phenotypes, alleles, gene expression, gene sequences, linkage maps and mapping data, mammalian orthology, mouse tumour biology, probes and clones, nomenclature, inbred strains and their origins and characteristics and access to the mouse phenome database.

## Glossary

**Allele** One of a pair of alternative, contrasting characters of which one is sometimes dominant and the other recessive. Each is determined by a gene occupying the same locus in a pair of homologous chromosomes.

**Alloantigen** An antigen which is capable of being recognised immunologically as foreign by another member of the same species.

**Autosomes** All chromosomes except the sex chromosomes.

**Backcross** A cross of an F1 hybrid to one of the parental strains or of a heterozygote to either of the parental homozygous types.

**Coisogenic strains** A pair of strains which are genetically identical apart from a single gene due to a mutation within an inbred strain followed by maintenance as two separate lines. Targeted mutagenesis also results in a pair of such strains.

**Congenic strains** A pair of strains which approximate a coisogenic status as a result of backcrossing a specified gene to an inbred strain. Usually 10 to 12 backcross generations are required. Partially congenic strains are recognised after five backcrosses.

**Dibybrid cross** A cross between two individuals which differ with respect to two specified pairs of genes.

**DNA** A macromolecule of genetic material which carries the genetic code specifying an individual.

**Dominant** The phenotypic expression of a character to the exclusion of its allelic (recessive) character.

**Epistasis** The dominant action of a gene over a non-allelic gene at a different locus, for example, the albino gene is epistatic to other coat colour genes.

**Expressivity** The degree of expression of a character controlled by a gene, in contrast with the frequency with which a gene produces its effect (penetrance).

**F** Coefficient of inbreeding. Probability (in the range 0.0 to 1.0) that two alleles at a locus are identical by descent.

**F1, F2** etc. Indicates the filial generation following a specified cross between genetically dissimilar parents.

**Forced heterozygosity** Continuous matings of type  $Aa \times aa$ , thereby ensuring that the locus is segregating among the progeny. In contrast a mating of type  $aa \times aa$  would lead to the  $a$  allele becoming fixed in the progeny.

**Gene** A hereditary element comprising a specific location (locus) on a chromosome, and which either alone or in combination with other genes determines a heritable character.

**Genetic monitoring** Routine procedure for testing whether individuals are of the stated strain or genotype.

**Genetic profile** List of the alleles at certain specified loci which are present in a given inbred strain.

**Genotype** The genetic constitution of an individual.

**Haplotype** Composition of a specified group of closely linked genes which act as a functional unit (eg, the major histocompatibility complex).

**Hemizygote** An organism carrying a gene which is present on one chromosome, but absent on the homologous chromosome. In mammals it usually refers to males carrying an X-linked gene, there being no homologous locus on the Y chromosome. When a transgenic strain is crossed with

- a normal strain the progeny will also be hemizygous for the transgene.
- Heritability** Proportion of the total phenotypic variation which can be accounted for by heritable factors (H, in the broad sense) or by factors with an additive mode of inheritance (H, in the narrow sense).
- Heterozygote** An organism which has inherited from its parents different genes at a locus controlling a particular character. Adjective: heterozygous.
- Histocompatible** Ability to accept grafts of skin, tumours or other tissue from another individual without immunological rejection.
- Homozygote** An organism which has inherited from its parents identical genes controlling a particular character. Adjective: homozygous.
- Hybrid** In laboratory animal genetics, a hybrid is usually the F1 (first generation) offspring of a cross between two inbred strains. However, it can also be applied to the offspring of parents of unlike genetic composition such as animals known to differ at a single locus, or at several loci even though they are not fully inbred (eg, a cross between breeds of rabbits or outbred stocks of rats).
- Inbreeding** The mating of related individuals. In mammals brother  $\times$  sister mating leads to the fastest inbreeding (see Strain (inbred)).
- Intercross** A cross between two hybrids.
- Isogenic** Genetically uniform. All individuals of identical genotype.
- Knockout** Strain developed by inactivation of a specific gene.
- Linkage** The non-random assortment of characters due to the genes for these characters being on the same chromosome. A series of linked gene pairs on the same chromosome is known as a linkage group.
- Locus** Position on a chromosome at which a gene is located. Each locus is given a name (eg, the 'agouti' locus) and a symbol usually consisting of one to three letters (eg, a).
- Marker gene** Gene which may be used to indicate the genotype at some other specified locus as a result of being closely linked to that locus. May also be applied to genes which are used to distinguish between different populations (eg, two inbred strains).
- Mass selection** Selection of the individuals which are in some sense 'best', without regard to their pedigree.
- Mendelian inheritance** Controlled by a pair of determinants (genes), which segregate during the formation of the gametes and recombine at random in the zygote.
- Minisatellite** Sequence of DNA of a few to several hundred bases in length, which is present at multiple locations in the chromosomes of an individual and which may differ between individuals in the number of repeats.
- Microsatellite** Simple sequence of bases often just two to four bases long (eg, CA), which is repeated up to a few tens or hundreds of times at each locus. These may be present at thousands of loci throughout the genome of an individual, but they very often have unique DNA flanking sequences which are used as the 'primers' in the polymerase chain reaction when used as genetic markers.
- Modifiers** Genes or non-genetic factors which alter the expression of a particular genotype.
- Monoybrid cross** A cross between two individuals which differ at one specified genetic locus.
- Mutant** Individual bearing a mutation.
- Mutation** A change in the nuclear substances (genes, chromosomes) of an organism. A mutation may arise from a change in the number of chromosomes, a change in part of a chromosome, or a change at a particular base in a gene. The latter is known as a 'point mutation'.
- Outbred** Usually refers to a genetically variable breeding group of animals maintained by random mating, maximum avoidance of inbreeding, or a haphazard mating scheme.
- Penetrance** Percentage frequency with which a particular gene produces its effect.
- Phenotype** The total expression of the genetic characteristics of an individual. Individuals of the same phenotype will look alike, but may differ genetically (ie, in genotype).
- Polygenic** Character whose mode of inheritance depends on many gene loci, whose individual effects are too small to be analysed individually without using special techniques. Polygenic characters are usually also dependent on non-genetic (ie, 'environmental') influences. See also QTL.
- Population** Group of organisms which potentially or actually may interbreed.
- Primers** Short, defined DNA sequences typically of about 20 bases which are used in the polymerase chain reaction to amplify a particular section of DNA.
- Progeny test** Evaluation of the genotype of an organism by a study of its offspring under controlled conditions.
- QTL or Quantitative trait locus** A genetic locus associated with a quantitative trait or character such as body weight, reproductive performance or susceptibility to the induction of tumours. Typically, such 'polygenic characters' (see above) will be controlled by many different loci and will also be influenced by environmental factors.
- Random** Occurring by chance.
- Recessive** Refers to a member of an allelic pair of genes which does not produce its effect in the presence of the other (dominant) gene.
- Recombinant inbred strains** A set of inbred strains produced by 20 generations of brother  $\times$  sister mating of the offspring of a cross between two standard inbred strains.
- Reporter gene** A protein coding gene which encodes an enzyme or protein not normally present in the transgenic animal, and for which a sensitive assay procedure exists. For example the *lac Z* gene encodes bacterial beta-galactosidase which can be used to produce a blue-coloured stain in tissues in which it is expressed.
- Segregating inbred strain** An inbred strain produced by brother  $\times$  sister mating in such a way as to maintain genetic segregation at a specified locus (eg, by mating  $m/m \times +/m$  animals each generation). May also be produced by backcrossing the mutant to an inbred strain and subsequent matings as above.
- Segregation** The separation of the chromosomes and genes in the formation of the germ cells (ie, during meiosis). Each germ cell receives only one chromosome (and therefore gene) of each pair.

**Sex-linked** A character associated with one sex, due to the genes for the character being located on the sex chromosomes.

**Shuttle vector** A DNA construct which can be incorporated into a transgenic animal, but which can also be extracted again from the host DNA using defined restriction enzymes and packaged into a plasmid or bacteriophage so that it can be cloned into a bacteria again.

**SNP or single nucleotide polymorphism** Genetic variation among individuals due to a single DNA base change (or possibly a few close bases) which may or may not alter phenotype depending on where it occurs and the nature of the change.

**Stem-line colony** Small nucleus breeding colony of an inbred strain which reproduces itself specifically to perpetuate the strain, and which also produces surplus animals which may be used for further breeding in an 'expansion' or 'multiplication' (the terms are synonymous) colony.

**Stock** A closed colony of genetically heterogeneous laboratory animals maintained without deliberate inbreeding.

**Strain (inbred)** A group of laboratory animals produced as a result of at least 20 generations of brother × sister mating (or its genetic equivalent using other mating systems), with all individuals tracing back to a single breeding pair in the 20th or a subsequent generation.

**X, Y chromosomes** The sex chromosomes. In mammals the female has two X chromosomes, one of which becomes inactivated during early embryonic development. Males have an X and a Y chromosome. The latter has few genes, but determines sex. In birds the female has XY and the male XX chromosomes. The sex chromosomes in birds were once designated W and Z.

# 5 Phenotyping of genetically modified mice

Rikke Westh Thon, Merel Ritskes-Hoitinga, Hilary Gates and Jan-Bas Prins

## Introduction

The development of techniques to create genetically modified mice has allowed tremendous progress in the fields of comparative medicine and genetics during the last decades. These animals have been used to provide a multitude of new disease models and their use has increased dramatically.

Each new genetically modified mouse generated is a potential new strain, which may or may not show altered characteristics (phenotypic changes) compared to the wild type. The phenotype of a genetically modified mouse is the sum of observable characteristics of an induced or spontaneous mutation.

The phenotypic consequences of a genetic modification cannot always be predicted and, consequently, it is necessary to characterise each new genetically modified animal's phenotype. Phenotypic characterisation, or phenotyping, is the discipline of identifying and describing new characteristics as compared to the non-mutated wild type. Ideally, phenotyping should uncover any new trait and a vast number of tests could be applied to the mouse in order to ensure that such traits are actually revealed. It is necessary to know the characteristics of an animal model so that decisions can be made as to whether the animal will be suitable for a particular line of research. The knowledge also helps with making welfare decisions for these animals.

Due to the tremendous increase in the number of newly generated genetically modified mice over the last decades, phenotyping has received considerable recent scientific attention and has become established as a discipline within laboratory animal science. Several journals have published special issues on phenotyping including *Lab Animal Europe* (Vol. 2, 2002), *Laboratory Animals* (vol. 37, Supplement 1, 2003) and the *ILAR Journal* (vol. 47, 2006). Even though much effort has been put into developing phenotyping protocols, the use of these protocols in practice lags behind, and the production of new strains far exceeds the number of strains that are characterised. Nonetheless, there are efforts to improve implementation (Hrabé de Angelis *et al.* 2006).

## Welfare issues

### The general situation

The current state of affairs regarding the welfare of genetically modified mice has been investigated in a survey of

users, from a variety of different disciplines, of genetically modified mice in Denmark, UK, Sweden, Finland and the Netherlands (Thon *et al.* 2009). Despite publication of detailed protocols for phenotypic characterisation, the results indicated that very few genetically modified mice were systematically characterised. Only one of those interviewed had SOPs (standard operating procedures) for phenotypic characterisation. The importance of the role of animal care staff has been pointed out by others (Morton & Hau 2003), and in this survey many used daily observation/visual inspection of animals by animal technicians. Some scientists knew about published protocols, but very few had practical experience with the test methods, and general knowledge about phenotyping strategies and protocols was low. On the other hand, phenotyping as a concept was widely understood and it was clearly regarded as an advantage to the science.

During the interviews, it became clear that there was considerable doubt amongst users of genetically modified mice as to whether the published protocols would actually fulfil their particular needs. Furthermore, concern was expressed about the comprehensiveness of the protocols and lack of resources and time for phenotypic characterisation. The survey also demonstrated that the reason for characterizing genetically modified mice depended strongly on the scientific reason for creating or using the strain. The kind of phenotype information that was required differed between scientists. For example, some needed to identify characters relating to diseases, whereas other kinds of information were required for those producing and establishing a modified strain for commercial purposes.

At least four levels of, or types of, characterisation were identified:

1. welfare assessment;
2. one-trait assessment focused on the expected phenotypic effect of the genetic modification;
3. basic characterisation;
4. comprehensive characterisation.

### The welfare of genetically modified animals

Genetic modification can give rise to unpredictable outcomes that may impact on animal well-being. Therefore, there is a need to pay special attention to the welfare of genetically modified mice. There has been a focus on animal

welfare since the beginning of the era of genetic modification as demonstrated by the inception of an EU workshop in 1995 named Welfare Aspects of Transgenic Animals (Van Zutphen & van der Meer 1997). Since then, several articles and reports have addressed the issue (eg, Mepham *et al.* 1998; van der Meer *et al.* 1999; Van Hoosier 1999; Wood 2000; Dennis 2002; Brown *et al.* 2006). One study has shown that approximately one third of genetically modified mice, as reported to the Danish Animal Experiment Inspectorate, showed welfare consequences arising from the genetic modification (Thon *et al.* 2002). Animals generated with the purpose of serving as disease models are particularly likely to show impaired welfare.

Phenotyping is important for keeping and breeding genetically modified animals. It should provide information about any special problems of a particular strain, thereby allowing the animal care staff to take action and improve the conditions of the animals. Once an animal has been phenotyped for welfare, special measures can be taken to actually improve welfare, such as providing a special diet, special housing or medication. Ultimately, this will improve animal welfare and the loss of valuable strains can be prevented. In addition, a better ethical evaluation of the research can be carried out and humane endpoints can be defined.

### Methods of welfare assessment

In the proceedings of the above-mentioned 1995 EU workshop, indices of good and bad welfare were defined (Broom 1995). Those relating to the former were listed as: changes to normal behaviours; changes to the ability of the animal to perform strongly preferred behaviours; and changes to physiological and behavioural indicators of pleasure. The list of indices reflecting poor welfare was much longer and included: reduced life expectancy; reduced ability to grow or breed; body damage; disease; immunosuppression; impairment of physiological and behavioural attempts to cope; behavioural pathology; self narcotisation when given the opportunity; changes to behavioural aversions; changes to normal behaviour; and changes to normal physiological processes and anatomical development.

The relevant tests for assessing the above mentioned indices can be roughly grouped into: (1) behavioural tests; (2) measurement of production parameters; and (3) physiological tests. The first two types of tests are performed relatively easily and require few resources. The last is more demanding. However, assessing animal well-being is always a laborious task and there are no 'easy' measures of welfare (Morton & Hau 2003).

van der Meer and co-workers have introduced a less comprehensive welfare test (van der Meer *et al.* 2001). It consists of non-invasive, mainly observational, easy-to-perform assessments based on three score sheets. One sheet is for scoring animals aged 0–6 days, one for animals 10–14 days and the last for animals around weaning. The indices used are: death in or out of the nest; milk spot; weight; fur growth; nipples; upper/lower incisors; and abnormalities. The most comprehensive (after weaning) test can be performed on an average litter of four to six pups by an animal technician within 15–20 minutes and requires a minimum of equip-

ment. The score-sheet approach to measuring welfare in young pups has been further developed by Marques *et al.* (2007). The method has been improved by adding further individual tests to the screening from the day of birth. A training film has been produced to facilitate implementation.

A working group has published recommendations on welfare assessment of genetically altered mice (Wells *et al.* 2006). These authors recommend that any institution using genetically altered animals should have a standard welfare assessment in place. Newly generated strains should be checked, and because of the risk that a changed environment could cause welfare issues, so should well known strains that have just arrived in an animal unit. When the institute has become familiar with the strain there is no need for retesting unless adverse effects are observed during the daily routine handling. The group suggested that animals should be checked as neonates, at weaning and for the normal lifespan of the particular strain. The tests should preferably be non-invasive and easy to implement. The importance of accurate recording of test results was stressed. Parameters such as teeth eruption, walking, righting, ears/eyes opening, posture and reaction to cage opening/handling were suggested, and examples of assessment forms were provided. For pups, parameters to be recorded include colour, activity and milk spot. Furthermore, mortality rates, appearance, coat condition, posture/gait, clinical signs, relative size and other unexpected characteristics were suggested in the assessment of older animals.

The group also recommended that the information obtained by the welfare assessment should be used for a mouse passport or certificate which would always follow the animal in order to facilitate correct husbandry and treatment. The introduction of an animal certificate or passport has also been recommended by others (Mertens & Rüllicke 2002; Jegstrup *et al.* 2003; Morton & Hau 2003). However, there has been some discussion within the phenotyping community as to whether the document should be both a physical paper certificate plus the corresponding information saved in a database, or just the information in a database. The first solution has the advantage of the information following the animal wherever it goes, but also includes the risk of paper documents disappearing or getting mixed up and the risk of circulation of outdated versions.

Morton and Hau (2003) present a very helpful guideline on how to establish a score sheet for assessment of animal welfare. They conclude that every welfare assessment is different depending on strain and experiment and, consequently, an individual score sheet should be designed for each new study covering the relevant welfare parameters.

Ironically, several of the tests suggested in phenotyping protocols may themselves impinge on the welfare of the tested animal. Hence, decisions on the potential adverse effect of chosen tests (eg, pain threshold and blood sampling) and on the number of mice tested should be made to avoid exposing mice to unnecessary suffering. The logical approach is to carry out a cost (harm)/benefit analysis (Richmond 2000) of the chosen test battery before phenotyping, and perform only the necessary tests based on these considerations.

## Other advantages of phenotyping

The benefits of a better understanding of the welfare impacts of a genetic modification are also that the information contributes to a better description of the model, which is important for the science. Phenotyping is obviously necessary for geneticists working on the relationship between genes and phenotype to characterise a genetically modified animal. The success of an approach, such as induction of mutations by the use of ENU (N-ethyl-N-nitrosourea), is totally dependent on effective phenotyping. ENU mutagenesis is aimed at introducing random and mainly point mutations in the genes of premeiotic spermatogonia. After breeding, successful mutations are identified through thorough phenotyping of every animal. This way, any new trait that has arisen as a consequence of the ENU treatment can be discovered (phenotype-driven approach) (Brown *et al.* 2005). Animals carrying mutations created by other techniques should also be subject to phenotypic characterisation. Since the phenotype of any genetic modification is a complex interaction between gene allele and genetic background, among other factors, one cannot be sure that an expected phenotypic change has taken place even after successful targeted mutation and whether it is the only phenotypic change. The phenotyping strategy should, furthermore, optimise the chance of detecting unexpected effects of the mutation as well (Brown *et al.* 2006).

For decades, it has been accepted that microbiological and genetic characterisation of laboratory animals was a necessity in order to reduce variability and increase replicability of studies. The same argument is true for phenotypic characterisation of genetically modified animals. Lack of phenotyping increases the risk that unidentified traits could cause extraneous variability, as they are not taken into account when designing the experiment. This could increase the risk of systematic errors which might intervene and confound results leading to false conclusions. Phenotyping the mutant model before setting up the experiment will provide the user with scientifically important information about the animal and allow him/her to implement a better design of the experiment leading to more valid results. Therefore, a precise characterisation must be considered as an essential aid in designing a scientific experiment (Barthold 2004).

Furthermore, new and unexpected traits may be detected that could be of scientific interest in other areas of research, or might provide an important model for work in other fields and which may contribute to the Three Rs (replacement, refinement and reduction) as well.

Studies may suffer or be aborted as a consequence of surprises regarding unexpected phenotypes, which may only become apparent at a late stage. Unfortunately, this kind of negative outcome is very rarely published and the scale of the problem is hard to estimate. However, it is the experience of the authors that the event is not rare, and every time studies are aborted it will inevitably lead to waste of animals, time and effort. The risk of ending up in this kind of unfortunate situation could be minimised by phenotyping right at the start.

A critical evaluation through a cost (harm)/benefit assessment (Richmond 2000) of the justification of the use of genetically modified animals should precede their use in

experiments. In order to assess the welfare 'cost', including the adverse effects of the genetic modification, it is crucial to characterise the animals. This can provide information about the potential suffering of the animal. Furthermore, phenotyping meets the needs of regulatory authorities as they increase their demands for information about genetically modified animals.

## Early protocols for phenotyping

As long ago as 1968, Irwin introduced protocols for systematic identification of behavioural and physiological phenotypes of mice (Irwin 1968). These protocols were designed for the pharmacological and toxicological fields and were not aimed at genetically modified strains. However, they have served as an inspiration for more recent protocols such as the SHIRPA protocols (SmithKline Beecham, Harwell MRC, Imperial College School of Medicine at St Mary's, Royal London Hospital Phenotype Assessment) (Rogers *et al.* 1997). The SHIRPA protocols were initially developed for characterisation of neurological models and were based on the principle of a broad primary test battery followed by more specialised secondary and tertiary tests. The SHIRPA protocols have been in use for many years (sometimes in a modified form) and they have had a profound influence on more recent comprehensive phenotyping protocols. In 1997 Crawley and Paylor published a detailed description of a battery of tests for the investigation of behavioural phenotypes (Crawley & Paylor 1997).

## The Mouse Phenome Project

The Mouse Phenome Project was initiated in 2000 by the Jackson Laboratories to develop a comprehensive database. The Mouse Phenome Database (MPD)<sup>1</sup> encompasses phenotypes from inbred mouse strains. It now also includes results of genetically modified mice. MPD aims at providing scientists with appropriate information about mice for: (1) physiological testing; (2) drug discovery; (3) toxicology studies; (4) mutagenesis; (5) modelling human diseases; (6) Quantitative Trait Locus (QTL) analyses and identification of new genes; and (7) unravelling the influence of environment on genotype (Bogue & Grubb 2004).

The data available at the MPD are the results of different research groups using different protocols and the database contains descriptions of how the data were generated. Due to their various origins, the protocols are of different designs, provide different levels of detail and vary in comprehensiveness. The protocols are organized in measurement categories in a hierarchical way starting with 15 top-level categories, such as anatomy, behaviour and heart/lung parameters, down to sub-levels of more detailed categories. The database provides several tools for downloading and viewing the phenome data. The tools can be used in combination to enable the scientist to mine the biological information for relevant patterns and correlations.

## The Eumorphia Project

Eumorphia (European Union Mouse Research for Public Health and Industrial Applications) was an integrated research programme funded by the European Commission. It was involved in the development of new approaches in phenotyping, mutagenesis and informatics leading to improved characterisation of mouse models for the understanding of human physiology and disease. Eighteen laboratories from eight European countries formed the consortium, which developed over 150 SOPs for phenotyping from 2002–2006<sup>2</sup>. The SOPs are standardised and validated on a cohort of inbred strains across a number of laboratories.

A primary screening protocol EMPReSS (European Mouse Phenotyping Resource for Standardised Screens) has been suggested for large-scale phenotyping (Brown *et al.* 2005). EMPReSS covers the major body systems and includes: clinical chemistry; hormonal and metabolic systems; cardiovascular system; allergy and infection; renal function; sensory function; neurological and behavioural function; cancer; bone/cartilage; and respiratory function; as well as generic approaches to pathology and gene expression. The Eumorphia project has established the EuroPhenome database to hold data on phenotypes obtained from the EMPReSS SOPs<sup>3</sup>.

The project was geneticist driven and mainly aimed at serving programmes of large-scale generation of mutant mice with no *a priori* hypothesis about the function of mutated genes. The goal was to systematically mutate every gene in the genome thereby shedding light on the relationship between gene and phenotype (Brown *et al.* 2006). The tools developed for this purpose adopted a phenotype-driven approach of comprehensive testing in order to maximise the capture of new traits.

Unfortunately the EMPReSS protocols do not include welfare assessment and so this important aspect must be evaluated according to other protocols. However, they do include SOPs for a broad spectrum of phenotyping areas and employ a hierarchical approach. They are validated and standardised to a high degree making results comparable over laboratories and time; and since these protocols have been developed across Europe and are still being developed, eg with the Mouse Phenome Database and the Mouse Clinics adhering to these protocols, this approach appears to be the future of phenotyping in Europe.

## The EUMODIC project

The European Mouse Disease Clinic EUMODIC<sup>4</sup> project started in 2007 and is funded by the European Commission. EUMODIC is undertaking a primary phenotype assessment of up to 650 mouse mutant lines, as a first step towards a comprehensive functional annotation of the mouse genome. In addition, a number of these mutant lines will be subject to more in depth secondary phenotype assessment. The

EUMODIC consortium is of 18 laboratories across Europe, expert in the field of mouse functional genomics and phenotyping and with a track record of successful collaborative research in Eumorphia. EUMODIC has further developed a selection of the EMPReSS screens, and this selection is called EMPReSSslim, which is structured for comprehensive, primary, high throughput phenotyping of large numbers of mice. The EMPReSS tests are run in two 'pipelines' in order to minimise the number of tests that each animal undergoes and to allow the testing to take place over a 6 week period from 9–14 weeks of age. The sequence of tests in the two 'pipelines' is designed to allow the individual tests to be run at relevant ages so that earlier tests do not unacceptably influence the outcome of those that follow.

Mutant lines will be made available from another EU initiative, EUCOMM, the European Conditional Mouse Mutagenesis project<sup>5</sup>. The primary phenotype assessment using EMPReSSslim, will be undertaken in four large-scale phenotyping centres at the German Mouse Clinic (GMC), GSF (National Research Centre for Environment and Health), Germany; ICS (Institut Clinique de la Souris), France; MRC (Medical Research Council, Mammalian Genetics Unit), Harwell, UK; and the Wellcome Trust Sanger Institute, UK. A distributed network of centres with expertise in various phenotyping domains will undertake more complex, secondary phenotyping screens and apply them to mice that have shown interesting phenotypes in the primary screen.

## Other protocols

The MuTrack<sup>6</sup> system was developed for the Tennessee Mouse Genome Consortium in connection with the National Institute of Health's neuromutagenesis programme (Baker *et al.* 2004). This is divided into ten primary screens covering aggression, aging, auditory, drug abuse, ethanol, epilepsy, eye, general behavioural, neurohistology and a social behaviour domain. Furthermore, it includes three secondary screens focusing on drug abuse, nociception and learning/memory. The protocols for screening are individually designed by different scientists and contain different details for screening purposes.

The protocols available at the PhenoSITE were developed in connection with the Japanese mouse mutagenesis program at RIKEN GSC (Genomic Sciences Centre)<sup>7</sup>. Their basic phenotype screen includes a modified SHIRPA and further tests, including: haematology and urine tests; radiography; seizure induction; home cage activity; open field and passive avoidance tests; and for late-onset phenotypes: fundus imaging, blood pressure, hearing and tumour development. The mice are tested between the ages of 8 and 12 weeks.

Mertens and Rüllicke (1999, 2000, 2002) have developed a protocol with a slightly different and broader objective than that of the programmes above (Mertens & Rüllicke 2000, 2002). It is based on two comprehensive standardised forms and covers registration of animals, recommendations for

<sup>7</sup><http://www.gsc.riken.go.jp/mouse/aboutus/screening.htm>

husbandry and breeding, phenotyping, welfare assessment and animal certificate/passport. The first form 'Data record form' includes score sheets for litters and individual health and development monitoring from birth until death or euthanasia. The tests are based on observation or other very simple tests. The second form 'Characterisation of genetically modified animal lines: Standard form' includes 'General information' which addresses the genetic modification, phenotype and clinical burden, ethical evaluation and information on breeding, husbandry and transportation, and 'Detailed information on genotype and phenotype' which goes into detail with new traits/observations that are specific for the particular strain.

### Mouse clinics

The need for facilities and expertise for phenotyping is growing and, consequently, the concept of mouse clinics has emerged. However, there are still relatively few mouse genetics institutes around the world that have broad experience in phenotyping and which can be categorised as phenotyping centres or mouse clinics.

The German Mouse Clinic (GMC) at GSF, Munich<sup>8</sup> is an open platform for phenotyping and offers a service of examination of mouse mutants for external scientists, using a broad standardised phenotypic check-up with more than 300 parameters. The screens cover behaviour, bone and cartilage development, neurology, clinical chemistry, eye development, immunology, allergy, steroid metabolism, energy metabolism, lung function, vision, pain perception, molecular phenotyping, cardiovascular analyses and pathology. Mouse mutants accepted at the GMC are first examined in a primary screen. A standardised workflow for screening a mouse cohort of 40 animals (ten males and ten females of mutant and wildtype, respectively) has been developed according to EMPReSS protocols and takes about 10 weeks to complete. An application form and instructions for submission of a strain for free phenotyping can be found at the GMC website.

### Commercial phenotyping

Another option is commercial phenotyping performed by companies offering this service to their customers. The following two are examples of such companies and the reader is encouraged to search the internet for others.

Charles River Laboratories<sup>9</sup> offer an extended range of tests, initially starting with a primary neurobehavioural observation based on a modified SHIRPA panel, which also includes basic pathology and clinical pathology. Necropsy is performed and tissues from 16 organs plus tissue from any identified abnormality are stained with haematoxylin and eosin and examined by a veterinary pathologist. Clinical pathology includes a complete blood count with differential and platelet count. Serum is submitted to a standard clinical

chemistry profile and so is urine. Furthermore, the company offers a range of supplemental phenotyping panels relating to obesity, diabetes, oncology, embryonic lethality, osteoporosis and several other conditions.

Frimorfo<sup>10</sup> offers a diagnostic pathology-based characterisation. They also offer, through a network, screens relating to genetics, physiology and behavioural analysis. The histopathology includes immunohistochemistry, *in situ* hybridisation, standard and customised tissue microarrays and microscopy. Genetics includes zygosity, gene expression, reporter gene assay, apoptosis assays and cell proliferation assays. *In vivo* physiology includes respiratory and cardiovascular tests and *in vitro* blood chemistry and haematology. Behavioural analyses are divided into primary, secondary and tertiary test batteries much like the SHIRPA protocols. The tests are composed in packages focusing on different organ/tissue functions.

### Before phenotyping – search for information

It is advisable to carry out a thorough literature/database search for existing information about a particular mouse strain before phenotyping. Results from animals with similar mutations and mutations in the same area of the genome also can be of great value when gathering information about the phenotype.

Regrettably, a comprehensive database of results from all genetically modified animals is not available; rather data are held in various forms at many sites worldwide and one has to carry out the laborious task of searching databases to retrieve information. Web addresses of screening protocols and databases of phenotypic characteristics can be found in the literature (Bolon 2006; Consortium (MPDIC) 2007). Furthermore, we have included a list of websites that we have found useful (see Useful websites at the end of this chapter). This list was made in 2008 and since web addresses frequently change, we urge the reader to make his/her own search as well.

The Mouse Phenome Database (MPD)<sup>11</sup> (Grubb *et al.* 2004; Blake *et al.* 2006) and the EuroPhenome resource<sup>12</sup> are central databases holding substantial information about phenotypes. The MPD contains information about both inbred and mutant strains. The EuroPhenome resource holds the results of the large-scale phenotyping projects from EMPReSS protocols. Both are annotated according to the Mammalian Phenotype (MP) Ontology (Gkoutos *et al.* 2005; Smith *et al.* 2005) and have tools for browsing and searching for phenotypes.

Phenomics data are fragmented and some are not publicly available. Various types have been generated (eg, detailed descriptions of mouse lines, first-line phenotyping data on new mutations and data on the normal features of inbred lines) depending on the groups presenting them. The issues arising as a result of there being several phenome databases using different systems is being addressed by the

<sup>8</sup><http://www.gsf.de/ieg/gmc>

<sup>9</sup><http://www.criver.com>

<sup>10</sup><http://www.frimorfo.com>

<sup>11</sup><http://phenome.jax.org/pub-cgi/phenome/mpdcgi?rtn=docs/home>

<sup>12</sup><http://www.europhenome.eu>

InterPhenome project<sup>13</sup>. A working group, the Mouse Phenotype Database Integration Consortium (MPDIC), representing large parts of the phenotyping society has been formed and is striving to link these databases, set standards for data and to set up mechanisms to facilitate data exchange between and searches across the various databases (MPDIC, 2007).

### Testing for new traits – the hierarchical approach

In principle any clinical test could be used to uncover phenotypic details about a specific genetically modified mouse and a variety of SOPs for these tests can be found in the published protocols. In view of the huge number of possible tests, it is worth prioritising these to obtain relevant results as quickly and efficiently as possible. A practical approach to gaining useful information about a mouse strain is to first apply a battery of relatively unsophisticated tests or primary screens such as those of the SHIRPA test (Rogers *et al.* 1997). These provide a superficial but broad assessment of a mouse phenotype. Various protocols have been proposed which employ this hierarchical approach, focusing either on specific functional domains such as behaviour (Crawley & Paylor 1997a; Crawley 2003) or employing a wider selection of screens (Rogers *et al.* 1997; Murray 2002). Results from these primary screens should point the way for following more detailed tests. For example, if a mouse shows a hearing deficiency in the auditory startle test during the primary phenotyping screen, a comprehensive examination of the auditory tract should follow. In this way, phenotypes of interest identified by the primary screen are followed up by more time-consuming, detailed secondary screens.

### Delimiting the phenotyping process

When phenotyping a mouse strain, difficulties may be encountered in deciding how comprehensive the phenotyping project should be. How many and which tests should be included? Looking at the protocols for phenotyping published in the literature and on the internet, it is obvious that no working procedure is unanimously recommended. As pointed out earlier, genetically modified mice can be very different and are used in so many ways that specific phenotyping needs often arise. This is an area that needs further investigation to facilitate optimal choice of tests for the circumstances.

Therefore, before commencing the laborious task of phenotyping, some serious reflection on the level of characterisation is recommended. Firstly, consideration should be given to the particular need for information about a mouse strain. Some results are more relevant than others depending on what the strain is used for. Also, the resources (economy, time, expertise) available should be considered since there are limits in practice to how much can be investigated. Deciding how comprehensive the test battery should be is a difficult task, and this is usually made on the basis

of common sense, experience and tradition. However, these approaches carry a risk of being non-systematic and subjectively biased, thereby influencing their validity. It is therefore advisable to carry out a systematic investigation into the need for phenotyping and the contribution that the individual protocols can yield in every case of phenotyping, before the project is started.

The question of how wide-ranging a basic phenotyping protocol should be – or what the minimum requirement for phenotyping is for relevant results – is still open and needs further investigation.

### The dilemma of large-scale versus ‘home’ phenotyping

Huge efforts have been and are still being put into developing EMPReSS and the corresponding SOPs leading to better phenotyping tools. However, these developments will, in many cases, make the protocols more complex and demanding, and will require increased levels of expertise and further equipment.

The lack of phenotyping of mutants that are not part of large-scale projects, but have been locally produced and bred, is obvious. Scientists working with these animals are often more focused on their particular field of interest than on phenotyping, and protocols like EMPReSS are not easily implemented by people who are not phenotyping experts. It is probably unrealistic to expect many laboratories to develop the expertise, equipment, resources and infrastructure to carry out comprehensive phenotyping themselves. These two opposing tendencies raise the question as to whether, rather than ‘home phenotyping’, sophisticated phenotyping should be carried out at specialist centres. Phenotyping at specialist mouse clinics adhering to EMPReSS protocols has the advantage of a high professional standard, but might not always provide the user of a mutant with the specific information needed for their purpose and may not be affordable.

### Capacity and need

As pointed out earlier, only a minority of genetically modified mice are phenotyped. This could be due to a lack of knowledge about the possibilities or the advantages of doing so. Nevertheless, a central problem in phenotyping today is the issue of current capacity versus need. There is still a huge mountain to climb to complete the phenotyping of every mutant. The capacity of existing mouse clinics is absolutely insufficient to phenotype all the mice generated and it would be of benefit to have several more of these facilities established. These clinics would accumulate expertise in phenotyping and could serve as consultants to users planning to phenotype their animals themselves.

### New methods for phenotyping – speed and sophistication

The problem of capacity could be improved by developing new, inexpensive, rapid and reliable methods of phenotyp-

<sup>13</sup><http://www.interphenome.org>

ing. This challenge is being met by the introduction of new technology which meets the above criteria. For example, a new technology named Luminex enables the detection and quantification of multiple RNA or protein targets simultaneously. It combines a flow cytometer, fluorescent-dyed microspheres (beads), lasers and digital signal processing to allow multiplexing of up to 100 assays within a single sample, and it is expected to revolutionise the rapidity and scale of assaying a wide spectrum of blood parameters. In the future we can expect micro technologies, remote monitoring and new imaging methods to have a large impact on the speed, price and quality of phenotyping (Johnson *et al.* 2006). Moreover, technologies that take welfare into consideration and can minimise trauma to animals, while still retaining sufficient sensitivity and replicability, will become an integrated component of the future phenotyping process (Pinkert 2003).

### The environment – a challenge to phenotyping

The results of phenotyping not only depend on the genetic make-up of the mutant but can also be influenced by environmental factors, such as cage environment, diet and health status (Barthold 2004). Some phenotypes are not expressed by the animal until provoked by the environment; for example diabetes may not develop until the animals are fed a high-fat diet.

Another important environmental factor is the phenotyping test itself. One aspect of this is that different equipment may have different detection sensitivities and this must be considered. Also, many tests affect the animals in some way (eg, when taking a blood sample the animal is removed from its cage, immobilized and a vein is punctured). These procedures can significantly influence results obtained. Generally, when behavioural phenotyping results need to be comparable and replicable it is recommended that environmental conditions are standardised as much as possible and that the conditions under which the results are obtained are documented (Brown *et al.* 2006). Different environmental factors influence phenotyping results to different degrees and the results of behavioural tests are prone to being very sensitive to the environment. Research has shown that the environment of individual laboratories influenced behavioural results despite attempts to standardise between laboratories (Crabbe *et al.* 1999). On the other hand, some parameters seem rather resistant to environmental conditions. For example, caging and diet were found to have little effect on blood chemistry of a number of inbred strains (Arndt & Surjo 2001). It has been argued that when performing behavioural phenotyping, environmental background should be systematically varied instead of being standardised, because the parameters are so strongly modulated by the environment (Würbel 2002).

An open international network on behavioural phenotyping, the Mutant Mouse Behaviour Network (MMB) and the specific environmental challenges it offers has been established<sup>14</sup>. MMB was founded within the framework of the

conference 'Behavioural Phenotyping of Mouse Mutants', February 2000, held in Cologne, Germany.

### Further phenotyping issues to consider

The user of a genetically modified mouse should keep in mind that some phenotypic changes are subtle and can be compensated for by other mechanisms. Some may not be apparent in the young animal but are exposed at a later stage of life. Some phenotypes are seen only at a specific developmental stage and some in connection with specific physiological conditions such as pregnancy. For those reasons, animals should be characterised at different stages of their lives. It has been suggested that animals should be tested at three ages: young, adult and geriatric (Broom 1995; Morton & Hau 2003; Wells *et al.* 2006). Both homo- and heterozygous animals should be tested, and within every group they should be the same age as far as possible (age-matched). Also, one should be aware that a phenotype could vary between sexes and so both male and female animals should be tested.

Use of the pronuclear injection method can give rise to the formation of concatemers, head to tail, multicopy gene arrays of extrachromosomal DNA which might enter the genome, thereby generating a mutant carrying a transgene concatemer at one or more loci in the genome. Alternatively the result may be silencing of genes, transgene instability, low degree of transmission to offspring and somatic mosaicism of the F1 generation (Clark *et al.* 2007).

Some new traits have been shown not to reveal themselves until after a couple of generations (Van Hoosier 1999). Therefore, consideration should be given to phenotyping strains for several generations. Depending on the method of modification, new strains become genetically more 'stable' after breeding for some generations and characterisation of the strain at a 'stable' point will give the most reliable result (Mertens & Rüllicke 2000). However, establishing this point by breeding several generations can be difficult and also contradictory to welfare considerations in case the strain has problems.

The order in which the individual tests are performed can influence the results. This has been investigated in behavioural tests and it has been reported that certain test variables are sensitive to the test order while others are resistant (McIlwain *et al.* 2001). Mice that have become experienced through their participation in some tests change their behaviour significantly in subsequent tests compared with naïve mice (Voikar *et al.* 2004). For this reason it is best to start with tests that assess anxiety and exploratory activity and to perform the cognitive tests at a later stage.

When phenotyping genetically modified animals, the question of controls needs to be dealt with. The most obvious choice is probably to use wild-type siblings as controls (Charsa *et al.* 2003). If the strain is kept by homozygous breeding and no wild-type siblings are available, the corresponding inbred strain should be used as a control. Wild-type siblings of a mixed genetic background are not ideal controls as one cannot be sure how much donor/recipient strain is represented in each animal and backcrossing to a congenic strain before phenotyping is therefore recommended.

<sup>14</sup><http://www.medizin.uni-koeln.de/mmb-network/index.html>

## Background of animals

Identical mutations might have different phenotypes because of their different genetic backgrounds, as when, for example, different inbred mouse strains carry the same mutation. The majority of phenotypic traits are of complex polygenic origin and their inheritance does not follow a simple single locus Mendelian pattern. In this case, the different phenotypes of mice with identical mutations in different strains can be attributed to independent modifier genes with allelic variations. In the end, it is not just the genes, but also other genetic modifiers that lead to the combined action of many genes and the differential patterns of transcription and translation that influence the development and phenotype of a genetic modification (Barbaric *et al.* 2007). Despite this, the phenotypic changes of genetically modified mice are still frequently attributed to just the induced mutation but, according to the above, it could be argued that testing the trait in different genetic backgrounds/strains would provide a clearer picture of the mutation.

## Backcrossing of animals

Some mutant mice are kept of a 'mixed genetic background'. This means that the animals are not congenic, but a mixture of the strains used in the generation of the mutant (typically 129 and C57BL/6). With modifier genes in mind, there is no doubt that the 'mixed background' will give variations in the phenotype of these animals – even among siblings.

The Banbury Conference on Genetic Background in Mice (1997) recommended that backcrossing is carried out to obtain a congenic strain with the genetic background of an inbred strain. This is obtained by a minimum of ten generations of backcrosses to the recipient strain counting the first hybrid generation as F1 and the following backcrosses as N2–N10.

As backcrossing for ten generations is a very time-consuming exercise (2–3 years) an accelerated method for the production of a congenic strain has been developed which is based on background selection. This is called 'speed congenic' or 'marker-assisted selection'. The principle of this is to select breeders from each new generation with a genome as similar to the recipient strain as possible. This cuts the backcrossing time down to approximately 1 year (Wakeland *et al.* 1997; Wong 2002).

Furthermore, in order to prevent the mutant strain from accumulating genetic changes as a result of genetic drift over time it is recommended that the strain should be backcrossed to the parental inbred background every five to six generations (Banbury Conference on Genetic Background in Mice 1997).

Despite these recommendations, situations might occur where animals are not completely backcrossed to a congenic state before they are used. In that case, it is best to use a larger number of animals for the tests to compensate for the variation in the genetic background (Zeiss 2004). However, using more animals for the test has welfare aspects which should be considered beforehand.

## Number of animals

The aim of phenotyping is to find new traits either for welfare assessment or scientific use. In order to optimize the chance of detecting these, a sufficient number of animals must be tested. As outlined earlier, traits might be subtle or only identifiable under certain conditions (eg, with age, stress or feeding a specific diet) (Fitzgerald *et al.* 2003; Davey & Maclean 2006). Furthermore, different test methods have different levels of sensitivity. Such factors make it difficult to estimate how many animals should be used for phenotyping a particular strain.

Mertens and Rülcke (2000) concluded that for animal welfare, time and expense reasons it is important to consider the number of animals thoroughly. They have stated that it is not feasible to make a clear-cut recommendation as many factors, such as genetic background, penetration and expression of the mutation and welfare implications, would influence the size of the group necessary. However, they recommended starting with approximately ten wild-type, ten hemi- or hetero- and ten homozygous animals (50% males and 50% females). This would allow statistical calculations and should be regarded as the minimal number of animals for testing. Depending on the results more animals could be included. This recommendation was supported by others (Bailey *et al.* 2006).

Some of the protocols mentioned earlier give recommendations on the number of mice that should be tested. The SHIRPA protocol does not *per se* give a recommendation regarding number of animals. However, Rogers *et al.* (1999) used two separate cohorts of ten males and ten females for the SHIRPA tests. One cohort was used for the elevated plus-maze and open field tests; the other cohort was used for the remaining tests. The order of testing was designed such that the procedures most likely to be affected by prior handling were carried out first (Rogers *et al.* 1999).

In the protocols of the Mouse Phenome Project some recommend a specific number of mice for the particular test, whereas others do not. The general recommendation is ten males and ten females at the age of 10–14 weeks (Bogue & Grubb 2004). The MuTrac system of the Tennessee Mouse Genome Consortium also recommends number of mice in some protocols varying from two to eight mice per test. To date, the EMPReSS protocols do not include recommendations for numbers of animals. However, at this moment ten males and ten females for each of the two 'pipelines' are used at MRC, Harwell, UK and at the German Mouse Clinic.

The issue of sample size has also been addressed by Meyer *et al.* (2007). The 'background noise' defined as the difference in response to the same test by mice of the same strain but from different laboratories/suppliers has been investigated. This intra-strain variability of response to a specific test will affect the number of mice recommended for each test, as the 'background noise' might mask potential phenotypic differences. Other parameters such as the variance of the trait in question (subtle/strong phenotype) will also influence this. A pilot study should be carried out in order to establish the values of the above parameters and calculate sample sizes accordingly (Meyer *et al.* 2007).

To conclude, several suggestions have been made regarding the optimal number of animals for phenotyping and the

scientific rationale has not always been clear. This issue would benefit from further consideration.

A different, but often very troublesome issue that can affect the number of animals available for phenotyping is the breeding capability of genetically modified strains. Many mutants have reproduction problems making it difficult to get enough pups at approximately the same age (age-matched) for testing. This should be taken into consideration when planning the breeding of animals for phenotyping.

### Summary of phenotyping issues to consider

In this paper we have tried to call attention to the many important aspects of phenotyping. Bearing in mind the many reasons for using genetically modified mice we shall not attempt to suggest which set of tests to use. Rather, we urge the scientist responsible for the characterisation of the animal to give the issue careful consideration based on the information in this chapter. We would, however, make the following outline as a guide to running a basic phenotyping project:

1. search for existing information;
2. conduct a welfare assessment;
3. investigate the basic functions of the animal, eg:
  - growth and development of the animal;
  - lifespan and age-specific mortality;
  - fertility;
  - physical examination;
  - clinical chemistry and haematology;
  - behaviour;
4. conduct necropsies.

In summary, we recommend testing every new strain at three stages: young, adult and geriatric. The mice in each group should be approximately the same age. Homo-, heterozygous and wild-type mice should be tested in both sexes. The strain should be backcrossed to congenicity for 10 generations or the number of backcrossings by marker assisted selection to obtain equivalent congenicity before phenotyping and the order of tests should be considered to minimise one test affecting the result of the next.

It is worth considering testing the strain for several generations and investigating the mutation in different inbred strains. Based on the literature, the number of animals in every test group should be at least 10 for the initial testing. Pilot studies for the identification of the optimal number of animals could be carried out.

### Concluding remarks

Only very few genetically modified mice are systematically phenotyped – often the process involves no more than daily observation by animal technicians. The widespread use of such observation for the detection of welfare impingement and new phenotypic traits is in many cases regarded as sufficient. There is no doubt that a talented and experienced animal technician is likely to discover even subtle deviations in a genetically modified mouse. Nevertheless, there are

traits that produce no immediately observable symptoms. Systematic testing using phenotyping protocols increases the chance of identifying traits, and should be carried out.

For welfare assessment, observation is an excellent tool, as much welfare assessment is based on behavioural studies. However, observation of behaviour alone is not sufficient to evaluate welfare. Observations should always be recorded for later reference.

Phenotyping takes time. Testing requires a certain number of age-matched pups. Producing these from a founder animal is a laborious and time-consuming task. Furthermore, carrying out the actual phenotyping tests can take months and if the mouse is tested at different ages, the time needed, of course, increases. However, the advantages of thoroughly phenotyping before using an animal for scientific purposes are obvious and the time for phenotyping should be allocated to any project including genetically modified rodents.

Phenotyping requires expertise. The tests that are used to identify new traits are often complicated and demanding to perform. Behavioural testing is the classic example of a task which requires special skills. Also laboratory animal histopathologists need many years of specialised education and training. The tendency of phenotyping protocols to grow both in size (by adding more tests) but also in complexity (by developing more sophisticated methods) is increasing the demand for specialised expertise and it cannot be expected that a research group or even a university animal facility, will possess all this know-how without the necessary investments.

Phenotyping costs money and a major issue may be the ability or willingness to meet the costs of detailed phenotypic characterisation. Today, many scientists are funded by time-limited grants and in order to obtain the next grant, they must provide satisfactory scientific results at the end of the previous period. Establishing the phenotype of a mouse model is, unfortunately, not yet regarded as a scientific result, and often the experimental work is initiated without previous phenotyping. The risk is that research may be carried out using animal models which later appear to be sub-optimal or may even be invalid.

In summary, the implementation of phenotyping will undoubtedly improve as new cheaper and faster high-quality methods are developed and the concept becomes further scientifically accepted.

British National Centre for Replacement, Refinement and Reduction of Animals in Research (NC3Rs)

<http://www.nc3rs.org.uk>

CF2 Mouse Phenotyping Platform

<http://davinci.crg.es/mpc/cf2.php>

Objectives are:

- to share common phenotyping protocols for large phenotypic analysis on mouse models;

- to share protocols and apparatus (EUMORPHIA-based protocols);
- to facilitate research/learning stages within the consortium;
- to define common strategies and/or establish different lines of phenotyping (eg, cardiovascular/general morphology and behaviour/neurology/imaging etc);
- to perform in depth studies of a limited number of aneuploid transgenics workshops.

#### Functional Annotation of Mouse (FANTOM)

<http://www.ddbj.nig.ac.jp/>, <http://fantom2.gsc.riken.jp>, <http://fantom3.gsc.riken.jp>

The large mouse transcriptome project, Functional Annotation of Mouse (FANTOM), provides a wealth of data on novel genes, splice variants and non-coding RNA, and provides a unique opportunity to identify novel human disease genes. It will also facilitate the creation of transgenic mouse models to help elucidate the function of potential human disease genes (Hayashizaki & Kanamori 2004; Kiyosawa *et al.* 2004). After the development of original technologies (such as full-length cDNA libraries, CAGE, GSC) followed by massive application, the data have been analysed by the members of the Fantom-3 consortium ((Carninci *et al.* 2005; Katayama *et al.* 2005). The information is available to the public on the servers of DDBJ, National Institute of Genetics and RIKEN.

#### The Gene Expression Database (GXD)

<http://www.informatics.jax.org> or [http://www.informatics.jax.org/menus/expression\\_menu.shtml](http://www.informatics.jax.org/menus/expression_menu.shtml)

The GXD is a community resource for gene expression information in the laboratory mouse. By collecting and integrating different types of expression data, GXD provides information about expression profiles in different mouse strains and mutants (Hill *et al.* 2004).

#### GeneLynx Mouse

<http://mouse.genelinx.org>

Gene Lynx Mouse is a meta-database providing an extensive collection of hyperlinks to mouse gene-specific information in diverse databases available via the Internet. The GeneLynx project is based on the simple notion that given any gene-specific identifier (eg, accession number, gene name, text or sequence), scientists should be able to access a single location that provides a set of links to all the publicly available information pertinent to the specified gene. The recent climax in the mouse genome and RIKEN cDNA sequencing projects provided the data necessary for the development of a gene-centric mouse information portal based on the GeneLynx ideals. Clusters of RIKEN cDNA sequences were used to define the initial set of mouse genes. Like its human counterpart, GeneLynx Mouse is designed as an extensible relational database with an intuitive and user-friendly web interface. Data is automatically extracted from diverse resources, using appropriate approaches to

maximise the coverage. To promote cross-database interoperability, an indexing utility is provided to facilitate the establishment of hyperlinks in external databases. As a result of the integration of the human and mouse systems, GeneLynx now serves as a powerful comparative genomics data mining resource (Lenhard *et al.* 2003).

### The German Mouse Clinic

<http://www.gsf.de/ieg/gmc>

The German Mouse Clinic is an open access platform for standardised phenotyping (Gailus-Durner *et al.* 2005).

### Institut Clinique de la Souris (ICS)

[http://www-mci.u-strasbg.fr/service\\_intro.html](http://www-mci.u-strasbg.fr/service_intro.html)

### The Integrated Genomics Environment

<http://rgd.mcw.edu/VCMAP>

Integration of the large variety of genome maps from several organisms provides the mechanism by which physiological knowledge obtained in model systems such as the rat can be projected onto the human genome to further the research on human disease. Twigger *et al.* (2004) use new data and introduce the Integrated Genomics Environment, an extensive database of curated and integrated maps, markers and physiological results (Twigger *et al.* 2004).

### The Jackson Laboratory

<http://www.jax.org>

### LIFEdb

<http://www.dkfz.de/LIFEdb>

LIFEdb is implemented to link information regarding novel human full-length cDNAs generated and sequenced by the German cDNA Consortium with functional information on the encoded proteins produced in functional genomics and proteomics approaches. The database also serves as a sample-tracking system to manage the process from cDNA to experimental read-out and data interpretation. A web interface enables the scientific community to explore and visualise features of the annotated cDNAs and ORFs combined with experimental results, and thus helps to unravel new features of proteins with as yet unknown functions (Bannasch *et al.* 2004).

### The Mouse Brain Library (MBL)

<http://mbl.org>

The MBL is comprised of four interrelated components: The Brain Library, iScope, Neurocartographer and WebQTL. The centerpiece of the MBL is an image database of histo-

logically prepared museum-quality slides representing nearly 2000 mice from over 120 strains – a library suitable for stereologic analysis of regional volume. The iScope provides fast access to the entire slide collection using streaming video technology, enabling neuroscientists to acquire high-magnification images of any CNS region for any of the mice in the MBL. Neurocartographer provides automatic segmentation of images from the MBL by warping precisely delineated boundaries from a 3D atlas of the mouse brain. Finally, WebQTL provides statistical and graphical analysis of linkage between phenotypes and genotypes. This website provides universal access over the web to tools for the genetic dissection of complex traits of the CNS – tools that allow researchers to map genes that modulate phenotypes at a variety of levels ranging from the molecular all the way to the anatomy of the entire brain (Rosen *et al.* 2003).

### The Mouse Genome Database (MGD)

<http://www.informatics.jax.org>

The MGD forms the core of the Mouse Genome Informatics (MGI) system: a model organism database resource for the laboratory mouse. MGD provides essential integration of experimental knowledge for the mouse system with information annotated from both literature and online sources. MGD curates and presents consensus and experimental data representations of genotype (sequence) through phenotype information, including highly detailed reports about genes and gene products. Primary foci of integration are through representations of relationships among genes, sequences and phenotypes (Eppig *et al.* 2005).

### The Mouse Phenotype Database Integration Consortium (MPDIC)

<http://interphenome.org>

### Multicentre Mouse Behavioural Trial

<http://www.albany.edu/psy/obssr3>

### The Mutant Mouse Behaviour Network (MMB)

<http://www.medizin.uni-koeln.de/mmb-network/index.html>

The non-profit international MMB was founded within the framework of the conference 'Behavioural Phenotyping of Mouse Mutants', February 2000, held in Cologne, Germany. It intends to be a forum for presenting and discussing all topics dealing with the behavioural phenotyping of mice. The major aim of the MMB is to support the interdisciplinary finding of a consensus on the methods and techniques used for behavioural phenotyping of mouse mutants. That means that scientists involved in the development of mouse models have to consent to the fact that a consideration of all the parameters that might affect the behaviour is necessary. The network will provide a standardised database that includes detailed descriptions of test methods and of the relevant background parameters that might influence the behaviour of mice. Information will range from detailed descriptions of test methods, specifications of the equipment used, housing conditions and specifications of the animals used according to the international nomenclature. A mailing list has been established to provide a platform for the continuous exchange of information between the network members. Scientists from all research areas involved are free to provide detailed information about their experimental work. (Crabbe *et al.* 1999; Surjo & Arndt 2001).

### My Mouse

<http://www.gsc.riken.go.jp/mouse/aboutus/screening.htm>

### The Pharmacogenetics Research Network and Knowledge Base (PharmGKB)

<http://www.pharmgkb.org>

The National Institutes of Health, recognizing: (1) the need for fully disclosable and publishable research in this

domain; and (2) the need to store the results of this research in a public database, has funded PharmGKB. This will become a national resource containing high-quality structured data linking genomic information, molecular and cellular phenotype information and clinical phenotype information. For further information, please see <http://www.nigms.nih.gov/funding/pharmacogenetics.html>. The ultimate product of this project will be a knowledge base that will provide a public infrastructure for understanding how variations in the human genome lead to variations in clinical response to medications (Klein *et al.* 2001).

### PRIME – Priorities for Mouse Functional Genomic Research Across Europe

<http://www.prime-eu.org>

### The Rat Genome Database (RGD)

<http://rgd.mcw.edu>

The RGD aims to meet the needs of its community by providing genetic and genomic infrastructure while also annotating the strengths of rat research: biochemistry, nutrition, pharmacology and physiology. RGD works towards creating a phenome database. Recent developments can be categorised into three groups: (1) improved data collection and integration to match increased volume and biological scope of research; (2) knowledge representation augmented by the implementation of a new ontology and annotation system; (3) the addition of quantitative trait loci data, from rat, mouse and human to our advanced comparative genomics tools, as well as the creation of new, and enhancement of existing, tools to enable users to efficiently browse and survey research data. The emphasis is on helping researchers find genes responsible for disease through the use of rat models (De La Cruz *et al.* 2005).

# 6 Brief introduction to welfare assessment: a 'toolbox' of techniques

Naomi Latham

## Introduction

Animal research will often impact on the welfare of the animals: either, for example, because animals are deliberately exposed to, or genetically altered or manipulated to exhibit disease (eg, mouse models of Huntington's Disease, Mangiarini *et al.* 1996), or because animals are housed in 'standardised' laboratory environments which may not fully meet their natural adaptations and needs (Latham & Mason 2004). Methods of assessing welfare allow us to gauge the level of suffering in research (and indeed other) animals, and to find ways of refining research techniques and housing or husbandry practices so that we can minimise that suffering and increase positive feelings, such as pleasure. This chapter will start by identifying what is meant by welfare, why animal welfare is considered important and who is responsible for ensuring the welfare of research animals. It will then go on to discuss some of the commonly used welfare assessment methods (the welfare assessment 'toolbox').

## What is animal welfare, and why is it important?

Over 200 years ago the barrister and philosopher Jeremy Bentham wrote of animals, *'The day may come, when the rest of the animal creation may acquire those rights which could have been withholden from them but by the hand of tyranny. ... The question is not, Can they reason?, nor Can they talk?, but Can they suffer?'* (Bentham 1789). Since then, the question of what constitutes good animal welfare has been addressed in a number of ways, with some focusing on physical fitness and others on the ability of animals to 'live a natural life' (Duncan & Fraser 1997). However, Bentham's concerns about animal suffering continues to be at the core of animal welfare principles – most closely reflected by the so-called 'feelings-based' conception of welfare, whereby welfare is about the subjective feelings of animals (Dawkins 1988; Duncan 1993). Animal welfare is thus treated as analogous to human welfare – indeed, the term 'welfare' is sometimes used interchangeably with other terms commonly used to describe human welfare, such as 'quality of life' and 'well-being' (Christiansen & Forkman 2007). Like human welfare, current consensus is that good animal welfare is based upon good health and positive subjective states (also referred to as

affective states or emotions, Rolls 1999); while poor welfare occurs when individuals experience negative subjective states, such as suffering, due to disease or injury, or as a result of aversive or frustrating environments (Dawkins 2006; Boissy *et al.* 2007; Yeates & Main 2008). However, unlike humans, the welfare of animals cannot be assessed by asking for a direct verbal indication of their subjective state (which is generally accepted as the 'gold standard' indicator of subjective experiences) (Paul *et al.* 2005). Instead, there is a range – a 'toolbox' – of indirect measures of the behavioural, physiological and neurophysiological/-chemical components of subjective states (measures that will be discussed later in the chapter). These tools can be used to ask two questions that, between them, capture both the physical and mental aspects of animal welfare: 'are animals healthy?' and 'do they have what they want?' (Dawkins 2004). Since these tools only provide an indirect indication of an animal's health or its subjective state it is usually considered good practice to base welfare assessments on a number of parameters rather than a single measure. There are several reasons why good laboratory animal welfare and appropriate, evidence-based assessment techniques are important.

The first of these reasons relates to the ethical obligations of researchers and animal facilities to ensure the welfare of sentient laboratory animals. For a general discussion about the ethical issues associated with animal research see Sandøe *et al.* (1995) and the 2005 report published by the Nuffield Council on Bioethics (Nuffield Council on Bioethics 2005). National regulation, eg, The Animals (Scientific Procedures) Act (1986) in the UK, may also place on researchers legal requirements to ensure the welfare of their animals. There is still debate about whether or not non-human animals are capable of consciously experiencing affective states (Dawkins 1993; MacPhail 1998; see also Mendl & Paul 2004). However, given that many vertebrates possess the brain structures associated with the initiation of emotional arousal (eg, the amygdala) some researchers suggest that we should *'remain open to the possibility that ... primary-process forms of affective experience evolved long before human brain evolution allowed us to think and to talk about such things'* (Panksepp 2003; also, Burgdorf & Panksepp 2006; Kirkden & Pajor 2006). Concern about the ethics of animal research (particularly studies that involve suffering) also influences public support for animal research, and researchers and animal facilities need to be mindful of this. Thus, for example, polls of public opinion

often reveal that the general public are in favour of animal research provided that the research is for serious medical purposes, that there are no alternatives and that animal suffering is minimised (Festing & Wilkinson 2007). However, while being mindful of ethical obligations and the public concern regarding animal research, animal welfare assessment must be rigorous and evidence-based. Moreover, welfare concerns must be assessed from the animals' view-point, not merely from an anthropomorphic view-point, which may be extremely inappropriate. Indeed, for a clear demonstration of the dangers of unfettered anthropomorphism see a recent article by Bekoff in *New Scientist* (Bekoff 2007) – in particular, the counter-argument by Dawkins in the same article.

A further reason for ensuring good welfare in research animals is the often mooted argument that '*good welfare = good science*' (Poole 1997). For example, one of the main behavioural welfare indicators used in research (and other captive) animals is highly repetitive stereotypic behaviour, eg, bar-chewing in mice. However, there is now a large body of evidence indicating that stereotypic behaviours not only stem from frustration (hence their use as a welfare indicator), but that they may also reflect underlying changes in CNS functioning which cause animals to become less able to inhibit responses even if they become inappropriate (termed 'perseverative' behaviour) (reviewed Garner 2006). Stereotypic behaviour has also been directly correlated with changes in neurotransmitter functioning in a variety of captive animals (McBride & Hemmings 2005; Lewis *et al.* 2006), and may reflect stress-induced sensitisation of the dopaminergic pathways (Cabib 2006). These changes then raise questions about whether research animals housed in stereotypy-inducing environments are valid models in ethological and biomedical research. This is just one example of ways in which 'standard' laboratory housing may produce subjects whose validity as models in ethological and biomedical research is questionable (see Sherwin 2004a for a review of numerous other potentially undesirable effects of 'standard' housing). Furthermore, it has been argued that impoverished environments (which are often used in the name of standardisation) may in fact reduce the reproducibility and external validity of results – the so-called '*standardisation fallacy*' (Würbel 2000). Indeed, a series of studies by Crabbe, Wahlsten and colleagues elegantly demonstrated that even when conditions were rigorously standardised conditions across three laboratories, there were significant strain differences in behaviour in a battery of standard tests (Crabbe 1999; Wahlsten 2001). Hence, refining environments and experimental procedures may be beneficial for both animal welfare and the quality of research (Sherwin 2004a; Würbel & Garner 2007; see also Ritskes-Hoitinga *et al.* 2006).

### Who is responsible for animal welfare?

Responsibilities for animal welfare will differ according to local regulation, but it may be helpful to provide a specific example. In the UK, ultimate responsibility for the welfare of animals used in Home Office licensed research lies with each project licence holder – usually the primary researcher on the project (Home Office 1989). This researcher is responsible for

checking the welfare of their animals both on a day-to-day basis and following any experimental procedures. Hence, he or she must not only be familiar with the normal physical appearance and behaviour of their animals, but also with the physiological and behavioural effects of any experimental treatments. This must be specific to their particular subject species, strain or even genotype. For example, researchers working with genetically altered animals must be aware of not only the 'normal' characteristics of the 'wild-type' (control) animals but also with the characteristics of animals with the 'modified' genotype (see Committee on Recognition and Alleviation of Distress in Laboratory Animals (CRADLA) 2008, p. 26). Furthermore, the 'normal' characteristics of animals may also depend upon their age and gender. For example, numerous age-related changes, including changes in pain sensitivity and emotional behaviour, have been documented in research animals; and there are many well documented gender differences in behaviour and physiological stress responses (reviewed CRADLA 2008, p. 27). Researchers should also ensure that they document any relevant information about the signs observed during disease progression or the after-effects of any experimental procedures so that changes in the condition of animals can be assessed and monitored accurately and efficiently (J. Rogers personal communication 2008). Finally, researchers should also try to ensure that they are familiar with the natural biology and behaviour of their subject animal, as this is often essential for understanding how the captive environment can influence welfare (Dawkins 1980), and identifying behaviours that indicate impaired welfare (discussed further later). Table 6.1 contains some key references for information about the natural ethology of the two most commonly used research animals, mice and rats.

However, as well as the main researcher there are various other people who can, and should, be involved in ensuring the welfare of research animals. These include animal care staff, NACWOs (Named Animal Care and Welfare Officers) – or comparable roles in non-UK facilities – and veterinarians (Home Office 1989). These members of staff can provide supplementary support, particularly where researchers are indisposed or unable to spend the time monitoring their animals' welfare, or if they are inexperienced at doing so. Animal care staff play a key role at the 'frontline' of animal husbandry. They may often notice small changes in the physical condition and behaviour of animals (eg, changes to the animal's coat, chromodacryorrhoea, lethargy etc) that may indicate welfare problems. These should be brought to the attention of the researcher or responsible person so that the cause(s) of the problem can be identified and, if possible, addressed. Veterinary staff can also become involved in order to advise animal care staff and researchers as to the best course of action. Indeed, input from animal care staff and veterinarians, who are impartial to the outcome of research, can be essential to avoid bias where the interests of the researcher may conflict with the welfare of the animals.

### The 'welfare assessment toolbox'

There are several different reasons for assessing welfare, and these influence which tool may be right for the job.

**Table 6.1** Key references providing information about the natural biology and behaviour of mice and rats (see also the species-specific chapters in this Handbook for information about these and other laboratory animals).

Species	Relevant publications

Thus, for example, the method will depend upon factors such as:

1. whether the day-to-day welfare of animals is being monitored;
2. whether welfare in particular environments is to be assessed, or how welfare changes following an environmental manipulation (eg, the provision of a potential environmental enrichment);
3. whether animals' preferences or strength of motivation for particular resources (ie, potential environmental enrichments) are being assessed; or
4. whether welfare (specifically pain) is being monitored following an experimental procedure.

The next sections describe the tools available to those wishing to assess welfare in relation to the conditions in which they might be useful. However, please note that this is only intended as a brief introduction to each of these methods. Many of the welfare assessment techniques described below could fill an entire chapter in themselves (and indeed do in other publications, eg, Appleby & Hughes 1995). Thus, those wishing to use any of the following methods are encouraged to familiarise themselves more fully with the literature about their chosen method(s) – particularly in relation to their subject animal of interest.

**Table 6.2** Examples of routine observations of physical appearance (note some of these are specific to certain species).

Body area	Observations
Head	Is the head consistently being tilted to one side?
Eyes	Are the eyes sunken or bulging? Are the pupils constricted or dilated? Are there signs of opacity in the eyes? Are there abnormal secretions, crusting or signs of inflammation of the mucous membranes? Are there signs of chromodacryorrhoea <sup>a</sup> ?
Nose	Are there abnormal secretions or crusting?
Teeth	Are the teeth overgrown or damaged?
Whiskers	Are there any signs of damage to the whiskers (possibly due to barbering) (Figure 6.1)?
Body	What is the body condition of the animal (eg, emaciated, obese etc)? Are there any obvious lumps? Is the body shape asymmetrical? Are there any wounds from fighting?
Fur	Is the fur dull? Are there signs of piloerection (raised fur)? Is there any hair loss?
Anogenital area	Are there signs of rectal or vaginal prolapse?
Breathing	Is the animal's breathing noisy or laboured?

<sup>a</sup>discussed in detail in Assessing welfare: physical and physiological measures section

## Routine welfare monitoring

### Physical condition

Monitoring the physical appearance of animals can be a quick and non-invasive method of assessing welfare, and one that can easily be incorporated into routine daily or weekly checks (Leach *et al.* 2008). Examples of some of the parameters that can be assessed are given in Table 6.2.

Physical condition measures such as these are often incorporated into distress scoring systems (see eg, the scoring sheets developed by Morton and Griffiths, originally published in 1985, and reproduced in CRADLA 2008 p. 109–110), body condition scoring assessments (Ullman-Cullere & Foltz 1999; Clingerman & Summers 2005) and guidelines for assessing health and physical condition in laboratory animals (eg, Foltz & Ullman-Cullere 1999). Many of these are general signs of an underlying problem and may not indicate the specific nature of that problem. Thus, animals exhibiting signs of poor physical condition (particularly multiple signs, or physical *and* behavioural signs (see later in this chapter)) should be assessed by a veterinarian. Assessment of such parameters is somewhat more qualitative (and hence can be more susceptible to between-observer variability, see eg, Beynen *et al.* 1987) than some other meas-

**Figure 6.1** (a) A mouse that has been barbered on its head and whiskers and on its back respectively. (b) A rat that has been barbered on its head. (Pictures: N. Latham.)

ures of physical condition, eg, body weight (which will be discussed later on). However, assessment of physical appearance can have benefits over other more quantifiable measures in certain situations. For example, physical appearance can be assessed non-intrusively (ie, the animals can be assessed visually and do not need to be removed from the home cage); and body scoring systems may be useful in cases where weight loss may be counteracted by eg, tumour growth, organ enlargement or fluid accumulation (Ullman-Cullere and Foltz 1999). In certain situations, though, it may be beneficial to supplement visual examinations of an animal's condition with a physical examination. For example, Beynen *et al.* (1987) found that gallstone-bearing mice did not differ in physical appearance from non-gallstone-bearing individuals, but did differ by exhibiting signs of discomfort during abdominal palpitation.

### Behaviour

Routine checks of home-cage behaviour can also be used to monitor welfare in laboratory animals (Leach *et al.* 2008) and, like physical parameters, behaviour is often incorporated into distress scoring systems (CRADLA 2008, p. 109–110) and guidelines on assessing health and welfare (Foltz and Ullman-Cullere 1999). Examples of home-cage behaviours that might indicate health and/or welfare problems are given in Table 6.3. (Note that this table deals primarily with those behaviours that might be observed in quick, routine checks on animals – it does not include those behaviours that must be assessed over longer time periods, such as stereotypic behaviour, as these will be addressed later in the chapter.) Observations of home-cage behaviour (eg, the frequency of twitching, writhing and rearing behaviour) can also be useful in assessing pain following experimental procedures (see section on Assessing pain).

### Cage observations

Evidence of welfare problems may also come, indirectly, from observations of the cage. For example, evidence of unconsumed food or diarrhoea, blood or other secretions around the cage walls or bedding should lead to a closer examination of animals within the cage (and possibly also

**Table 6.3** Examples of home cage behaviours that may indicate health and/or welfare problems in laboratory animals.

Social isolation
Hunched posture
Huddling
Ataxia (lack of coordination)
Signs of paresis or paralysis

within neighbouring cages) to check for physical signs that may identify the affected individual(s), eg, matted fur around the anogenital area, signs of dehydration (eg, as assessed by the skin tent test) (Thurman *et al.* 1999). The resources provided within a cage may also stimulate questions about welfare, particularly if resources known to improve welfare are absent (eg, nesting material for mice). These types of measures have been termed 'resource input' measures of welfare assessment (Leach *et al.* 2008).

### Assessing welfare and changes in welfare: physical and physiological measures

#### Chromodacryorrhoea

Chromodacryorrhoea (also sometimes known as 'red tears' or 'bloody tears') is the name for red staining around the eyes and nose that occurs when the Harderian glands over-secrete porphyrin. This is commonly used as a welfare indicator in rats, with chromodacryorrhoea occurring (or becoming more severe) following 'stressors' such as cage-cleaning, handling or restraint (Harkness & Ridgway 1980; Mason *et al.* 2004; Abou-Ismaïl *et al.* 2008; Burn *et al.* 2008). Chromodacryorrhoea has also been used (in rats and other species) to assess the effects of certain pharmacological manipulations (Bürgen 1949; Harkness & Ridgway 1980; Rupniak & Williams 1994), including the pharmacological

induction of acute inflammation (Harper *et al.* 2001). Gender differences have been observed in studies assessing chromodacryorrhoea, but the differences are not consistent (Kerins *et al.* 2003; see also Harkness & Ridgway 1980; Martin *et al.* 1984). Chromodacryorrhoea has a number of advantages over other physiological measures of 'stress'. For example, it can be assessed non-invasively and relatively non-intrusively, and unlike other physiological stress responses (eg, hypothalamic–pituitary–adrenal (HPA) axis activity) it has not yet been reported to be increased by physical activity *per se* or 'excitement' (Burn *et al.* 2006). However, this measure has the disadvantage that it is of limited use in species other than rats (since many other laboratory species do not exhibit chromodacryorrhoea), and it is a product of parasympathetic activity, which is not well understood in terms of welfare.

The onset of chromodacryorrhoea is relatively quick. For example, chromodacryorrhoea has been reported to occur within 10 minutes of handling or 20 minutes of restraint (although onset can vary according to the size of the individual) and ceases after approximately 2h (Harkness and Ridgway 1980; Burn 2005). Since grooming (which can also be elicited by 'stressors') removes evidence of chromodacryorrhoea, observations must be made within the initial time period during which chromodacryorrhoea occurs (Burn *et al.* 2006). Numerical scoring systems are generally used to grade the severity of chromodacryorrhoea; for one example of a scoring system see Figure 6.2.

### Body weight

Body weight is commonly used as an indicator of health and/or welfare in research animals. Body weight is often

measured repeatedly during a study, in order to allow ongoing assessment of this measure as well as comparison between treatments (Spangenberg *et al.* 2006; Abou-Ismaïl *et al.* 2008; Simone *et al.* 2008). However, a number of other factors may also influence this measure, including age, activity levels and reproductive cycling (Spangenberg *et al.* 2005; CRADLA 2008, p. 34), as well as tumours and fluid accumulation (as discussed above). Thus assessments of body weight should ideally include comparisons with appropriate (eg, age- and sex-matched) controls. Body weight may also be used as a criterion for humane endpoints in studies, as the rapid loss of a certain percentage of weight can be considered one criterion for euthanasia, eg, 20% in rodents (Ullman-Cullere & Foltz 1999) or 20–25% of body weight in primates (Association of Primate Veterinarians 2008).

### HPA axis activity

HPA axis activity culminates in the release of glucocorticoids – usually corticosterone in rodents and cortisol in other animals – from the adrenal cortex. This release of glucocorticoids functions to mobilise energy stores (CRADLA 2008, p. 37), and so HPA axis activity often increases in conditions where an increase in activity may be appropriate. For example, glucocorticoid levels exhibit circadian variation, with peak levels occurring prior to the onset of the active phase (Terlouw *et al.* 1995). Increases in HPA axis activity then additionally occur during flight/fight responses in aversive situations, but they also occur during other heightened states of arousal, including during coitus and hunting prey (Szechtman *et al.* 1974; Rushen 1991; Walker *et al.* 1992; Toates 1995). Thus, although HPA axis

**Figure 6.2** Scoring system for assessing severity of chromodacryorrhoea in rats. Note that the pictures are not actual photographs of chromodacryorrhoea of differing severities. The pictures have been digitally altered to illustrate the severity of chromodacryorrhoea required for each of the scoring grades. (Picture: Charlotte Burn.)

activity is commonly referred to as the 'physiological stress response', it is necessary to remember that increases in glucocorticoids are not restricted to aversive situations. Hence measures of HPA axis activation must be interpreted cautiously (and, preferably, in combination with other indices of welfare).

Glucocorticoids, or their metabolites, can be assessed in blood (Vahl *et al.* 2005), saliva (Lutz *et al.* 2000), urine (Touma *et al.* 2003), faeces (Lepschy *et al.* 2007) or even hair samples (Davenport *et al.* 2006), and the timescales differ for each of these sampling methods. Thus, glucocorticoids are released into the blood within a few minutes; they appear in the saliva a few minutes later (Kirschbaum & Hellhammer 2000); their metabolites appear in urine and faeces roughly 1–2h and 9–10h later respectively, although this varies according to species, sex, and the time of glucocorticoid release (Touma *et al.* 2003; Lepschy *et al.* 2007); and changes in glucocorticoid levels can be measured in hair samples some weeks later (Davenport *et al.* 2006). Due to the differences involved in sample collection and the timescales over which the responses appear there are pros and cons to each of the sampling techniques listed above, and these are detailed briefly in Table 6.4.

#### Other 'stress' hormones

Although HPA axis activity is the most commonly assessed hormonal 'stress' response, plasma levels of various other hormones are also sometimes monitored. These include catecholamines, such as adrenaline (epinephrine), prolactin, growth hormone, luteinising hormone and oxytocin (Manteca 1998; Paul *et al.* 2005; CRADLA 2008). Similar caveats to those that apply to HPA axis activity also apply to

many of these measures in terms of the influence of circadian variation, invasive sampling techniques and the fact that these hormones are also released in response to neutral or even pleasurable stimuli. Indeed, oxytocin release (in contrast to many physiological measures) often occurs during bonding experiences, such as suckling and maternal care, and so tends to be interpreted as indicating positive affective responses (Carter 2001). Hence this may be a potential measure if we consider welfare to be not only about the reduction of negative feelings but the promotion of positive feelings (Paul *et al.* 2005; Boissy *et al.* 2007; Yeates & Main 2008).

#### Autonomic responses

Autonomic responses, such as heart rate (particularly 'stress-induced' elevations from baseline levels), heart rate variability, blood pressure and respiratory rate, are frequently used to assess welfare in farm animal and equine studies (Boissy *et al.* 2007; von Borell *et al.* 2007). Autonomic responses are also commonly used to monitor physiological functioning in biomedical research and to monitor general activity levels (Irvine *et al.* 1997; Gross *et al.* 2008). However, these measures seem to be less commonly used, at present at least, to assess welfare in research animals (although some examples include Beerda *et al.* 1998; Duke *et al.* 2001; Sharp *et al.* 2002; Arras *et al.* 2007). Autonomic responses may be less commonly used here because monitoring them often requires the use of telemetry devices that: (i) must be surgically implanted into the research subjects; and (ii) are still relatively large and heavy compared to the body size of most research animals (the vast majority of which are mice and rats). Thus, although some researchers report that telemetric

**Table 6.4** Pros and cons of the different methods of glucocorticoid analysis.

Sample type	Pros	Cons
Blood	Allows accurate assessment of acute glucocorticoid responses	Sample collection is invasive Potential risk of sampling procedure influencing sample levels (if sample is not collected quickly enough) Provides information about levels at one moment in time ('point sample' <sup>a</sup> ) Vulnerable to circadian variation <sup>b</sup>
Saliva	Allows accurate assessment of acute glucocorticoid responses Non-invasive sampling method	Only non-invasive in species that can be trained to provide samples or that readily chew the collection device Training may be lengthy and not always successful <sup>c</sup> Provides information about levels at one moment in time ('point sample' <sup>a</sup> ) Vulnerable to circadian variation <sup>b</sup>
Urine/faeces	Non-invasive sampling method (unless urine is forcibly extracted at a particular time-point) Less vulnerable (but not invulnerable) to circadian variation Provides an assessment of glucocorticoid levels over several hours ('steady state' sample <sup>a</sup> )	Assessment of acute responses may require repeated sampling during the time period at which responses typically appear in the urine/faeces
Hair	Non-invasive sampling method Not vulnerable to circadian variation	Provides only a chronic index of glucocorticoid responses

<sup>a</sup>CRADLA (2008)

<sup>b</sup>samples must be collected at the same time of day

<sup>c</sup>Lutz *et al.* (2000)

assessment of autonomic responses provides information about welfare that otherwise may not have been observed (Arras *et al.* 2007), the low popularity of this method may stem from the desire to avoid using a method that requires surgical implantation of a device that may cause discomfort once implanted. Nonetheless, where animals are telemetered for the purposes of research, there is an opportunity to use the data for assessing welfare.

### Assessing welfare and changes in welfare: behavioural measures

Behavioural signs associated with reduced welfare range from gross changes in the home cage behaviour of animals, to subtle (but significant) changes in cognitive testing paradigms. As alluded to earlier, the ability to identify changes, particularly in spontaneous home cage behaviour, that (are likely to) indicate reduced welfare requires an understanding of the species' natural behaviour and the animals' normal behaviour under captive conditions. Thus, researchers assessing behavioural measures of welfare should ensure that they are familiar with both of these aspects of their subject animals' behaviour.

#### Stereotypic behaviour

Stereotypic behaviours are highly repetitive behaviours caused by frustration or central nervous system dysfunction (Mason 2006). They are also often somewhat invariant, and they can appear to lack function; note that these descriptive characteristics also form the basis for more 'classical' definitions of stereotypic behaviour (Mason 1991). Common examples of stereotypic behaviour in laboratory rodents include bar-biting (Figure 6.3), somersaulting ('back-flipping') and jumping (Würbel 2006), while examples in research primates include pacing, rocking and digit-sucking (Novak *et al.* 2006). There is also an enormous diversity in the prevalence and severity of stereotypic behaviour observed in different laboratory species. For example, stereotypic behaviours have been estimated to develop in approximately 50% of mice in standard laboratory cages, but they appear to be much less common in rats and possibly even absent in guinea pigs (Würbel 2006, p. 88); lower

Figure 6.3 Bar-biting in rats. (Picture: Charlotte Burn.)

prevalence of stereotypic behaviour has been reported more recently in mice, but behavioural observations were made during the light portion of the light cycle, when mice are typically less active (Leach & Main 2008). However, species differences may be due, in part, to inconsistencies in whether or not comparable behaviours are defined as stereotypic in different studies (see the example of bar-biting in rats cited by Würbel (2006) and discussed later in this section).

Stereotypic behaviour is the most commonly used behavioural measure of welfare, but the relationship between stereotypic behaviour and welfare is somewhat complex. The diversity of stereotypic behaviours performed by animals may reflect the diversity of underlying mechanisms that can cause their performance. Some stereotypic behaviours may indeed stem from repeated, frustrated attempts to perform motivated behaviours. Indeed, although stereotypic behaviours often superficially appear to be functionless, a number of studies have elegantly demonstrated the underlying motivation leading to the behaviour. For example, bar-biting in mice stems from attempts to escape from the cage (Nevison *et al.* 1999b) and stereotypic digging in gerbils stems from the desire for a naturalistic burrow (Wiedenmayer 1997). However, in some cases the performance of the stereotypic behaviour itself may be rewarding, acting as a substitute behaviour for motivated behaviours (termed 'DIY enrichments'). In other cases, the stereotypic behaviour may reflect environmentally induced changes in behavioural control processes that cause animals to be unable to inhibit behavioural responses to environmental stimuli ('perseverative' behaviour) (Mason & Latham 2004). Stereotypic behaviours may also, through frequent repetition, become performed out of habit (and shifted into an automatic form of processing known as 'central control'). As a result, different types of stereotypic behaviour (within the same species, and even within individuals) should not necessarily be considered directly comparable in their implications for welfare. Hence, while it is generally accepted that environments that increase stereotypic behaviour are associated with decreased welfare, those individuals exhibiting the most stereotypic behaviour within stereotypy-inducing environments may not have the worst welfare (as assessed by other welfare measures) – perhaps because they have found a stereotypic behaviour that helps them to 'cope' with their poor environment, or because their stereotypic behaviour reflects changes in behavioural control processes (Mason & Latham 2004).

The diversity of stereotypic behaviour, and the question of when the 'normal' performance of a behaviour becomes 'stereotypic' makes scoring the behaviours somewhat complex: and this is one method of welfare assessment that can be greatly enhanced by understanding the subject animals' natural behavioural repertoire (see references in Table 6.1 for information about the natural behaviour of mice and rats). Stereotypic behaviour can be scored from direct observations or video recordings of home-cage behaviour, and is often assessed by scan sampling (observing whether the behaviour occurs *at* specific time intervals, eg, every minute) or one-zero sampling (observing whether the behaviour occurs *during* specific time intervals) (Martin & Bateson 1993). Stereotypic behaviour is often used to compare different environments or treatments (Podberscek

*et al.* 1991; Nevison *et al.* 1999a; Latham *et al.* 2008); or to assess the effects of adding environmental enrichments (Lidfors 1997); or even a rebound effect following the removal of enrichments (Bayne *et al.* 1992). However, one of the problems of using stereotypic behaviour is that scoring these behaviours is often somewhat subjective: researchers may make different decisions about when a behaviour is classed as stereotypic. For example, some authors score bar-biting as stereotypic after only 1s of continuous bar-biting (Garner & Mason 2002), others score it as stereotypic after 10s (Würbel & Stauffacher 1998). Furthermore, some researchers may not define behaviours as stereotypic if they are perceived as functional, or if they are not perceived as reflecting poor welfare. For example, Hurst *et al.* (1999, cited by Würbel 2006) did not classify bar-biting in rats as a stereotypic behaviour because it was considered to be 'functional' escape-related behaviour, yet bar-biting is commonly accepted as a stereotypic behaviour in mice (Würbel *et al.* 1996; Nevison *et al.* 1999a) even though it has also been shown to stem from escape behaviour (Nevison *et al.* 1999b). See also Mason (2006) and Latham and Würbel (2006) for discussions about whether wheel running, tail-chasing in dogs and the use of dummies (pacifiers) by human babies can or should be considered stereotypic behaviours. Thus, researchers/staff must ensure that they detail fully how they have scored stereotypic behaviour, and be careful about drawing comparisons between studies where stereotypic behaviour has been defined and scored in different ways.

### Vocalisations

Vocalisations, including those outside the range audible to humans, have been well studied in research animals for many years, often in relation to reproductive behaviour (rats, McIntosh *et al.* 1984; gerbils, Holman 1980; hamsters, Cherry 1989; deer mice, Pomerantz & Clemens 1981; mice, Warburton *et al.* 1989). However, vocalisations are increasingly also being used as a tool to assess welfare. Much of this research has focused on vocalisations in rats (Brudzynski & Ociepa 1992; Burman *et al.* 2007; Mällo *et al.* 2007; Cloutier & Newberry 2008). However, vocalisations have also been used as a method of welfare assessment in a variety of other species (eg, olive baboons, Crowell Comuzzi 1993; dogs, Gazzano *et al.* 2008; marmosets, Cross & Rogers 2006). Most attention has been paid to vocalisations associated with negative subjective states, such as ultrasonic alarm calls (22kHz) (Cuomo *et al.* 1992; Litvin *et al.* 2007; Wöhr & Schwarting, in press) or audible vocalisations (Burman *et al.* 2008) in rats. Indeed, questions concerning the welfare of animals within auditory range of conspecifics producing such vocalisations have also been raised (Burman *et al.* 2007). Since welfare researchers are increasingly acknowledging the importance of positive subjective states for good welfare (Boissy *et al.* 2007; Paul *et al.* 2005; Yeates & Main 2008), there is an increasing focus upon vocalisations that indicate positive feelings. The best known and most commonly studied of these is the 50 kHz call in rats – the so-called rat 'laughter', which can be elicited by tickling rats and mimicking play behaviour (Panksepp & Burgdorf 2000, 2003) or which increase during food consumption, mating, electrical self-

stimulation of the brain or the use of addictive drugs (Wöhr *et al.* 2008). However, some researchers have recently suggested that experience, context and individual differences can influence 50kHz calls, and that some caution is required when interpreting these calls with respect to their welfare implications (Wöhr *et al.* 2008).

### Anticipatory behaviour

Anticipatory behaviour is the behavioural response that is 'elicited by rewarding stimuli that lead to and facilitate consummatory behaviour' (Spruijt *et al.* 2001). Anticipatory behaviour is associated with feelings of 'wanting'; this is termed 'incentive salience' and is different to 'liking', which is the hedonic pleasure associated with consummatory behaviour (Berridge & Robinson 1998). Anticipatory behaviour has mainly been investigated in rats using classical Pavlovian training tasks, whereby a 'reward' (such as a sugary food, the opportunity to mate or interact with others) is announced by a 'conditioned stimulus', eg the sound of a bell. The amount of active behaviour performed by the animal(s) is then scored during the intervening period between the animal hearing the bell and the presentation of the reward (Van den Berg *et al.* 1999, 2000; Von Frijtag *et al.* 2000, 2001). This activity score is then compared with that of control animals that heard the bell but did not receive the reward. However, anticipatory activity is not expressed in the same way in different species. For example, rats exhibit an increase in anticipatory activity in the period between the conditioned stimulus and the arrival of the reward, while domestic cats exhibit a decrease in the number of behavioural transitions during this time. It has been suggested that this may reflect species differences in food-acquisition behaviour: for example, rats actively explore for food while cats often employ a 'sit-and-wait' strategy when close to prey (Van den Bos *et al.* 2003). Anticipatory behaviour can be used to assess sensitivity (incentive salience) to different types of rewarding stimuli (Van Der Harst *et al.* 2003b, 2005), or to assess (poor) housing-induced sensitisation of the mesolimbic dopaminergic system (Van Der Harst *et al.* 2003a).

### Cognitive bias

Tasks assessing cognitive bias are one of the newest tools in the welfare assessor's toolbox. This method of animal welfare assessment was proposed by Mendl, Paul and colleagues (Mendl & Paul 2004; Harding *et al.* 2004; Paul *et al.* 2005), and is based on the wealth of evidence from the human literature that people who report negative feelings tend to make negative judgements about ambiguous stimuli or anticipated events, while those reporting positive feelings tend to make more optimistic judgements (Paul *et al.* 2005). In humans, cognitive biases are typically investigated using linguistic tasks (Mathews *et al.* 1989; Eysenck *et al.* 1991): for example, Mathews *et al.* (1989) found that clinically anxious subjects are more likely to interpret ambiguous words or phrases in a threatening sense (eg, die vs dye) than normal controls. Recently, these tasks have been modified for use in animals. Thus, Harding *et al.* (2004) trained rats to perform a lever press to one auditory stimulus (a tone) in order to receive a food reward and to refrain from pressing the lever

following a different tone in order to avoid 30 s of loud white noise. The rats were then housed in different types of housing and subsequently tested with the training tones and three intermediate (ambiguous) tones. Harding and colleagues found that rats housed in 'unpredictable' housing made fewer and slower responses to the tone associated with food and the ambiguous tones that were closer to it – findings that are comparable with those in anxious or depressed humans. Similar techniques and results indicating 'pessimistic' and 'optimistic' behaviour have subsequently been published in further studies on rats and in European starlings (Bateson & Matheson 2007; Matheson *et al.* 2008; Burman *et al.* in press). Given the increased emphasis on positive subjective feelings in welfare research (Boissy *et al.* 2007; Yeates & Main 2008), tasks which enable us to assess positive feelings (such as optimism) are thus an important addition to the welfare assessment toolbox.

### Assessing welfare and changes in welfare: brain measures

The processes that lead to affective states and the physiological and behavioural indicators of welfare that we assess are regulated by the brain. Thus, affective states are elicited by neural processing (eg, in the amygdala and limbic regions) of the rewarding and punishing properties of sensory stimuli (Rolls 1999; Panksepp 2003). Stimuli then elicit physiological responses by additional processing through regions including the hypothalamus, pituitary and brainstem; and behavioural responses by additional processing through the basal ganglia, ventral tegmental area, motor cortical areas and cerebellum (Sapolsky 1992; Toates 2004). Thus, welfare can be assessed by monitoring activity or changes in these regions: for example, by assessing glucocorticoid activity or receptor levels or neurotransmitter functioning (eg, dopaminergic functioning) (Broom & Zanella 2004). Indeed, a number of aspects of brain functioning have been correlated with physiological or behavioural indicators of welfare: for example, numerous studies have found a correlation between aspects of dopaminergic functioning (particularly dopamine receptor levels) and stereotypic behaviour (McBride & Hemmings 2005; Lewis *et al.* 2006). One disadvantage of assessing brain function is that it can be invasive, such as requiring surgical electrode implants or requiring *post-mortem* brain analysis, and in some cases the most humane killing methods cannot be used because they disrupt the brain regions of interest. However, technological advances mean that, with the right equipment, eg, functional magnetic resonance imaging (fMRI) or positron emission tomography (PET), it may be possible to assess brain activity during pleasant or unpleasant experiences non-invasively, although such methods are generally currently limited to the assessment of human emotional states (Phan *et al.* 2004).

### Assessing animals' preferences and motivation for resources

In addition to assessing welfare itself, the welfare researchers' toolbox also includes tools for identifying potential

methods of improving welfare. Thus, we can assess animals' preferences and motivation for resources by asking animals to 'vote with their feet' and tell us how they feel about their environment and choices that we offer them (Dawkins 1980; Kirkden & Pajor 2006). This is often used as a way of identifying potential refinements to laboratory housing (eg, environmental enrichments), and the two most commonly used methods (and hence those that will be discussed here) are preference tests and consumer demand studies. However, while these tools enable us to identify potential refinements, the long-term effects of these refinements should then be double-checked using the tools described in previous sections. This additional assessment is necessary because, for example, defensible resources may elicit undesirable behaviours such as territorial behaviour in group-housed animals; and animals (like humans) do not always make choices or behave in ways that maximise their long-term welfare (Silverman 1978; Rutherford 2002).

### Preference tests

Preference tests (as their name implies) investigate the preference of animals for particular resources when given a choice, and they have been a popular tool in welfare research for many years (Fraser & Matthews 1995). Preference tests can be used to assess animals' preferences for different environmental characteristics such as: cage height and light intensity (Blom *et al.* 1992, 1995); different substrates (Van de Weerd *et al.* 1996); nesting material vs nest boxes (Van de Weerd *et al.* 1998); climbing structure orientation, eg, with marmosets (Pines *et al.* 2005); and social contact (Held *et al.* 1995). Preference for the resources is usually measured by time spent with (using) the resources (whereby most time = most preferred). However, there are a number of criticisms that have been levelled at preference tests and *caveats* that should be borne in mind when using them. These have been addressed in detail in a number of places (Duncan 1978; Fraser & Matthews 1995; Bateson 2004; Kirkden & Pajor 2006), so the main criticisms detailed in these other reviews will only be briefly discussed here. The first of these is that preference tests only tell you about the relative preference for different resources, not the absolute strength of motivation for any of the resources. Thus, a preferred resource may only be weakly more reinforcing – eg, a preference for strawberries over blackberries – or alternatively it may be much more reinforcing – eg, copulatory rather than exploratory behaviour.

Secondly, short-term and long-term welfare are not necessarily always compatible. Hence animals may exhibit preferences for resources that maximise their immediate welfare, but may adversely affect their longer-term welfare. For example, certain strains of rodents have long been used as models in studies of alcohol abuse (Green & Grahame 2008). A further interesting example is provided by Silverman (1978), who describes an inhalation toxicity study in which various rodent species were exposed to cigarette smoke. During the initial stages of the study a number of rats, mice and hamsters quickly developed a behaviour whereby they blocked the inlet tube with their faeces: thus apparently demonstrating an aversion to the cigarette smoke. However, later in the study some of the mice developed an apparent

attraction to the cigarette smoke, persistently jamming their noses as far into the inlet pipe as possible.

Thirdly, behaviour in preference tests may be confounded by differential use of the resources, for example due to time of day effects (Van de Weerd *et al.* 1998), or strong but periodic motivation to use resources that provide opportunities for motivated behaviours (such as an enhanced motivation for nesting material in pre-parturient animals, or access to a potential mate when females are in oestrus). Fourthly, preferences can be influenced by the prior experience of the animals. Thus, for example, animals that are used to living in cages may initially show a preference for cages rather than an outdoor pen, a preference that may then change following exposure to the outdoor pens (eg, hens, Dawkins 1980; for some other interesting examples see, Fraser & Matthews 1995).

Finally, preference tests are designed to test preference between two substitutable resources (ie, two resources that satisfy the same motivation). Kirkden and Pajor (2006; see also Fraser & Matthews 1995) suggest that a preference test between non-substitutes (eg, food vs litter) would have little meaning from the animals' point of view since the comparison would not be between the resources but between the strengths of the different motivations. Thus, preference tests can provide useful information about environmental features that may enhance animals' welfare. However, preference tests must be carefully designed so that the link between an animal's preferences and their welfare is valid and reliable.

### Consumer demand

Consumer demand tasks were introduced into animal welfare research in the 1980s, and they are based on ideas traditionally used by economists studying the spending patterns of humans faced with a choice of products and limited income (Dawkins 1983). The basic premise behind consumer demand tasks is that there is an inverse relationship between the price of a resource and the amount that a consumer will buy. By increasing the price of the resource the researcher can then quantify the value that the consumer places on the resource, measuring one or more of the following: (1) the top price that the consumer is willing to pay ('reservation price'); (2) the total amount of income spent on the resource ('consumer surplus'); and (3) the willingness of the consumer to keep on paying for the resource as the price increases ('elasticity of demand') (Varian 1993; Gwartney *et al.* 2005 pp. 56–82). The advantages and limitations of these methods in animal welfare research are addressed in detail by Kirkden and Pajor (2006; see also Jensen *et al.* 2004).

Consumer demand studies have an advantage over preference tests in that they can tell us about the strength of motivation for different resources; we can even determine the absolute strength of this motivation if we 'titrate' it against motivation for essential resources, such as food (termed '*yardstick*' resources, Dawkins 1983; see also Warburton & Mason 2003). In animal welfare studies, consumer demand tasks require animals to 'pay' to gain access to resources, either by performing an operant task (eg, lever pressing – termed fixed ratio (FR) schedules) (eg, Sherwin 2004b, 2007), or by increasing the effort required to acquire

the resource (eg, pushing weighted doors or traversing water) (Sherwin & Nicol 1995, 1996; Seaman *et al.* 2008). Consumer demand tasks can thus be used to assess (quantitatively) motivation for different environmental characteristics in laboratory animals (Manser *et al.* 1996; Sherwin 1998; Seaman *et al.* 2008) and, indeed, farmed animals, where consumer demand techniques are probably even more extensively utilised (Gunnarsson *et al.* 2000; Mason *et al.* 2001; Jensen *et al.* 2004).

However, like preference tests, there is a number of factors that must be borne in mind when designing consumer demand tasks; these are also reviewed in more detail by Kirkden and Pajor (2006). For example, motivation for some resources may be influenced by whether or not the resource can be seen (ie, for some resources '*out of sight = out of mind*') (Warburton & Mason 2003), and where the cost of accessing the resource must be '*paid*', eg, whether the cost is paid on entry or exit from the resource (Warburton & Nicol 1998). Furthermore, many consumer demand tasks use animals that are individually housed, yet individual housing may affect motivation for resources (Sherwin 2003; Cooper 2004; see also the Anticipatory Behaviour section). Thus, finding methods of assessing motivation in group-housed animals (Sherwin 2004b, 2007) may be more complex, but ultimately more appropriate where animals are typically group housed (as most laboratory animals are).

### Assessing pain

Animals' experience of pain has been the centre of as much debate as animals' experience of affective states ('emotions') such as pleasure or suffering. Pain in humans is defined as '*an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage*' (International Association for the Study of Pain (IASP) 1979). However, this definition relies on verbal self-report and hence is not suitable for defining pain in animals (or indeed small children or mentally handicapped humans) (Rutherford 2002). Thus, a number of other definitions of animal pain have been proposed: for example, Rutherford (2002) cites a definition by Zimmerman that '*pain in animals is an aversive sensory experience caused by actual or potential injury that elicits protective motor and vegetative reactions, results in learned avoidance behaviour, and may modify species specific behaviour, including social behaviour.*' The relatively recent nature of this debate is perhaps not surprising given that it was less than 150 years ago that it was still commonly felt that people of some races, the poor and the uneducated were insensitive to pain: indeed, even within the last decade there has been discussion about whether very young human children experience pain (Weary *et al.* 2006). However, despite the debate about whether animals consciously experience pain, it is generally accepted that mammals and birds at least do have the underlying physiological and neurological structures necessary to experience pain, and exhibit physiological and behavioural responses comparable to human responses (Rutherford 2002).

As in general welfare assessment, the ability to assess pain is greatly enhanced by understanding animals' normal appearance and behaviour and species-typical pain

responses (Flecknell & Molony 1997; American College of Laboratory Animal Medicine (ACLAM) 2007). Indeed, additional training in pain assessment techniques (particularly using visual examples of pain-related behaviour) may help researchers to identify and score pain more accurately and reliably (Flecknell & Roughan 2004); see Roughan and Flecknell (2006) for an example of a researcher training system. Like welfare, pain is often assessed by monitoring general measures of body functioning, such as changes in body weight, reduced feeding and drinking (Weary *et al.* 2006), physiological responses, including HPA axis activity (Wright-Williams *et al.* 2007) and behaviour, including pain-related behaviour and vocalisations (Cooper & Vierck 1986; Jourdan *et al.* 1998); see also ACLAM (2007) and Table 6.5.

In addition to the general observations in Table 6.5, pain assessment can measure the prevalence and severity of specific pain-related behaviours. Pain-related behaviour in laboratory animals has probably been most studied in rats, and four behaviours have been identified as likely reliable indicators of pain in rats: cat-like back arching, horizontal stretching followed by abdominal writhing, and twitching while inactive (Roughan & Flecknell 2001); the nature of the primary pain-related behaviour may, however, depend upon the nature and location of the pain (Flecknell and Roughan 2004). Four similar behaviours have also been identified as likely pain indicators in mice: flinching, writhing, rear leg lift and pressing the abdomen to the floor (Wright-Williams *et al.* 2007). These behaviours can be scored from direct observations or video recordings of animals in their home cages (or recovery cages), but observing and scoring these behaviours can be very time-consuming, and thus may not be practical in all situations (Flecknell and Roughan 2004). However, technological advances mean that such behaviours can now be scored in a fraction of the time by shape recognition software packages, such as HomeCageSys software (M. Leach, presentation at the inaugural symposium of the CIMPP, Sept 2007).

## Concluding remarks

Animal welfare, like human welfare, is generally accepted to be about subjective feelings, such as pleasure and suffering. Despite ongoing debate about whether or not labora-

tory animals are capable of consciously experiencing subjective feelings, laboratory animal welfare is widely considered important, not only for ethical reasons but increasingly also because of its potential impact on scientific validity. Although animals cannot be asked about their feelings directly, there is a broad (and increasing) range of tools available which can be used to provide an indirect indication of animals' subjective states. Many of these tools have been described in this chapter. The diversity of tools in the welfare assessor's toolbox means that different methods are available for the different types of welfare assessment that might be necessary during the course of a research animal's life. Thus, the physical appearance and home-cage behaviour of animals can be used to monitor their welfare on a day-to-day basis; while longer-term or treatment effects on welfare can be assessed by measuring physiological responses (eg, HPA axis activity – the physiological 'stress response'), home-cage behaviour (eg, stereotypic behaviour), vocalisations and performance in behavioural paradigms that reveal sensitivity to rewarding stimuli and cognitive states, such as optimism.

Tools are also available (tasks designed to assess preference and motivation for resources) that enable potential refinements to laboratory housing to be identified – techniques that are regularly used in the growing field of refinement research. When used, and appropriately analysed, these techniques can help the identification and assessment of animals' negative and positive subjective states, and find techniques of refining housing and husbandry practices and experimental procedures that make a genuine and meaningful difference to the welfare of research animals. Thus, for example, such research has shown that laboratory mice prefer environments that contain nesting material and indeed will work to get nesting material (Roper 1975; Van de Weerd *et al.* 1998), and that providing nesting material can help to reduce behavioural problems such as aggression (Van Loo *et al.* 2002). Hence, the provision of nesting material is now widely recommended for laboratory mice (Jennings *et al.* 1998), and its presence in mouse cages is used as a 'resource input' measure of welfare by animal care staff and researchers (Leach *et al.* 2008).

Finally, for many years (even dating back to the thoughts of Jeremy Bentham) questions about welfare have focused upon animal suffering. Therefore, it is encouraging that the

<sup>a</sup> citing Karas *et al.* 2001 and Goecke *et al.* 2005

increased interest in finding tools that enable us to assess positive subjective states reflects the increasing emphasis on the importance of ensuring that research animals not only do not suffer any more than is necessary, but that they experience positive subjective states, such as pleasure, and hence actually have good (and not just the absence of poor) welfare.

## Acknowledgements

I would like to thank Charlotte Burn for the use of her pictures and chromodacryorrhoea scoring system, and Janet Rogers and Manuel Berdoy for helpful discussions about welfare assessment during the production of this chapter. I would also like to thank the two reviewers, whose constructive comments have helped to improve this review.

# 7 Welfare and 'best practice' in field studies of wildlife

Julie M. Lane and Robbie A. McDonald

## Introduction

Wildlife research is exciting and is an appealing career for many aspiring scientists. The life of the wildlife biologist or vet and the thrill of capturing and handling wild animals are glamorised by the media, and the professions are often treated as being synonymous with working to promote animal welfare and conservation. However, field studies of wild animals carry with them multiple risks for the animal subjects. Unfortunately, these risks and problems are sometimes given scant consideration by practitioners, often because they are judged relative to natural processes or are incurred 'for the good of the species' or population. Whilst wild animals undoubtedly suffer a range of markedly inhumane fates in the wild, and while some are in grave need of intervention for conservation and management reasons, the ethical/moral absolute of the welfare of the individual animal and the corresponding deep concern felt by society, mean that field research on wild animals requires an approach to ethical issues and the implementation of the Three Rs (3 Rs, see Chapter 2) that is as rigorous as for other areas of research using animals.

For a range of historical and subjective reasons, 'wildlife' is most commonly construed as naturally free-living vertebrates, most commonly mammals and birds, and to a slightly lesser extent, reptiles, amphibians and 'fish'. The huge diversity within and among these taxa, means that there is little consistency in their physiology, let alone their behaviour. Even within species, individuals and populations are likely to be behaviourally distinct; indeed this fine-scale variation is itself often the focus of field investigation. Generalising the needs and responses of individuals of particular populations and species is, therefore, an ambitious and probably unrealistic endeavour. All investigators and regulators must view field studies on a case-by-case basis, bringing relevant experience to bear where possible, but being prepared for exception and novelty. Since much of the legislation dealing with scientific procedures on animals is restricted to vertebrates (see Chapter 8), invertebrates will not be considered in this chapter. *Octopus vulgaris*, for example, is covered by legislation in the UK and, at a European level, protection may be extended to all cephalopods and decapod crustaceans. Kept animals, such as companion animals and farm livestock, will also not be considered. However, cats (*Felis catus*), dogs (*Canis familiaris*), pigs/boar (*Sus scrofa*), goats (*Capra aegagrus hircus*), horses (*Equus caballus*) and other kept animals, such as

ferrets (*Mustela furo*), mink (*Neovison vison*), often return to a free-living state, sometimes outside of their native range, where they can revert to wild-type appearance and behaviour. Such feral animals are, to all intents and purposes, wild and so they fall within the scope of this chapter.

The object of field studies is to examine how wild animals behave in the wild or in as natural a situation and habitat as possible. Observations in the field might require little direct intervention, and be as apparently straightforward as observing animals from a distance, comparable to a bird-watcher's hobby. However, other treatments, procedures and initial observations might take place in the laboratory, or in other situations where wild animals are held captive for periods of time. Interventions might carry forward into the field, obviously when animals are equipped with tags or telemetry devices and less conspicuously if they are treated with internal markers, drugs or if their social or physical environment is manipulated around them. Therefore, this review extends to any interaction with wild animals in the field, the taking of animals from the wild and includes making observations or applying treatments in captivity, where captivity is temporary and takes place in the field or requires holding animals for periods of between a few hours and a few days. We will not dwell on the use of wild-caught animals in prolonged or terminal laboratory work, but focus on cases where animals are subsequently released back to the wild.

When working with animals in the wild, the work and its potential effects on the animals are often subject to uncertainty and unpredictability. It is never certain, for example, how many animals might be caught in a trap round or cannon net or how individuals might behave or respond to capture or interventions. With experience, many of these risks can be identified and mitigated. Expecting the unexpected and building appropriate contingency plans and budgets carries financial costs, but these are usually minor relative to the cost of mistakes and misjudgement which may lead to the projects being abandoned because of failures to comply with legislation and/or public opposition.

## Reasons for wildlife research

The management of wild animals is an intrinsic part of land management. Often these practices have developed over centuries of common practice and form part of routine pest management for disease control and crop protection, as well

as for food and sport. More recently, as awareness of the threats to biodiversity conservation has increased, management is frequently undertaken to enhance the status of threatened species. As society and the environment change, it is becoming much more important that we understand how wild animals might respond to management actions. Regulatory authorities and private sector interests can also intervene in management, by requiring evidence of humane treatment, efficacy or cost-effectiveness.

Studies may be carried out to examine wild animal biology, including population dynamics and individual behaviour and welfare. Wild animals are also used as indicators of environmental health. For these studies, the benefits in terms of knowledge, understanding and the conservation of the species are usually clearly articulated, however, the costs incurred to the individual animals are often not as well understood.

One critical difference between wild animal studies and the use of laboratory animals in research is that the subject of interest and focus of investigation is usually the subject animal in its own right rather than it serving as a model for the human condition or as a model of any other living system. For this reason, total replacement of animals in wildlife research (unlike, for example, clinical studies) will never be a feasible option (see Cuthill (2007) and Barnard (2007) for fuller discussions on this topic) and for many wildlife studies captive or captive-bred animals will never be a substitute for free-living animals. Nonetheless, due consideration should always be given to seeking alternatives where possible.

## Welfare implications of wildlife studies

### Effects of stress

All interactions between humans and animals have the potential to cause stress and behavioural or physiological changes and this is particularly likely with wild animals, where any kind of direct interaction is usually perceived as a threat. Stress is an integral part of all animals' lives and the body has developed many mechanisms for coping with both psychological and physical stressors (Broom & Johnson 1993). However, acute or prolonged stress can have diverse, profound and deleterious effects on the psychological and physiological health of animals and it is usually in the latter case that animals are said to be 'suffering from distress'. In wildlife studies the onset of these stress-related effects is of particular importance as the effects are difficult if not impossible to determine. This is because animals are normally released into the wild before any symptoms become apparent and, unlike laboratory subjects, wild animals are not constantly provided with the essentials of life (such as food, water, shelter) and so their survival is routinely challenged on a range of fronts.

In severe cases, acute stress can cause death from cardiac failure, but in the majority of instances the effects of acute stress will be more long term and harder to define. Physiological indicators of stress that may be observed during capture include shortness of breath (panting) and tachycardia (racing heart). However, from a behavioural

point of view stress reactions are more difficult to ascertain and very much rely on having detailed knowledge of the biology of the study animals. For example, some animals become motionless (eg, rabbits (*Oryctolagus cuniculus*)) or may appear relaxed (eg, badgers (*Meles meles*)) when confronted with a stressor, whereas other animals will be hyperactive and spend a great deal of time in escape behaviours (eg, rats (*Rattus* spp.)). In addition, variation in response to stressors can occur within a species, with differences apparent in the reactions of dominant and subordinate animals and between genders (Overli *et al.* 2006).

The long-term physiological components of stress can affect most aspects of an animal's biology. High levels of stress hormones (such as glucocorticoids) are linked to poor reproductive success in males and females (Rivier & Vale 1984; Sapolsky *et al.* 2000) and reduced immunity from disease (Munck *et al.* 1984), both of which have the potential for significant impact on a wild animal's life and fitness.

### Injuries

Apart from physiological effects there are also adverse physical consequences of field studies, primarily arising from capture and captivity. These range from minor injuries such as skin abrasions and tooth and claw damage in animals attempting to escape from cage or box traps and abrasions from external devices (eg, radiocollars) up to more severe injuries such as broken limbs (eg, birds in mist nets, 'foul' captures in traps), adverse reactions to drugs, predator attacks or death (eg, fish in gill nets).

One particularly serious problem associated with capture of wild animals is myopathy. This can occur when an animal is subjected to stress and intense physical exertion. It is unusual with cage trapping but can be found with netting or prolonged pursuit and handling of large mammals, particularly deer (Haulton *et al.* 2001). The condition is caused by a build up of lactic acid in muscles leading to stiffness, paralysis and, in extreme cases, eventual death (Conner *et al.* 1987). Symptoms normally have a delayed onset (sometimes over 1 week) and hence are rarely identified during capture. It is imperative, therefore, that stress levels are kept low by ensuring confident and effective handling and brief periods of pursuit and capture.

### Other welfare effects

If the welfare status of an animal is unduly compromised this has repercussions, not only in ethical terms, but also on the validity and rigour of the scientific study itself. The stress associated with capture (and particularly when associated with anaesthesia) can have wide-ranging effects on an animal's biology, behaviour and ecology, and allowances must be made for these. Poor welfare arising from studies can have effects on the areas discussed in the following paragraphs.

### Social structure and behaviour

The establishment and maintenance of social status within animal groups is complex and varies greatly with taxonomy,

environment and among individuals. Social rank in a group is determined by many factors, but higher rank is often gained through aggressive behaviour linked to levels of the male hormone testosterone (Abbott *et al.* 2003; Schaffner & French 2004). Stress can alter levels of testosterone and hence may have an impact on the dominance hierarchies of a population, particularly in group-living animals such as wolves (*Canis lupus*). In addition, even the temporary removal of an animal from its social group (especially the dominant male and female), may affect its position and the relative status of several others and be the cause of unrest and heightened aggression in the group. The effect of large-scale permanent removal of individuals on social structure has been well documented in badgers. Badger culling employed for the control of TB has resulted in disruption of territoriality, increased ranging behaviour and mixing between social groups (Carter *et al.* 2007).

### Reproductive behaviour

The effect of stress on levels of sexual hormones is well documented and could have wide-ranging effects for males and females, with respect to their reproductive investment and success. Anaesthesia has the potential to cause abortion in the early part of gestation and premature birth in late pregnancy. It has also been shown that handling young can cause the mother to kill or abandon them. Therefore, where reproduction is not a focus of the research, studies might, where possible, avoid the sensitive parts of breeding seasons. There are also instances where the procedure itself can influence mating behaviour. This has been demonstrated in bird species that use 'badges of status', where ringing these birds can have an impact on mate choice (Burley 1986).

### Foraging behaviour

Anaesthesia and stress can affect the metabolic condition and cognitive ability of an animal in the short term rendering it less able to forage. Alternatively, periods of captivity in the absence of preferred food may affect an animal's nutritional status and foraging choices upon release. This problem can be minimised if studies are conducted at times when there are fewer external pressures such as low food availability.

### Spatial behaviour

Some animals have been shown to move away from an area from where they have experienced capture and anaesthesia presumably as the stress of this experience is associated with this geographical area (Teixeira *et al.* 2007). Others tend to be more sedentary than normal after capture and release. This has, potentially, wide-ranging effects on the population dynamics of group-living animals and also on the survival of individual animals that forsake their known home ranges and food sources.

While such changes may be temporary, resulting measures may give a misleading impression of typical ranging behaviour. Where observation periods are brief, these measures will be even more prone to bias.

### Survival and mortality rates

Even the ringing of birds can have an effect on mortality in a population (Recher *et al.* 1985; Inglis *et al.* 1997). The procedure itself can directly affect the probability of survival and in addition, wild animals often carry underlying latent infections such as toxoplasmosis (eg, in sparrows) that may, as a result of lowered immunity due to stress, develop into clinical disease (Bermúdez *et al.* 2009).

### Population dynamics

There is always the potential that the study itself might have a direct effect on the results. Increased mortality and disease are both possibilities but more subtle effects may be more difficult to determine. Moorhouse and Macdonald (2005) demonstrated that the sex ratio of a population of water voles was affected by the trapping and radio-tracking programme over a 3-year period. Over this time one discrete population of the water voles was regularly trapped and anaesthetised whereas a separate population was left undisturbed. After 3 years, both populations were trapped and the numbers estimated. It was found that the first population had a significantly higher ratio of males to females than the undisturbed voles. The conclusion being that the stress of capture and tracking had caused the mothers to produce higher levels of testosterone leading to an increase in male births.

### Effects on others

One of the main differences in welfare terms between laboratory and wildlife studies is the fact that the latter have the potential to affect not only the study animals but also many other individuals in the surrounding area. Although this may not be avoidable it is always important to be aware of the consequences of any study and factor it into the ethical assessment.

### Conspecifics

The effect of a study on an individual also has potential repercussions for conspecifics especially with respect to group living animals. This includes changes in dominance hierarchies and the onset of disease (see section on Survival and mortality rates).

### Dependents

Removing parent animals from their dependents may cause malnutrition and, in severe cases, death of the young, particularly among animals with altricial young and those in the earliest stages of life. Treatment with drugs, including anaesthesia, has the potential to affect lactation (Yokoyama 1965), potentially exacerbating nutritional problems. Where breeding is not itself the focus of the study, trapping when young are dependent is a risk that should be avoided or mitigated. If there are obvious signs that the animals caught have dependent young (eg, lactation, brood patches), then it is advisable to release them as soon as possible, which may involve a judgement as to whether to carry out all of the intended procedures.

### Non-targets

Capturing non-target species or individuals is almost unavoidable in wildlife studies, but the consequences can be more severe than those for the intended subject. For example, while the research might not be carried out during the breeding season of the subject it may be during that of non-target species; or the trap may not be appropriate (eg, weasels (*Mustela* spp.) caught in uncovered cage traps can die through hypothermia).

## Three Rs and welfare

Exact numbers of wild animals used in regulated procedures are difficult to ascertain, and are not often collated specifically. In the UK, Home Office statistics<sup>1</sup> provide numbers of each species used in a range of subjects but it is not clear how many wild animals are studied in the field. For example 90 419 animals were used in the field of ecology in 2007. Of these 84 252 were fish, many of which were tagged and released as part of fisheries research though others were captive animals used in behavioural ecology research in the laboratory. The remaining individuals largely fell into the categories: Other rodent, Other carnivore, Other mammal (1405) and Other bird (3628) and Any amphibian (1027). Many of these studies of 'non-standard' species may have involved wild animals and will have been carried out at least partly in the field. In addition, wild species are also likely to have been used in other fields of study (eg, zoology, animal welfare). Many wildlife studies, including observational studies or minor interventions such as bird ringing, may not be regulated but nonetheless could affect the welfare of the subject animal.

Although the original definition of the Three Rs (replacement, reduction and refinement) was developed with laboratory studies in mind the principles and philosophy of this concept can be extended to many other areas in which there are human-animal interactions, as a means of ensuring the highest standards of welfare (Cuthill 2007). Unfortunately most of the information readily available with respect to the Three Rs tends to be aimed at their implementation in laboratory studies and many examples are not applicable to wildlife research (eg, cell culture, refinement of housing). This, however, should not lead to the conclusion that implementation of the Three Rs within wildlife research is not necessary or relevant. Here, a number of practical examples of how the Three Rs can be addressed in field studies is provided.

### Replacement

Replacement is often not considered a viable option in studies of the behaviour and ecology of wildlife species, where the specific animals and their natural behaviour are intrinsic to the study (see section Reasons for wildlife research). However, there are alternative techniques that can give us a greater understanding of these topics without the use of animals themselves.

### *In silico* studies (computer modelling)

This approach can be used to generate predictions of treatment effects, often taking into account uncertainty associated with observations and outcomes. In this way, the results of modelling can be more general than those of specific or localised observational studies. While such modelling requires understanding of the quality and representative nature of input data, modelling can also help evaluate the most important avenues of investigation allowing the field study to be refined. This approach has proven particularly effective in estimating population changes and for evaluating methods of management and disease control (Wilkinson *et al.* 2004).

### Use of less sentient species

The substitution of a less sentient and/or non-protected species is usually classed as a form of replacement; this is not appropriate for the majority of wildlife studies, where the species itself is the subject of investigation. However, there is potential for using this type of replacement in ecotoxicology studies, where invertebrate models (eg, amphipods (*Gammarus pulex*)) can be used to assess levels of pollutants (Ashauer *et al.* 2007).

### Read-across approach

This approach is more commonly associated with pharmaceutical and toxicity testing, usually in combination with computer modelling (Schultz *et al.* 2009). At a basic level it involves using data from one species to predict the outcome in others. Although this may not be appropriate for many field studies it may have uses, particularly in more heavily regulated areas such as ecotoxicology and developing population control methods. For example, if determining the effect of pesticides on non-target species data from wood mice (*Apodemus sylvaticus*) may be used to extrapolate to other small rodents such as harvest mice (*Micromys minutus*).

### Reduction

Most of the principles and techniques of minimising animal use in the laboratory are also applicable to studies in the field.

### Statistical design

The use of robust statistical approaches before, during and after the study can help ensure an efficient study where minimum numbers of animals are used and resources are deployed to best effect. Power analysis, where the project scale and sampling techniques are evaluated with respect to a range of probable effect sizes, is particularly important in planning investigations. It can now be applied to a range of complex analytical approaches, though this often requires repeated simulations of statistical outcomes rather than the off-the-peg power analyses available in standard packages (Dytham 2003).

As with laboratory studies, the precision and accuracy of observations in relation to the magnitude of any effect size

<sup>1</sup> <http://www.homeoffice.gov.uk/rds>

are vital in considering the required sample size. Similarly variance in outcomes can be inflated by sampling across outwardly similar groups or environments, potentially masking treatment effects. Sampling design may need to be modified to account for, or avoid, these sources of potential variance. However, sample size and sampling design cannot be easily controlled in the field, and natural error variance and sampling error, if anything, tend to be more pronounced (Feinsinger 2001). The following factors often confound field investigations and should be taken into account in developing the study design:

- species, sex and age;
- weather conditions;
- presence and number of non-targets;
- interference by others (eg, members of the public).

The other factor to consider is that if the sample size is too small, repeating field studies to gain the data required is more difficult than in the laboratory, due to the inability to mimic the exact conditions used in previous trials.

### Sequential testing

Sequential testing (or phasing) is where the sample size is not fixed in advance. Instead, data are evaluated as they are collected and further sampling is stopped in accordance with a predefined stopping rule as soon as significant results are observed. Thus a conclusion may sometimes be reached at a much earlier stage than would be possible with more classical hypothesis testing or estimation, with the potential to use fewer animals. With these techniques, as the study progresses, the design can be refined or the study halted as appropriate.

### Using published or available data

Literature and other resources should be used to inform experimental design, perhaps in a power analysis, and hence reduce the number of animals or trials needed. It is important to note that the read-across approach works in this instance as well (ie, if no data are available for a particular species, searches should be made for data on related animals).

### Sharing data

Data sharing is an important method for reducing animal use across the whole spectrum of animal-related studies. Data are normally shared within a scientific discipline via publications or presentations at conferences but this tends to focus only on positive results and finalised studies. It is as important, if not more so, that negative results and potential pitfalls of animal work are highlighted and a particularly good way of achieving this is by the use of specialist user groups on the web. These can provide an easily accessible and low-cost method to exchange data and ideas.

Samples can be shared as well as information. If different research teams (especially in the same geographical area) all require samples (eg, blood, hair, swabs) from the same species then it may be possible to work together so that the animals only need to be caught and sampled once. This

needs to carry the caveat that the numbers, quantities and types of samples taken from an individual must remain within the best practice guidelines (see later in this chapter) and have the appropriate licensing authority.

### Multi-use technique

This technique is particularly applicable to field use. It is a method of minimising the overall number of animals used by gaining data from one event that may be required for different parts of the study or for a completely separate study (eg, trapping animals for marking for ecological study and taking blood samples for a disease-monitoring programme). A good degree of forethought needs to be exercised when undertaking multi-use studies so that appropriate permissions are in place for all uses and any caveats observed before the studies are initiated.

### Refinement

The main way of addressing refinement with respect to wildlife studies is through opting for the least invasive techniques and always to referring to 'best practice' guidelines and recent experience for capture, handling, marking and sampling appropriate for the species (see section Capture, handling, release). More specific, less-invasive methods are discussed in the following paragraphs.

### Remote cameras

This method involves using remotely triggered cameras to gain information without any capture or manipulation of an animal. With digital technology, these cameras are more sophisticated and can create photographs in various formats, use time-lapse technology, can be motion-sensitive, and can operate at night using infra-red (Figure 7.1). Using video recording and/or still photographs has the advantage over direct observations in that there is less interference (and hence less stress imposed) on the animal and it requires less input from the investigator.

### Non-invasive sampling methods

Many field studies involve taking samples to measure physiological parameters or pathological indicators. Although most of these factors have been traditionally measured in the blood, other less invasive approaches to sampling (eg, saliva and faeces) can be used in many instances to gain the same data. Faecal sampling is of particular interest as it can be used easily without disturbing the subject and without interfering with other welfare measures running in parallel, such as behavioural assessment (Lane 2006). Faecal sampling can be used to investigate hormone levels (eg, cortisol, testosterone), DNA analyses and for bait-marking purposes (Figure 7.2).

### Identification

For some species natural markings can be used as a completely non-invasive method of identification (see Marking).

**Figure 7.1** Image of wild boar using an infra-red camera trap.

**Figure 7.2** Coloured beads as bait markers in badger latrine. A non-invasive and effective method to monitor bait uptake and to determine territory structure is to add coloured beads to baits which can then be detected in the faeces negating the need for any procedure or capture of the animal.

It is also important to be aware of techniques that should not be used in most circumstances due to the availability of more refined alternatives. A good example of this is the use of toe-clipping to permanently mark small mammals and amphibians. This invasive technique causes tissue damage (Golay & Durrer 1994; Reaser 1995), affects survival (Clarke 1972) and has been demonstrated to cause pain and suffering (May 2004). For these reasons it should, wherever possible, be replaced by a non-invasive technique such as natural markings or, if this is not possible, a less damaging technique such as microchipping.

With respect to refinement it is always important to consider the fate of non-targets as well as study animals. Non-targets may encounter the same potential costs to welfare as the target animals such as stress and injury caused by cage trapping or mist netting. Hence, it is vitally important that best practice methods of capture are employed to reduce the incidence of non-target captures (see next section).

## Capture, handling, release

Most wildlife studies in the field include the use of capture, mark and release programmes. The techniques adopted in these programmes can have far-reaching consequences, so it is important to be aware of, and where possible, minimise the potential adverse effects not only on the study animals but also the other animals in the environment.

### General welfare issues

#### Time of year

Research may lead to disruption of normal animal activities, whether as part of the study procedure or incidental to it. Disturbance of breeding individuals and dependent juveniles is of particular concern. Investigators should be aware of the breeding seasons of the species that they propose to

study and ensure that there are no significant welfare implications associated with the timing of their research.

### Time of day

An awareness of an animal's circadian activities is essential for appropriate capture and handling. Nocturnal animals should be kept in darkness when held in traps, as being away from cover during daylight hours will cause them further stress. Animals that are caught without the use of food baits (eg, mist netting of birds and bats) should be released with enough time to forage. If this is not possible, consideration should be given to provision of supplementary food and water or a glucose solution before release.

### Extreme weather conditions (heat or cold)

Checking weather forecasts should always be a priority when carrying out field work. In the UK, the Met Office provide a pay-for service in which detailed, tailored forecasts can be sent directly to an email account. Trapping should be avoided during extreme weather conditions to reduce the possibility of hyper- or hypothermia. Shelter and extra warmth should be considered especially when anaesthetising animals in cold conditions (eg, heat pads, blankets, bubble wrap).

### Non-targets

The capture of non-targets is always a possibility with live trapping so, where possible, use methods which maximise capture of the intended target and reduce capture of other species (eg, set restraining traps on a run). However, always be prepared to deal with non-targets if the need arises. In some cases certain non-target species, usually invasive non-native species (eg, grey squirrel, mink in the UK) may not be released back to the wild under conservation legislation, hence provision for humane euthanasia of these species should be made.

### Capture

The choice of capture method should be made according to the species involved and availability of technology and personnel, potentially including veterinary cover. Methods of capture may be physical, such as the use of traps and nets. Small-medium mammals and birds are often caught in live traps, and netting tends to be the most common method for catching small birds and bats. Larger mammals may be trapped by a variety of methods (live trapping, netting) and may also be chemically sedated using darts. Capture efficiency and capture-related mortality rates have been found to differ considerably between methods and operators and this should be considered before a decision is made.

### Live trapping

It is vitally important that only as many animals as can be effectively and safely dealt with in the time period available are caught. The number of cage traps set, should be the number able to be checked and processed within the allo-

cated time (usually a maximum of 24h, though note that traps checked once in a 24h period could in theory hold animals captive for nearly 48h). It is also beneficial to have a good idea of variation in trap efficiency in the study system (eg, number of captures/100 trap night) so that it can be checked that the plan is achievable. Traps should always be securely shut down or wired open if they cannot be checked with the required frequency.

Being caught and held in a trap can be a very stressful experience for an animal but the trauma can be minimised by:

- avoiding exposed areas (so they are less likely to be bothered by predators, noise, etc);
- providing shade/cover and bedding or similar material where applicable – apart from calming the animal this can also reduce biting and scratching (Figures 7.3, 7.4);
- ensuring traps (and animals) are clearly labelled, particularly if the animals are being moved for processing so that it is known exactly where to return them for release;
- checking frequently – especially with small animals such as shrews (preferably at least twice a day);
- with netting, being able to close down the nets as the handling capacity is approached in the specified time period; small animals have high metabolic rates and can quickly lose condition, so efficiency is of the essence.

Most cage traps rely on a baiting system so food is usually available but it is also recommended that water or food with high water content is provided. In addition, if using live traps for small mammals, food for shrews (eg, fly pupae) should be provided even if they are not the target.

**Figure 7.3** Brown hare (*Lepus europaeus*) in cage trap. Covering traps prevents exposure to the elements and predators and has a calming effect on most species.

## Handling

Wild animals should not be handled unless necessary for the procedure. If handling is required the amount of contact should be kept to a minimum and the safety of the handler and of the animal needs to be considered (Figure 7.4). Wild animals are likely to bite or peck and scratch and are carriers of many zoonotic diseases (eg, *Leptospira*, *Cryptosporidium*) and so caution needs to be exercised at all times and risk assessments carried out before handling any wild animal. The method of handling will depend on the species of the animal and on the procedure to be carried out. However, there are key rules that should be followed:

- Handling should be kept to a minimum.
- Most animals like to be covered as it produces a calming effect. This is *not* the case for some species of deer (eg, muntjac (*Muntiacus reevesi*)), which find being covered more stressful.

**Figure 7.4** Transferring wild rat from cage trap. When dealing with wild animals it is always beneficial if they can be studied with minimal handling. A simple black bag provides a device to extricate wild rats simply and safely from a cage trap. The rats, seeking cover in the darkness, will run directly into the bag avoiding direct handling.

- Handlers need to be confident and competent at dealing with the appropriate species.
- Rodents should never be lifted by the end of tail.
- With birds the hold must include the wings and legs in order to prevent damage to these appendages. Certain species may have specific requirements for physical restraint, including those with long legs and necks (Figure 7.5). Birds breathe by a bellows-like action of the ribs and sternum. Therefore, care should be taken so that the method of restraint does not interfere with the ventilatory movements of the sternum or impede the respiratory air flow.

## Anaesthesia

Under Schedule 2(A) of Animal Scientific Procedures Act, anaesthesia should be used for all regulated procedures unless the use of these compounds is likely to cause more harm and distress. For wild animals, it may be that some procedures that are not inherently painful (eg, fitting a radiocollar) may still require sedation and/or anaesthesia, even if brief, for the handler's safety and the animal's welfare.

With all wild animal anaesthesia, veterinary input and advice should be sought from the outset. Doses, routes and recovery should be discussed fully with a veterinary surgeon before embarking on anaesthetising any wild animal. The following information is for guidance only.

After administering an anaesthetic the animal must be monitored to check that they are at the required depth of anaesthesia and that their vital body functions have not become dangerously depressed. Respiratory and cardiac function must both be monitored closely. When anaesthetising wild animals in the field, inhalation or injectable anaesthetics may be used (see Hall *et al.* 2000 for overview, and see also Flecknell 2009).

### Inhalation anaesthetics

These types of anaesthetics tend to be used for small mammals and birds. There are portable versions of gaseous

**Figure 7.5** Correct handling of a pheasant. Wings and feet are safely secured so the bird cannot damage itself or the handler.

**Figure 7.6** Anaesthesia of a wild boar. Portable gaseous anaesthetic machines are an effective and safe way of maintaining anaesthesia (after initial darting or injection) in medium- and large-sized mammals in field situations.

anaesthetic machines (Figure 7.6) or anaesthetics can be delivered in a chamber in which the liquid compound is poured onto a gauze or cotton wool pad. The former set-up is preferable as it allows much more control of the depth and recovery from anaesthesia and hence should be used whenever it is possible and practical to do so. In the latter device the gas concentration is dependent on the temperature, and in cold winter weather it may be difficult to ensure that the anaesthetic agent actually vaporises. All volatile anaesthetics are irritant when in their liquid state, so the chamber must be designed to separate the anaesthetic-soaked gauze or cotton wool from the animal.

It can be more difficult to safely judge the correct depth of anaesthesia for birds. The avian respiratory system, which consists of a pair of relatively fixed lungs and a group of mobile air sacs, is more efficient at gas exchange than that of mammals and, therefore, birds will often demonstrate a more rapid response to the effects of inhaled anaesthetics. In addition, due to the large volume of stored gases in air sacs, birds can be slow to eliminate the anaesthetics. Recovery from anaesthesia can be facilitated by maintaining the bird in lateral recumbency and turning it every few minutes.

#### Injectable anaesthetics

These are commonly used for larger mammals. They may be delivered through a hypodermic syringe to a trapped or caged animal (eg, badgers, wild boar), or from a distance via a dart (eg, wild boar, deer) and will usually be delivered intramuscularly.

Injectable anaesthetics may be used to induce anaesthesia, which is then maintained with a gaseous anaesthetic. In some instances, particularly with small animals that are highly active, such as weasels (*Mustela nivalis*) the opposite may apply, with short-term anaesthesia induced by inhalation and maintained by injection. It should also be noted that the injectable agent ketamine (when used in isolation) has been shown to cause psychosis in humans particularly with repeated use and hence should be avoided for wild animal anaesthesia unless used in a cocktail with other drugs (such as metomidine) (de Leeuw *et al.* 2004).

#### Darting

Use of a dart-gun to dart wild animals is a specialist skill and may be subject to a number of restrictions. In the UK, dart rifles and blow pipes are classified as Section 5 prohibited weapons under the Firearms Act and require both a permit from the Home Office and permission from the statutory authority before use. Furthermore, there are restrictions on the number of darts that may be held by one individual. Details may vary between authorities and advice should always be sought. When firing a dart, the aim is for the dart to hit the animal at right-angles, ensuring that the needle penetrates the subcutaneous fat and enters the muscle. The propellant pressure of the rifle should be adjusted depending upon the distance between the operator and the animal to ensure that the dart has sufficient velocity to penetrate to the muscle, but not so much that it enters the body cavity. It is essential to practise thoroughly and regularly before using this equipment on animals.

#### Sampling

Methods and volumes for blood sampling of wild species are similar in many instances to those for laboratory species (Joint Working Group on Refinement (JWGR), 1993), although sedation or anaesthesia may be needed for restraint. Due consideration should be given to the health and physiological status of the animal as this can affect the level of handling or the amount of blood withdrawal that can be safely undertaken without causing the animal to go into hypovolaemic shock. As with laboratory animals, no more blood should be taken than is necessary and where alternative less invasive methods are available (eg, use of saliva (Figure 7.7) or faeces) these should be chosen.

If hair and/or whiskers (vibrissae) are to be taken, cutting/shaving rather than plucking is preferable if the follicles are not required. Whiskers should be taken equally from both sides of the face and only a small percentage of the total number of whiskers should be removed at any one time. Feathers should be taken from less essential areas of birds (eg, from the back rather than the wings). For stable isotope

**Figure 7.7** Salivary sampling of a serotine bat. Saliva can be collected without anaesthesia in many species and used instead of blood for a variety of physiological measures (eg, immunoglobulins, stress and reproductive hormones).

sampling of tissues it is important to consider the time at which tissues were formed.

Risk of infection is high in wild animals (perhaps particularly in fossorial species) and hence the use of antibacterial sprays and/or use of surgical glue, is recommended for skin protection following invasive sampling.

## Marking

Recognition of individual animals plays an important part in most wildlife research. Marking can provide information about survival, site fidelity, population dynamics, social behaviour, feeding ecology and almost every facet of an animal's ecology. Several techniques are available (see also Chapter 18), such as:

- telemetry: external and internal, VHF, GPS and proximity transmitters;
- external ringing and tagging (bird and bat banding, mammal ear tags, wing tags);
- physical marking (tattooing, fur clipping, scale marking);
- internal marking (microchips, fish wire tags);
- natural markings.

### Telemetric/GPS devices

A wide variety of attachment methods for both types of transmitters exists (collars, tags, implants). External devices should be as light in weight as possible and should not usually exceed 5% of the body mass of the animal (<3% is recommended). Devices that break away after sampling, at the end of the useful life of the transmitter or those with a remote release are preferable. Collars/harnesses should always be fitted to allow room for growth and natural variation in body mass, which can be pronounced in some species. For example, when fitting collars on small-medium mammals, insert fingers between the neck and the collar to judge the appropriate fit (Figure 7.8).

**Figure 7.8** Fitting a radio collar to a red fox. It is essential that fitting of the collar is comfortable and allows for growth.

### Ringing

This is the most accepted method of marking birds. In the UK, ringing is not regulated under legislation relating to animals used in research but attachment of any marks or tags to wild birds requires formal training and a permit from the British Trust for Ornithology<sup>2</sup>. Scientists can obtain scientific permits that are more restricted in their scope, but may require less diverse training and accreditation.

### Tagging

When tagging animals, bright colours should be used with caution as they may affect camouflage and act as an attractant for predators – they also make the animals visible to members of the public. In addition, tags should be thoughtfully placed so that they are not likely to snag or get caught on vegetation, potentially leading to tissue damage, this is of particular relevance for animals that squeeze through crevices or holes (eg, bats, rats).

### Physical marking

Fur clipping is a good non-invasive method of temporary marking an individual but its use is limited in most studies due to its short duration. In contrast, tattooing is a permanent mark and of great benefit in long-term population studies. However it should be noted that it always requires anaesthesia and does pose a risk of infection (especially for fossorial animals) and hence the use of antiseptic sprays or creams on the tattooed area is recommended.

### Microchipping

Microchipping or the use of passive integrated transponders (PIT tags) represents a relatively recent advance in animal marking technologies (Camper & Dixon 1988) and has become the most popular method of choice for many small mammals and amphibia. The tag itself is a small cylinder (approximately 12mm in length) and it is usually injected

<sup>2</sup> <http://www.bto.org/ringing>

subcutaneously in the scruff of the neck or can be implanted in the lymphatic cavity (particularly in amphibians or reptiles). Although available data suggest no strong evidence for lasting detrimental effects of these tags (Brown 1997) most studies concentrate on efficacy and cost rather than welfare, behaviour, growth and survival. There is anecdotal evidence suggesting that subcutaneous PIT tags can occasionally migrate, potentially leading to problems with the tag moving around the scapular region or even being expelled from the body. There is also some concern that implanting tags into the abdomen through the muscle is a relatively invasive procedure and has the potential to cause pain, necrosis of tissue and/or inflammation around the site. In addition, in some cases PIT tags are not retained as reliably as other marking techniques (Ott & Scott, 1999).

### Natural marking

Individual identification based upon natural markings is an under-utilised refinement method. The theory behind individual identification involves the use of physical markings, patterns or coloration to distinguish between conspecifics. The advantage of this method is that it enables identification without extended periods of handling, therefore minimising disturbance to the animal. It also has low cost compared to other methods (Doody 1995). The age of digital photography has also provided a method of storing a large number of pictures, which can be viewed easily and transferred between facilities. The method has now been used for range of different species including many types of amphibian (Doody 1995; Loafman, 1991), cetaceans (Rugh *et al.* 1992; Neumann *et al.* 2002), birds (Bretagnolle *et al.* 1994), cheetahs (Kelly 2001) and whalesharks (Arzoumanian *et al.* 2005).

### Invasive tissue marking

Marking techniques that cause significant tissue injury, such as branding and toe, ear and tail clipping, should be avoided. If no alternative methods can achieve the desired results then researchers need to ensure that the marking process does not cause unnecessary tissue damage, pain, and/or severe blood loss. Adequate pain control is a necessity when undertaking such procedures.

The method used will depend on the species and type of study. When choosing a marking technique, primary consideration should be given to methodologies that are the least invasive, do not require recapture for identification, and will remain visible for the duration of the study. In addition, marks should:

- be quick and easy to apply;
- be readily visible and distinguishable;
- persist on animals until all research objectives are fulfilled;
- not introduce bias by having variable tag retention rates;
- not cause long-term adverse effects on health, behaviour, longevity or social life;
- comply with any legal restrictions or regulations;
- allow for seasonal changes in mass and growth of juvenile animals.

### Release

Animals should be released back to the point of capture when fully recovered from the procedures performed. If an animal is injured or showing signs of illness euthanasia may be required. The most humane method of dispatch in the field will depend on the species and the experience of the investigator. Table 7.1 lists some suggested methods but see also Chapter 17 and AAZV (2006). The investigator should always have the necessary equipment to euthanase target or non-target animals where appropriate (eg, anaesthetics for overdose) or, in the case of larger animals where veterinary advice may need to be sought, contact numbers for 24-hour cover.

### To treat or not to treat?

There are often ethical and moral dilemmas to be faced in the treatment of wild animals. Interference with a natural process could lead to perturbation of the ecological balance and this must be considered when deciding whether or not to treat a wild animal. As a general guideline, it is accepted that injuries and illnesses that have anthropogenic causes should be treated (see Figure 7.9 for an example flow chart). In many other cases, the researcher must make an informed choice based upon his/her knowledge of the animal, the injury (or illness) and the situation. The final decision should be one that the researcher has the ability and confidence to defend.

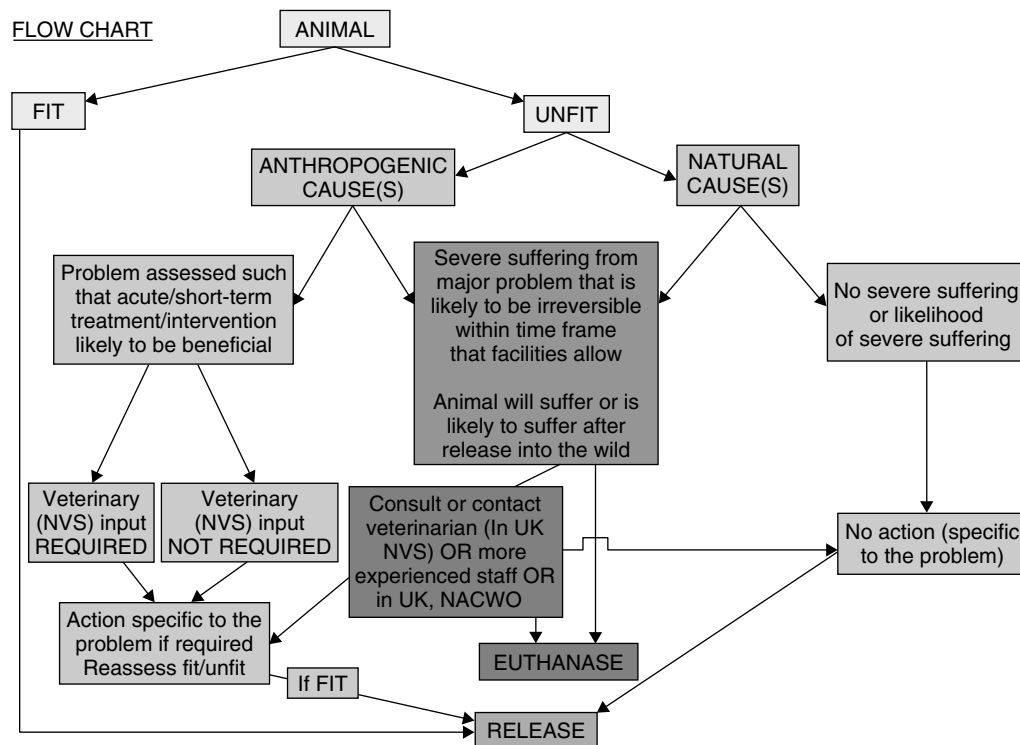

### Legislation appropriate to wildlife studies

Anyone proposing to conduct research on, study, capture, hold or release wildlife should be familiar with, and comply

**Table 7.1** Methods of dispatch. Please note that these methods are not the only, or necessarily the most appropriate methods to be used in all situations. The method of dispatch used should always be decided depending on the health status of the individual, the situation, the setting, the competence of the personnel and local regulations.

<i>Animal</i>	<i>Suggested method of dispatch</i>
Small rodents Rats Birds	Dislocation of neck or overdose of gaseous anaesthesia
Rabbit	Dislocation of neck (requires highly skilled operator)
Hedgehog	Overdose of gaseous anaesthesia
Badger	Overdose of anaesthesia (injectable)
Bats	Overdose of gaseous anaesthesia
Fox Deer Wild boar	Overdose of anaesthesia (injectable) or shooting

**Figure 7.9** Example flow chart on dealing with injured animals in the field. It is vital that all field workers are aware of how to deal with injured target and non-target animals. This flow chart shows an example of strategies for dealing with injuries that are due to the procedure (iatrogenic) or for which the animal sustained prior to capture. In the UK veterinary advice is likely to come from the named veterinary surgeon (NVS). NACWO stands for named animal care and welfare officer, who in the UK is responsible for the day-to-day care of protected animals used in research.

with, the relevant legislation governing their use. In many cases, licences or permits are required to conduct work with wildlife. As an example, the paragraphs below list some of the provisions pertaining to wildlife research in the UK.

### Legislation relating to the use of animals in research

In the UK, the Animals (Scientific procedures) Act 1986 (A(SP)A) states that all regulated work must be carried out at a designated establishment (DE) unless the work requires:

- wild animals or farm species at sites that could not be reasonably part of a DE;
- studies that depend upon access to the wild environment or commercial husbandry standards.

When regulated work under A(SP)A is carried out at field sites these are classed as PODEs (places other than designated establishments). At PODEs procedures must be conducted and welfare standards maintained as near as practicable to those achievable in DEs. Additional conditions also apply to PODEs to enable appropriate controls to be applied, such as notification conditions (ie, usually the inspector is required to be notified of all PODE sites at least 72h before the onset of a regulated study). Land-owner's consent, where appropriate, must be obtained prior to applying for a licence under A(SP)A and provision must be made to allow inspectors onto all PODE sites.

Wildlife studies and/or techniques that are not regulated under A(SP)A include:

- the ringing, tagging or marking of an animal or the use of any other humane procedure for the sole purpose of enabling an animal to be identified is not a regulated procedure under A(SP)A if it causes only momentary pain or distress and no lasting harm;
- humane killing by a recognised method;
- procedures applied in the course of recognised veterinary practice;
- capture and release of wild animals unless the method of capture itself is being studied.

However, it should be noted that any of the above do become regulated if anaesthesia is used. Advice should always be sought from the local Home Office inspector in case of any doubt as to whether a procedure is regulated or not.

Certain species to be used in research may be obtained only from a designated breeding establishment, unless an official exemption is granted. Therefore, it is also illegal to trap these animals in the wild without an exemption granted by the Home Office. The animals on this list include mouse, rat, rabbit, ferret and quail. Moreover release of animals back to the wild will only be authorised if:

- the maximum possible care has been taken to safeguard the animal's well-being;
- the animal's state of health allows it to be set free;

- setting the animal free poses no danger to public health and the environment.

A(SP)A licences do not absolve the licensee from their duties under other wildlife legislation. Hence all work must comply with other appropriate legislation and other applicable licences must be in place before any studies commence.

### Wildlife and Countryside Act

The Wildlife and Countryside Act 1981 is the principle mechanism for the legislative protection of wildlife in Great Britain but does not extend to Northern Ireland, the Channel Islands or the Isle of Man; the Wildlife (Northern Ireland) Order is equivalent in many respects. Most countries have similar legislation, particularly in the EU. This legislation is the means by which the Convention on the Conservation of European Wildlife and Natural Habitats (the 'Bern Convention') and latterly the Council Directive on the Conservation of Wild Birds (79/409/EEC) are implemented in Great Britain. Similar legislation is enacted to fulfil these obligations elsewhere in the United Kingdom. The Wildlife and Countryside Act (WCA) is divided into four parts with Part I being concerned with the protection of wildlife.

Part I of WCA protects all wild birds and protected animals (includes some mammals, all species of bat; species of dolphin; porpoise; otter; amphibians; reptiles; and many species of insects). A wild bird is defined as any bird of a species that is resident in or is a visitor to the European Territory of any member state in a wild state. Under the WCA it is an offence to:

- take, injure, kill or sell a protected species;
- disturb a protected species in its nest or place of shelter;
- possess a protected species.

There are additional clauses and various additional forms of protection.

However, many activities prohibited under the WCA can be carried out after acquiring a licence issued by the appropriate authority to avoid committing an offence. For example scientific study that requires capturing protected animals can be allowed by obtaining a licence.

### Other wildlife legislation

#### The Conservation (Natural Habitats, etc) Regulations 1994

These implement the Council Directive 92/43/EEC in Great Britain under which it is an offence, with certain exceptions, to:

- deliberately capture or kill any wild animal of a European protected species;
- deliberately disturb any such animal;
- deliberately take or destroy eggs of any such wild animal;
- damage or destroy a breeding site or resting place of such a wild animal;
- deliberately pick, collect, cut, uproot or destroy a wild plant of a European protected species;

- keep, transport, sell or exchange, or offer for sale or exchange, any live or dead wild animal or plant of a European protected species, or any part of, or anything derived from such a wild animal or plant.

#### Wild Mammal Protection Act 1996

This act covers unprotected mammals to prevent unnecessary suffering by certain methods such as self-locking snares, explosives, drowning, asphyxiation and use of live decoys. The Wild Mammal Protection Act 1996 does not apply in legal pest control or in the humane killing of an injured animal.

#### Animal Welfare Act 2006

This act ensures that it is not only against the law to be cruel to an animal, but also the welfare needs of the animals must be met. A 'protected animal' under this act is domesticated, not living in a wild state, or under control of man (either permanently or temporarily). The latter does include wild animals captured even for a short period. An offence is caused when an '*act of a responsible person causes an animal to suffer ... and suffering is unnecessary*'. '*Suffering for a legitimate purpose*', eg, research is permissible but only if suffering is proportionate to purpose of the conduct, and it could not have been avoided or reduced, and the conduct concerned was that of a reasonably competent and humane person.

#### CITES

The Convention on International Trade of Endangered Species provides protection to specified endangered species and on the taking, handling and transport of samples taken or collected from them<sup>3</sup>. This can constrain the international movement of samples collected for scientific purposes so advice should always be sought about the application of CITES regulations in research on CITES listed species.

Other examples of legislation include acts that are designed for the protection of specific groups of wildlife. In the UK this includes acts such as:

- The Protection of Badgers Act 1992;
- The Deer Act 1991;
- The Ground Game Act 1880;
- The Whaling Industry (Regulation) Act 1934;
- The Conservation of Seals Act 1970;
- The Salmon and Freshwater Fisheries Act 1975;
- The Dangerous Wild Animals Act 1976;

Some of these acts have parallel legislation in Scotland and Northern Ireland.

#### Licences

Natural England (the Countryside Council for Wales, Scottish Natural Heritage and Northern Ireland Environ-

<sup>3</sup> <http://www.defra.gov.uk/animalhealth/CITES/>

ment Agency have similar arrangements) is responsible for issuing licences and permits through their Wildlife Management and Licensing Service under a range of wildlife legislation for activities that would otherwise be illegal but where a valid justification exists.

### International legislation

Many countries have their own guidance and legislation regarding the use of animals in research and the protection of animals in the wild. It is important that researchers are aware of the local regulations in different countries and abide by these and the best practice guidelines (see below). Links and information are available regarding animal research and welfare legislation for many areas in the world, including USA, New Zealand, Canada and Europe<sup>4</sup>.

### Best practice guidelines

The key to carrying out wildlife studies in the field to the highest standards is to follow best practice guidelines wherever possible. Below is a selection of relevant websites, most of which have links to further resources.

#### UK

##### **National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs)**

<http://www.nc3rs.org.uk>

Microsites on a number of topics with relevance to field studies; of particular interest is their site on Three Rs and wildlife research, but also there are sites on dosing and sampling and anaesthesia that include information appropriate to studying animals in the field.

##### **Association for the Study of Animal Behaviour (ASAB)**

<http://asab.nottingham.ac.uk/ethics/guidelines.php>

Guidelines relating to conducting animal research with some areas particularly associated with field studies (eg, marking) and also has links with other websites that contain information with respect to welfare and ethical treatment of animals.

##### **British Association for Shooting and Conservation (BASC)**

<http://www.basc.org.uk/>

Although not a welfare organisation, BASC has codes of practice on trapping of pest mammals and pest birds which include information on the different legislations, and practical tips on topics, such as how to reduce non-targets and the appropriate setting and positioning of traps which may be of help in conducting field studies of these species.

#### Worldwide

##### **Norwegian Consensus-platform for Replacement, Reduction and Refinement of Animal Experiments (norecopa)**

<http://www.norecopa.no>

Guidelines for wildlife research particularly relating to the Three Rs.

##### **Canadian Council for Animal Care (CCAC)**

<http://www.ccac.ca>

Three Rs microsite with a special section on its implementation on wildlife research and refinement alternatives for marking and tagging.

### Concluding remarks

This chapter is intended as a signpost to the issues that a potential researcher should be considering but does not cover all outcomes that are possible in an ever-changing environment. Before embarking on a field study, preparation is key. A checklist of considerations can be of great benefit, an example of which is given below:

- Do you need to use animals to achieve your aims?
- Are you using the lowest number of animals to achieve your aims?
- Are you using the least invasive but effective methods?
- Have you checked best practice guidelines?
- Have you got the appropriate legal authorities (eg, licences)?
- Have you sought advice from others (eg, veterinary surgeon)?
- Have you checked the weather forecast?
- Have you checked breeding seasons?
- Have you checked your field equipment is the most appropriate for your target species and is fully functional?
- Have you minimised non-target risk?
- Do you know how to treat/dispatch injured animals?
- Do you know how to check and ensure the welfare of the animals before discharging them from your care?

The wildlife researcher has to be prepared for any eventualities and ensure the welfare of the animals within their care is maintained at the highest possible level. This is best achieved by always considering the Three Rs, being aware of best practice guidelines and taking advice from colleagues and other experts in the relevant scientific fields.

# 8 Legislation and oversight of the conduct of research using animals: a global overview

Kathryn Bayne, Timothy H. Morris and Malcolm P. France

## Introduction

This chapter serves to highlight key aspects of laws, regulations, policies and/or codes that apply to the use of animals in biomedical research and testing. An exhaustive review of all relevant, but adjunct regulations (eg, pertaining to animal transportation both domestically and internationally; occupational health and safety; importation/exportation; etc) is beyond the scope of this chapter. In addition, in some jurisdictions the conduct of veterinary clinical research and veterinary clinical trials of new devices, vaccines and pharmaceuticals may be covered by separate mechanisms of oversight. However, as these subjects can have a significant role in the operation of an animal facility, readers are encouraged to review applicable standards in these areas.

Many, but not all, countries and jurisdictions around the world have laws, regulations, policies and other systems of oversight relating to the use of animals in science. There are variations in scope, scale, approach; in legal basis; in social and cultural perspectives; and in implementation. Variability in regulatory delivery and application of such oversight is likely to continue, but there is increasing convergence of the outputs of this oversight. In particular, there is increased emphasis on a wider scope of oversight to include all facets of animal use, in particular on ethical aspects, and on standards and approaches to animal care and welfare.

The regulatory environment for animals in biomedical research and testing is, therefore, both variable across countries, and also in many parts of the world is in a state of evolution. Different approaches have been taken by various countries to improve the welfare of animals used in research, to develop and maintain high-quality science and to address ethical issues. In some countries, the individual scientist is licensed to conduct research, while elsewhere the institution (eg, university or pharmaceutical company) may hold the licence to do animal-based research. In some countries, a wide range of animals (vertebrate and invertebrate, warm and cold blooded) is covered by government standards, while in other countries there are no government regulations, or government standards cover select species of animals. Some countries require ethical review of proposed research, while in others no institutional or governmental review of the proposed study is necessary before work can begin. Similarly, some countries require researchers to have appropriate training and qualifications while others do not. Voluntary oversight schemes are of importance in several

countries. This chapter describes some of the similarities and distinctions between countries/regions where biomedical research is conducted by describing the regulatory climate and systems of oversight in several countries. Its purpose is to provide an introduction to the range of legislative approaches, and it is neither a summary of all national regulations nor a critical review.

The increasing availability of laws and regulations in an electronic format has enhanced access to this information by countries that are in the process of developing their own standards. Some countries (eg, Singapore) have assessed the regulations of many different countries and selected those that apply best for their cultural and scientific environment. Such action can lead to a convergence of approaches in providing animal research oversight, as oversight systems viewed as useful are used as resources for developing a customised regulatory framework. In general, such increased availability of information has increased harmonisation in approaches to assuring research animal welfare.

The increasing internationalisation of research has led to greater interest in systems of accreditation, both for institutions in emerging scientific locations to demonstrate their standards and for institutions in established scientific areas to assure standards. Non-governmental oversight bodies (eg, the Association for Assessment and Accreditation of Laboratory Animal Care International) have a key role, and in some cases the primary role, in harmonising standards for animal care and use around the world, for example by requiring committee review of proposed research at institutions in countries where there is no such requirement. Thus, while approaches may differ among countries, the goals of good animal welfare, attention to ethics and high-quality science are the same. Nonetheless, differences remain in the standards required by different nations. Therefore, there is an ongoing imperative, both for animal welfare reasons and to ensure a level playing field, that regulations and other means of oversight should reflect current knowledge of animal welfare science.

## History

Animals have been used in science for centuries (Dunlop & Williams 1996), but formal oversight of such animal use developed from the eighteenth century. This was the period

when study of animals was revived on a larger scale in European and North American universities, having fallen into disuse after earlier extensive use by Greek and Arab societies. As this use grew, so too did concern, both for the animals themselves, and also about how lack of respect for animals and how they were used would 'corrupt' humans. Even before laws were proposed in the nineteenth century in the United Kingdom (UK), to regulate research using animals, the tensions between the need for such research and animal welfare were present. There was both support for animal use as well as concern for their 'pain and suffering' (Dunlop & Williams 1996). It is interesting that one prescient set of principles for research laid out at that time was that there should be: (1) no alternative; (2) a clear objective; (3) avoidance of repetition of work; (4) minimisation of suffering; and (5) full and detailed publication (Rupke 1987). See also the discussion of early proposals similar to the Three Rs (3 Rs) in Chapter 2.

A general trend in oversight has been to move the focus from avoiding 'cruelty' and on sanitary aspects, to a wider perspective on experimental animal health, welfare and ethics. Early laws and guidelines gave fellow scientists control over other scientists' specified use of animals (Select Committee on Animals in Scientific Procedures 2002) and were aimed at controlling and excluding diseases that clearly confounded early animal experimentation (Walker & Poppleton 1967).

It is important to reiterate that oversight can include voluntary as well as legally required activities, and both approaches may be useful mechanisms to address broader animal welfare and ethical issues (Orlans 2001). For example, the basic Russian law on animal experimentation (Russian Ministry of Health 1973) focuses on hygiene, husbandry and facilities but, in practice, establishments are becoming increasingly aware of broader issues. Key guidance documents have been translated into many languages, including Russian (eg, National Research Council 1996). A recent example of new regulatory requirements is the Japanese Guidelines on animal experimentation which now include aspects such as replacement, reduction and refinement (Science Council of Japan 2006).

## Principles

### The Three Rs

The principles of the Three Rs, consisting of replacement, reduction and refinement (see Chapter 2) were developed by the UFAW Scholars, Professors William MS Russell and Rex Burch. The Three Rs were first presented at a UFAW symposium in 1957 entitled '*Humane Techniques in the Laboratory*' and published as '*The Principles of Humane Experimental Technique*' in 1959 (Russell & Burch 1959). The term alternatives, while sometimes confused with replacement is commonly used to refer to all Three Rs. Definitions of the Three Rs have evolved over the last half century (Buchanan-Smith *et al.* 2005), but the original text (Russell & Burch 1959) remains valid and important:

We shall use the term 'replacement technique' for any scientific method employing non-sentient material

which may in the history of experimentation replace methods which use conscious living vertebrates.

Reduction means reduction in the numbers of animals used to obtain information of a given amount and precision.

Suppose, for a particular purpose, we cannot use replacing techniques. Suppose it is agreed that we shall be using every device of theory and practice to reduce to a minimum the number of animals we have to employ. It is at this point that refinement starts, and its object is simply to reduce to an absolute minimum the amount of distress imposed on those animals that are still used.

Since 1957, and in particular over the last 20 years, the Three Rs have increasingly become, either explicitly (eg, Science Council of Japan 2006) or implicitly (eg, Interagency Research Animal Committee (IRAC) 1985), a key, if not the leading, ethical principle for the care and use of animals used in science.

### International Guiding Principles for Biomedical Research Involving Animals

The International Guiding Principles for Biomedical Research Involving Animals were developed by the Council for International Organizations of Medical Sciences (CIOMS 1985). CIOMS is an international, non-governmental, non-profit organization established jointly by the World Health Organization and the United Nations in 1949 and is representative of a substantial proportion of the biomedical scientific community. These principles for animal experimentation were, in part, created because national and international ethical codes and laws for human experimentation mandate that new substances or devices should not be used for the first time on human beings unless previous tests on animals have provided a reasonable presumption of their safety. The principles provide a framework for ethical animal use (Box 8.1). Other areas covered include animal acquisition, transportation, housing, environmental conditions, nutrition, the provision of veterinary care, the maintenance of records, euthanasia, the monitoring of animal care and use, the implementation of the Three Rs, and the training of investigators and others in animal care and use.

### The World Organisation for Animal Health (OIE)

Recently the OIE have taken an interest in the use of animals in research. Proposals have been published for OIE members to follow when formulating regulatory requirements for the use of live animals in research, testing or teaching (World Organisation for Animal Health 2009). The proposed standards give prominence to the Three Rs, protocol and programme review, training of those involved in veterinary care, the animal facilities, as well as animal health control.

### Engineering versus performance standards

Standards can be performance based, specifying the outcomes but not the methods to achieve outcomes, or engineering based, specifying measurements, activities or

**Box 8.1** CIOMS International Guiding Principles for Biomedical Research Involving Animals

- I. The advancement of biological knowledge and the development of improved means for the protection of the health and well-being both of man and of animals require recourse to experimentation on intact live animals of a wide variety of species.
- II. Methods such as mathematical models, computer simulation and *in vitro* biological systems should be used wherever appropriate.
- III. Animal experiments should be undertaken only after due consideration of their relevance for human or animal health and the advancement of biological knowledge.
- IV. The animals selected for an experiment should be of an appropriate species and quality, and the minimum number required to obtain scientifically valid results.
- V. Investigators and other personnel should never fail to treat animals as sentient, and should regard their proper care and use and the avoidance or minimisation of discomfort, distress, or pain as ethical imperatives.
- VI. Investigators should assume that procedures that would cause pain in human beings cause pain in other vertebrate species, although more needs to be known about the perception of pain in animals.
- VII. Procedures with animals that may cause more than momentary or minimal pain or distress should be performed with appropriate sedation, analgesia, or anaesthesia in accordance with accepted veterinary practice. Surgical or other painful procedures should not be performed on unanaesthetised animals paralysed by chemical agents.
- VIII. Where waivers are required in relation to the provisions of article VII, the decisions should not rest solely with the investigators directly concerned but should be made, with due regard to the provisions of articles IV, V, and VI, by a suitably constituted review body. Such waivers should not be made solely for the purposes of teaching or demonstration.
- IX. At the end of, or, when appropriate, during an experiment, animals that would otherwise suffer severe or chronic pain, distress, discomfort, or disablement that cannot be relieved should be painlessly killed.
- X. The best possible living conditions should be maintained for animals kept for biomedical purposes. Normally the care of animals should be under the supervision of veterinarians having experience in laboratory animal science. In any case, veterinary care should be available as required.
- XI. It is the responsibility of the director of an institute or department using animals to ensure that investigators and personnel have appropriate qualifications or experience for conducting procedures on animals. Adequate opportunities shall be provided for in-service training, including the proper and humane concern for the animals under their care.

processes (National Research Council 1996). Performance standards have the advantage of flexibility, which may be useful where species, previous history of the animals, facilities, expertise of the people and research goals need to be taken into account, but are open to more variability. The performance approach requires professional input and judgement to achieve outcome goals. Engineering standards are useful to establish a baseline, but are not as useful when a goal or outcome, such as well-being, sanitation, or personnel safety, needs to be specified. Moreover, they may not encourage the development of higher standards. Optimally, engineering and performance standards should be used in tandem, thereby providing baseline standards while allowing flexibility and the application of informed professional judgement.

#### Adequate veterinary care

Veterinary care by trained and experienced specialists is fundamentally important to the delivery of a programme of humane and scientifically valid animal care and use. This is reflected in many countries' provisions for regulation or oversight.

The United States Department of Agriculture's (USDA) Animal Welfare Regulations (US Department of Agriculture 1991) and the Public Health Service (PHS) Policy on Humane Care and Use of Laboratory Animals (Policy) (Office of Laboratory Animal Welfare (OLAW) 2002) stipulate that the veterinarian has the authority to oversee several key com-

ponents of the animal care and use programme, including: animal procurement and transportation; quarantine, stabilisation and separation of animals; surveillance, diagnosis, treatment and control of disease; surgery; the selection of analgesic and anaesthetic agents; method of euthanasia; animal husbandry and nutrition; sanitation practices; zoonosis control; and hazard containment. The veterinarian must be qualified through either experience or training in laboratory animal medicine or in the species being used. The veterinarian brings a specific perspective to the deliberations of the Institutional Animal Care and Use Committee (IACUC), and is a voting member of the IACUC. The Animal Welfare Regulations describe the programme of adequate veterinary care as including:

- the availability of appropriate facilities, personnel, equipment and services;
- the use of appropriate methods to prevent, control, diagnose and treat diseases and injuries, inclusive of the availability of emergency, weekend and holiday care;
- daily observation of all animals to assess their health and well-being;
- guidance to researchers regarding handling, immobilisation, anaesthesia, analgesia, tranquillisation and euthanasia;
- nutrition;
- pest and parasite control;
- adequate pre-procedural and post-procedural care in accordance with current professional standards (see also Animal and Plant Health Inspection Service

(APHIS) Tech Note March 1999, Animal Care Policy #3<sup>1</sup>, and APHIS Form 7002 (APHIS 1992)).

The Report of the American College of Laboratory Animal Medicine on Adequate Veterinary Care in Research, Testing and Teaching (1996) describes a programme of adequate veterinary care as including:

- disease detection and surveillance, prevention, diagnosis, treatment and resolution;
- provision of guidance on anaesthetics, analgesics, tranquilliser drugs and methods of euthanasia;
- the review and approval of all pre-operative, surgical and post-operative procedures;
- the promotion and monitoring of an animal's well-being before, during and after its use;
- involvement in the review and approval of all animal care and use at the institution.

This report is used by the Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC International, see later in this chapter) as a reference standard in its assessments of animal care and use programmes.

More recently, the Federation of European Laboratory Animal Science Associations (FELASA), the European Society of Laboratory Animal Veterinarians (ESLAV) and the European College of Laboratory Animal Medicine (ECLAM) have produced European Guidelines for the Veterinary Care of Laboratory Animals (Joint Working Group on Veterinary Care 2008) These are designed to inform the general requirement for veterinary care and advise in the European Directive controlling animal experimentation (European Council 1986). Core veterinary roles include:

- all activities directly related to the animals to promote their welfare, such as during transportation, health monitoring and health management, husbandry, selection of environmental enrichment, surgery, anaesthesia, analgesia and euthanasia;
- scientific activities, often as a scientific collaborator and adviser in laboratory animal science;
- activities related to regulatory and administrative compliance; the veterinarian must be knowledgeable about relevant legislation, including any appropriate ethical review process;
- education and training of personnel and guidance of administrative staff, animal care staff and scientists to the benefit of the animals, the science and the institution.

The guidelines also emphasise the need for appropriate training and continuing professional development to ensure competence is established and maintained.

## Training

The importance of adequate training for all those involved in the animal care and use programme is underscored by

<sup>1</sup>[http://www.aphis.usda.gov/animal\\_welfare/downloads/policy/policy3.pdf](http://www.aphis.usda.gov/animal_welfare/downloads/policy/policy3.pdf)

the emphasis it receives in regulation and policy such as the US Animal Welfare Regulations, PHS Policy, the *Guide for the Care and Use of Laboratory Animals (Guide)* (NRC 1996), and the Council of Europe Convention for the Protection of Vertebrate Animals used for Experimental and other Scientific Purposes Resolution on education and training of persons working with laboratory animals (Council of Europe 1993). This emphasis is also reflected in other jurisdictions.

The US Animal Welfare Regulations and PHS Policy require institutions to ensure that people caring for or using animals are qualified to do so. The Animal Welfare Regulations stipulate that several key topics be included in the institution's training programme. They are:

- humane methods of animal maintenance and experimentation, including the basic needs of each species of animal, proper handling and care for the various species of animals used by the institution, proper pre-procedural and post-procedural care of animals, and aseptic surgical methods and procedures;
- the concept, availability and use of research or testing methods that limit the use of animals or minimise animal distress;
- proper use of anaesthetics, analgesics and tranquilisers for any species of animal at the institution;
- methods to report any deficiencies in animal care and treatment;
- use of the services at the National Agricultural Library, such as appropriate methods of animal care and use, alternatives to the use of live animals in research, prevention of unintended and unnecessary duplication of research involving animals, information regarding the intent and requirements of the Animal Welfare Act.

The *Guide* urges that adequate training should be provided to members serving on the IACUC so that they can appropriately discharge their responsibilities. In addition, the *Guide* recommends that the professional and technical personnel caring for animals should be trained, as should investigators, research technicians, trainees (including students) and visiting scientists. The *Guide* also endorses training in occupational health and safety, in procedures that are specific to an employee's job and in procedures specific to research (eg, anaesthesia, surgery, euthanasia, recognition of the signs of pain and/or distress, etc).

Over the last decade, there has been regionalisation and internationalisation of training standards. A particularly strong example is the development of training guidelines across Europe. These are based on a resolution adopted out of the Council of Europe Convention for the Protection of Vertebrate Animals used for Experimental and other Scientific Purposes (Council of Europe (COE) 1986). This resolution on education and training of persons working with laboratory animals (COE 1993) defined four categories of persons working with laboratory animals and their training needs:

- Category A: persons taking care of animals;
- Category B: persons carrying out procedures;
- Category C: persons responsible for directing or designing procedures;
- Category D: laboratory animal science specialists.

FELASA has elaborated these training requirements for each of these categories into training guidelines (FELASA 1995, 1999, 2000) and an accreditation scheme for provision of this training (FELASA 2002). These guidelines have become the *de facto* requirement for training and education across Europe, and are also being used elsewhere in the world.

This trend to wider application of guidelines is seen in other areas. Animal technology certification is heavily influenced by the certification programmes of the American Association for Laboratory Animal Science across the Americas, whilst in Europe and beyond, the European Federation of Animal Technicians is increasingly influenced by the programmes from the UK Institute of Animal Technology. More recently, there have been moves to share standards for certification of specialists in Laboratory Animal Medicine by the formation of an International Association of Colleges of Laboratory Animal Medicine<sup>2</sup>.

### Institutional and governmental authorisation

Institution-based review is the commonest method of authorisation around the world. Whilst there may be oversight of these activities by a national authority, often this is the single layer of authorisation.

The committee or process that is designated to review proposed uses of animals has been variously called the Animal Care Committee (Canada), Ethics Committee (Europe) and the IACUC (US). This group of individuals, operating as a committee or process, representing institutional and public interests, has the responsibility for oversight and evaluation of the entire animal care and use programme and facilities. Because they act on behalf of the institution, their role is pivotal to engendering a humane and progressive animal care and use programme. The term programme is used to describe all aspects of animal care and use. The successful programme is overseen by a committee that is engaged, knowledgeable and receives strong administrative support. Because the committee is responsible for investigating reports of concern regarding animal welfare, the committee's functions must be well known throughout the institution and there must be ready (and confidential) access to the committee.

Previously, where there was central authorisation by a national or regional authority, an approach common in Europe, this was often the sole process. The trend is now to include local institutional or regional 'ethical' review, in conjunction with governmental authorisation procedures. These two approaches can be complementary or additive, depending on the detailed requirements.

Special procedures often operate for approval of the use of certain species, such as non-human primates, dogs, cats, and equidae (eg, Council of Europe 1986; US Department of Agriculture 1991).

The ethical component of this review activity may be explicit or implicit, depending on regulatory requirements, but especially on the cultural norms in each jurisdiction. For example, in Europe, at present, it is commonly explicit but

not always legally mandated (FELASA Working Group on Ethical Evaluation of Animal Experiments 2007). In Asia it may be less explicit in terms of 'ethical review'; but ethics is implicit in approaches such as memorials to animals used in research which encourage reflection on ethical aspects of such animal use (Slaughter 2002).

### Inspection and compliance

Systems of inspection, with consequences for non-compliance, are operated in some jurisdictions, although they may or may not be perceived as fully or effectively implemented (European Parliament 2002). The inspection system is usually government controlled but there may also be other means of oversight, such as the peer-review system used by AAALAC International. Sanctions for non-compliance are highly varied and may include fines, imprisonment, denial of authority to conduct research or withdrawal of accreditation.

### International accreditation of animal care and use programmes

There are two systems currently in place that accredit programmes that use animals in research, testing or teaching. One is the accreditation offered by the Canadian Council on Animal Care (CCAC), which is generally limited to institutions located in Canada (see below). The other is AAALAC International's global accreditation system. AAALAC International is a non-profit organization that was formed in 1965. AAALAC's mission is to promote the humane treatment of animals in science through confidential, voluntary accreditation of animal care and use programmes. The Association is comprised of a Board of Trustees from 69 scientific organizations, patient advocacy groups, laboratory animal medical and science organizations and research lobby groups; a Council on Accreditation made up of veterinarians, animal researchers, research administrators and facility managers who are experts in the field of laboratory animal science and medicine; a roster of consultants who assist Council with the on-site evaluations and an office staff. The Board of Trustees sets the vision and general direction of the Association, the Council on Accreditation is responsible for the conduct of site visits and for determining the accreditation status of institutions, and the office staff (US, Europe and Pacific Rim regional offices) serves as a point of coordination of these activities and as an information resource to the laboratory animal using community.

AAALAC does not establish policies to which institutions must conform. Rather, AAALAC International relies principally on the *Guide*, as well as national laws, regulations and policies, and numerous scientifically based standards, referred to as '*reference resources*', which address specific subject areas (eg, recombinant DNA, surgery, euthanasia), for evaluation of animal care and use programmes around the world (Bayne & Martin 1998; Bayne & Miller 2000). The accreditation process includes an extensive internal review conducted by the institution, which is summarised in an animal care and use programme description. On-site visits are announced and conducted every 3 years. There is also

<sup>2</sup><http://www.iaclam.org>

an annual report requirement. The standards and process for accreditation are described in the Association's Rules of Accreditation. Non-conformance with AAALAC International standards results in formal notification that full accreditation has not been granted and provision of a timeline for correcting identified deficiencies. Sustained or serious non-conformance can result in revocation of accreditation.

### Regional and international harmonisation of guidelines

Regionally or internationally, some organisations promote greater harmonisation of standards. As examples, FELASA has also issued guidelines that include health monitoring, control of pain and distress and use of transgenic animals, and the International Council for Laboratory Animal Science (ICLAS) has a programme of producing harmonised guidance that includes euthanasia and humane endpoints.

#### Western Europe

After much public debate the UK passed the first legislation in the world to regulate animal research. The 1876 UK Cruelty to Animals Act made provision to permit certain experiments on live animals subject to support from eminent scientists (Nuffield Council on Bioethics 2005). This law was replaced in 1986 with the UK Animals (Scientific Procedures) Act. This introduced formal controls on sources of animals, re-use of animals and euthanasia. It also set out requirements to consider alternatives, to ensure training, to set up an advisory committee and to publish wide-ranging codes of practice on health, refinement, husbandry and care (Her Majesty's Stationery Office 1985). Previously, these wider aspects had developed as voluntary guidelines (Biological Council 1984). Such broadening of the scope was part of the trend for more comprehensive laws, such as the European Directive for the protection of animals used for experimental and other scientific purposes (European Council 1986) and the International Guiding Principles for Biomedical Research Involving Animals (Council for International Organizations of Medical Sciences 1985).

The use of animals in scientific procedures in Europe is covered by two overlapping legal instruments that are currently very similar. The first is the Council of Europe Convention for the Protection of Vertebrate Animals used for Experimental and other Scientific Purposes (Council of Europe 1986), and the second is the European Union's Council Directive on the approximation of laws, regulations and administrative provisions of the member states regarding the protection of animals used for experimental and other scientific purposes (European Council 1986).

The 47 member states of the Council of Europe can choose whether to participate in developing a convention, and can choose whether to ratify it. In 2007 less than half the member States of the Council of Europe had ratified the Convention for the Protection of Vertebrate Animals used for Experimental and other Scientific Purposes. In contrast, European Union directives must be implemented by member

states (through national law as, for example, with the Animals (Scientific Procedures) Act 1986 in the UK), and must be adopted by any new state which joins the Union. Both the European Convention and Directive provide a framework which member states may choose to develop into more detailed regulations and guidance in the implementation of their provisions. Box 8.2 gives an overview of the provisions of the Convention and Directive.

The methods of implementing the Directive and Convention vary among European states (Nuffield Council on Bioethics 2005) and they are permitted to adopt stricter measures. Some states have centralised national authorisation, some have regional authorisation. Some require authorisation for all procedures, some allow minor procedures to start after notification. Commonly among the states a two-licence system is operated: one for the establishment, one for the project. A few states also require individuals to be licensed. National inspection regimes vary, with inspection visits ranging from frequent to occasional. Increasingly, a formalised process of ethical review is used, either mandated by law or voluntarily (FELASA Working Group on Ethical Evaluation of Animal Experiments 2007). Further restrictions on animal species (eg, apes), purposes (eg, safety testing of cosmetics) or procedures (eg, the LD<sub>50</sub> test) have been implemented in one or more European states.

Two complementary changes are underway in Europe. The standards in animal care and husbandry listed in Appendix A of the Convention have been reviewed over several years as part of the Multilateral Consultation of Parties to the Convention. Discussions on this were informed by working parties comprising representatives of science, industry and animal welfare groups. The parties to the Convention ratified an updated Appendix A in June 2006 (Council of Europe 2006). The changes from the previous versions were considerable, with much greater emphasis on the quality of the environment and accommodation because of its potential to affect animal well-being. For some species, particularly birds, dogs and non-human primates, enclosure sizes were increased considerably (Federation of European Laboratory Animal Science Associations 2007). In June 2007, a Commission Recommendation (2007 526 EC) replaced the existing Annex II guidance, with new guidelines aligned to the revised Council of Europe guidelines (Appendix A of Convention ETS 123), on accommodation and care of laboratory animals.

In 2001, the European Commission proposed revision of the European Directive because of its concerns about variation in its implementation across Europe, changes in scientific practice and advances in science, and because of its concern for more explicit reference to the use and development of alternatives to animal use. Since then, various reports and assessments have been undertaken, including a report by the European Parliament's Environment & Public Health Committee; a Commission-sponsored technical review; input from the European Food Safety Authority; an impact assessment by the Commission; and a public consultation (European Commission 2007a). The Commission's proposal on the new Directive was published in November 2008 and is now subject to dynamic revision between the Commission, the European Parliament and the European Council of Ministers. Areas for revision include:

**Box 8.2** Overview of the provisions of the European Convention and 1986 Directive (C – unique to Convention; D – unique to Directive).

Animals protected:

- Live non-human vertebrates, including free-living and/or reproducing larval forms, but excluding other foetal or embryonic forms.
- Use of stray animals prohibited.
- Restrictions on the use of wild or endangered species (D).

Activities regulated:

- Experimental or other scientific use of an animal which may cause it pain, suffering, distress or lasting harm. Includes the birth of an animal in any such conditions.
- Excludes the least painful methods accepted in modern practice of killing or marking an animal.
- Non-experimental, veterinary and agricultural activities excluded.

Reasons allowed for one or more of the following purposes only:

- Avoidance or prevention of disease or abnormality in man, vertebrate or invertebrate animals or plants. Includes production and quality, efficacy and safety testing of drugs, substances or products.
- Diagnosis or treatment of disease in man, vertebrate or invertebrate animals or plants.
- Detection, assessment, regulation or modification of physiological conditions in man, vertebrate and invertebrate animals or plants.
- Protection of the environment.
- Scientific research (C).
- Education and training, and forensic inquiries (C).

Animal environment, care and husbandry:

- Standards for this in an Appendix (A) (C) or an Annex (II) (D).
- Environment checked each day and action taken if required.

Three Rs:

- Cannot use an animal if another scientifically satisfactory method is reasonably and practicably available.
- Choice of species to be carefully considered.
- Procedures selected which use the minimum number of animals, cause the least pain, suffering, distress or lasting harm, and which are most likely to provide satisfactory results.
- General or local anaesthesia or analgesia or other methods to eliminate as far as practicable pain, suffering, distress or lasting harm must be applied throughout the procedure unless they confound experiment or themselves cause more harm.
- The development of the Three Rs is encouraged.
- States to recognise the results of procedures carried out in other states.

Notification and authorisation:

- Procedures in which an animal will or may experience severe pain which is likely to endure must be specifically declared and justified to, or specifically authorised by, state authorities.
- Authorisation for any procedure shall be granted only to persons deemed to be competent by the state authorities, and if the experimental or other scientific

project concerned is authorised in accordance with the provisions of national legislation.

Actions at the end of experiments:

- Animal to be killed and this is required during the course of the experiment if the animal is in unrelieved severe pain or distress.
- Animals may be re-used, under certain conditions, or released, but not if not previously used in an experiment causing severe pain or distress.
- Animal may, under certain conditions, be released.
- There must be veterinary involvement in decisions made at the end of the experiment if the animal is not killed.

User establishments:

- Registered and comply with standards for animal environment, care and husbandry.
- Design, construction and functioning of facilities and equipment to ensure that the procedures obtain consistent results with the minimum number of animals and the minimum degree of pain, suffering, distress or lasting harm.
- Persons who are administratively responsible for the care of the animals and the functioning of the equipment to be identified.
- Sufficient trained staff.
- Adequate arrangements for the provision of veterinary advice and treatment.
- Veterinarian or other competent person charged with advisory duties in relation to the well-being of the animals.
- Persons who carry out procedures, or take part in procedures, or take care of animals used in procedures to have appropriate education and training.
- Records kept of animal acquisition and use.
- Periodic inspection by the state (D).

Breeding and supply establishments:

- Registered and comply with standards for animal environment, care and husbandry.
- Person in charge of the establishment competent to administer for suitable care for animals.
- Requirements for records, with special provision for records identification of dogs and cats
- Some species must be purpose bred unless specific exemption: mouse, rat, guinea pig, golden hamster, rabbit, dog, cat and quail.
- Periodic inspection by the state (D).

Statistical information made available to the public for each state:

- The numbers and kinds of animals used in procedures.
- The numbers of animals in selected categories used in procedures directly concerned with medicine and in education and training (C).
- The numbers of animals in selected categories used in procedures for the protection of man and the environment.
- The numbers of animals in selected categories used in procedures required by law.
- Commercial information protected (D).

- regulation of individuals, places and projects with prior authorisation of procedures;
- establishment of an inspection system in each member state and EU audit of inspection;
- requirement for member states to promote the Three Rs;
- establishment of institutional ethical review to advise on the Three Rs and review certain projects annually;
- classification of projects by severity;
- restrictions on the use, breeding and acquisition of non-human primates;
- prescribed minimum standards for animal care and accommodation;
- extension of the scope to some invertebrates, animals bred for tissues and immature forms;
- further restrictions on the re-use of animals;
- requirement for a national animal welfare and ethics committee and a national reference laboratory to validate alternatives;
- requirement for public non-technical summaries of projects;
- measures to promote the avoidance of duplication in regulatory testing.

The revised Appendix A of the Convention has therefore become the current standard for animal use in the European Union (European Commission 2007b), as well as in countries which have ratified the Council of Europe Convention, and it is now being implemented over a period of several years.

In addition, for the European Union states, the revised Directive will become the current regulation for standards for animal use, once the revision process is complete.

## North America

### Canada

The Canadian constitution precludes federal legislation pertaining to the use of animals in research, testing or education because such use is under provincial jurisdiction. Six provinces have established legislation regarding animal research, five of which reference the CCAC guidelines and policies. In addition, although there is no federal requirement to participate in the CCAC assessment programme, the two principal funding agencies require grantee institutions to have a Certificate of Good Animal Practice<sup>®</sup> and to comply with CCAC guidelines and policies for continued funding. Contractors performing work for the federal government are required to adhere to CCAC guidelines, as specified in the Public Works and Government Services Canada, Standard Acquisition Clauses and Conditions Manual, Section 5, Subsection A, Clause A9015C: Experimental Animals.

The CCAC, founded in 1968, places responsibility for humane animal care and use with the animal care committee (ACC) at each institution. The ACCs are granted specific authority and provided with terms of reference under which they operate (eg, membership, authority, responsibilities and functioning). The CCAC's mission is:

*to act in the interests of the people of Canada to ensure through programs of education, assessment and persuasion*

*that the use of animals, where necessary, for research, teaching and testing employs optimal physical and psychological care according to acceptable scientific standards, and to promote an increased level of knowledge, awareness and sensitivity to relevant ethical principles.*

Thus, the CCAC has two principal functions: (1) the development of guidelines and policies to govern experimental animal care and use; and (2) to monitor compliance with those guidelines and policies. The CCAC is an independent organisation and receives funding from the Medical Research Council (MRC) and the Natural Sciences and Engineering Research Council (NSERC).

The CCAC establishes guidelines for its certified institutions to follow, currently contained in the two-volume *Guide to the Care and Use of Experimental Animals* (CCAC 1984; Olfert *et al.* 1993). Adjunct guidelines address topics such as animal use protocol review, transgenic animals, selecting appropriate endpoints and developing an animal user training programme. The CCAC also has established several policies, including the ethics of animal research, review of scientific merit, social and behavioural requirements of experimental animals, acceptable immunological procedures and categories of invasiveness.

On-site assessments using panels of experts from the animal care and use community and a representative nominated by the Canadian Federation of Humane Societies are conducted triennially. An institution is deemed to be in compliance if the CCAC report prepared by the assessment panel and approved by the Assessment Committee, a standing committee composed of at least four Council members, contains only regular, minor and/or commendatory recommendations, and the institution submits an implementation report for any regular recommendations that is judged to be satisfactory. Institutions which have been found to be in compliance or conditional compliance will receive a CCAC Certificate of Good Animal Practice<sup>®</sup>. If the CCAC report contains major and/or serious recommendations whose correction does not require verification by an on-site reassessment, but rather can be verified through documentation and the institution provides to the CCAC an implementation report that is judged to be satisfactory, then compliance is maintained. An assessment report containing major or serious recommendations may place the institution in a status of conditional compliance, probation or non-compliance. All relevant funding agencies and government ministries and departments are notified of an institution's non-compliance with CCAC guidelines (Canadian Council on Animal Care 2000). Sustained non-compliance with CCAC guidelines and policies can ultimately result in withdrawal of all animal-based research funding to the institution.

### The United States

In the US, oversight of animal care and use for research, testing and teaching is achieved by numerous laws, regulations, policies and guidelines from two principal government organisations: the USDA and the PHS. Other guidance may be derived from scientific panels and endorsed by the government as required standards. Federal laws are annu-

ally compiled and categorised into their respective subjects (eg, agriculture) and published as the United States Code (USC). The USC includes a discussion of the intent of Congress for establishing the law and any interpretations from the courts. Regulations are promulgated to enforce the corresponding law. Proposed regulations are published in the Federal Register for public comment. After the responsible agency reviews and addresses the public comments, the regulations are again published in the Federal Register in final format and then incorporated into the Code of Federal Regulations (eg, 9 CFR) (Johnson & Morin 1983; Johnson *et al.* 1995). In general, laws address two specific areas: animal welfare and procurement, and animal importation and shipment.

#### *US Department of Agriculture*

Federal laws for the humane treatment of animals have been in place since 1873. The first federal law to protect non-farm animals was not passed until 1966 and was called the Laboratory Animal Welfare Act, administered by APHIS, USDA. The Laboratory Animal Welfare Act of 1966 was amended in 1970, 1976, 1985, 1990, 2000 and 2008 to broaden coverage of the law. Public Law 91-579, Animal Welfare Act of 1970, increased the species of animals covered under the law to include all warm-blooded animals and increased the scope of applicability of the law to include the time animals were held in the facility. Specifically exempted were horses not used in research and agricultural animals used in food and fibre research, retail pet stores, state and county fairs, rodeos, purebred cat and dog shows, and agricultural exhibitions. Public Law 94-279, Animal Welfare Act Amendments of 1976, included common commercial carriers, such as airlines, and this subsequently led to standards being developed for shipping containers and conditions of shipment. Public Law 99-198, Improved Standards for Laboratory Animals Act, added several new provisions to the law including: minimisation of animal pain and distress and consideration of alternatives to painful procedures; consultation with a doctor of veterinary medicine for any practice which could cause pain to animals; limitation on conducting more than one major survival surgery on an animal (ie, multiple major survival surgical procedures may be permitted if they are interrelated to the scientific goal of the study); establishment of an IACUC to provide oversight of the animal care and use programme and facilities; provision of specific training to personnel; provision of exercise to dogs; and a stipulation to promote the psychological well-being of non-human primates. The 1990 amendment to the Animal Welfare Act, Public Law 101-624, Food, Agriculture, Conservation, and Trade Act of 1990, Section 2503, Protection of Pets, established a holding period for dogs and cats at shelters and other holding facilities prior to sale to dealers supplying animals for research. The law also requires dealers to provide written certification to the recipient regarding the background of each animal.

The 1970 amendment to the Animal Welfare Act defined an animal as: '*any live or dead dog, cat, monkey (nonhuman primate animal), guinea pig, hamster, rabbit, or other such warm-blooded animal as the Secretary may determine is being used, or is intended for use, for research, testing, experimentation, or exhibition purposes, or as a pet.*' In this way, the Secretary of the

Department of Agriculture was provided the authority to determine which animals would be covered by the Act. In 1977 the USDA promulgated regulations that specifically excluded rats, mice and birds from the definition of 'animal'. The Helms amendment to the 2002 Farm Bill explicitly excluded rats, mice and birds used for research from the Act. Because the USDA regulates only those species covered by the Animal Welfare Act, the passage of this bill into law removed USDA oversight of these species. Rationale for Congress to accept their exclusion from the Act was based in large part on the fact that these species are covered by other federal (eg, PHS Policy) and private (eg, AAALAC International) systems of oversight, and there are reports that approximately 95% of research using rats and mice is funded by the National Institutes of Health and thus are covered by the Health Research Extension Act/Public Health Service Policy (Federation of American Societies for Experimental Biology 2002).

Since the 1966 Act, the USDA has been vested by Congress with both promulgation and enforcement authority. The USDA is required to conduct unannounced annual inspections of research facilities, with follow-up inspections until any cited deficiency has been corrected. Exempt from this provision are federal research facilities. Research institutions, intermediate handlers and common carriers are required to register with the USDA, while animal dealers and exhibitors must be licensed. Research facilities and US government agencies are required to purchase animals only from licensed sources, unless the source is exempted from obtaining a license. Failure to comply with regulatory requirements, despite formal notification of an item(s) of non-compliance and an opportunity to effect a correction, can result in fines levied on the facility, suspension of authority to operate and even permanent revocation of the facility's license to operate. Thus, the enforcement arm of the USDA's oversight responsibility is strong, and has been used over the years to improve animal welfare at dealers, exhibits and research facilities.

#### *Public Health Service Policy*

The other federal agency charged with oversight of research animal care and use is the PHS. The PHS Policy was implemented in 1973 and was revised in 1979. The PHS Policy covers all vertebrate animals used in research, testing or teaching. Today, the PHS authority is derived from Public Law 99-158, the Health Research Extension Act of 1985, Section 495, Animals in Research. Under this Act, institutions conducting animal research using PHS funding, such as through the National Institutes of Health (NIH), must comply with the PHS Policy on Humane Care and Use of Laboratory Animals (Office of Laboratory Animal Welfare 2002). The PHS Policy requires submission by the funding recipient (referred to as an '*awardee institution*') of an Animal Welfare Assurance Statement, and which must be approved by the PHS's Office of Laboratory Animal Welfare (OLAW), a component of the NIH, and commits the institution to following the US Government Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training (IRAC 1985) which are largely based on the CIOMS Principles, and the *Guide*. In addition to stating a commitment to animal welfare, the Assurance Statement

must designate clear lines of authority and responsibility for institutional oversight of the work, inclusive of a designated 'Institutional Official' who is ultimately responsible for the animal care and use programme; identify a qualified veterinarian who is involved in the programme; provide a description of the occupational health and safety programme for relevant personnel in the programme; describe mandated training; and describe the facility. The assurance is re-negotiated with OLAW every 5 years. OLAW can approve, disapprove, restrict or withdraw approval of the Assurance.

PHS awarding agencies, such as the NIH, may not make an award for an activity involving live vertebrate animals unless the prospective awardee institution and all other institutions participating in the animal activity have an approved Assurance with OLAW and provide verification that the IACUC has reviewed and approved those sections of the grant application that involve the use of animals. Applications from organisations with approved Assurances must address five specific points pertaining to the use of animals:

- a detailed description of the proposed work, including species, strain, sex, age and number of animals to be used in the proposed work;
- a justification of the use of animals, species and number of animals;
- information regarding the veterinary care for the animals;
- a description of the procedures for ensuring that discomfort, distress, pain and injury will be minimised;
- a description of the method of euthanasia and the reason for the selection of that method, including a justification for any method that does not conform with the American Veterinary Medical Association's (AVMA) Euthanasia Guidelines (2007).

Awardee institutions that do not comply with the standards of the *Guide*, the USDA Animal Welfare Regulations and other standards referenced in the PHS Policy (eg, the AVMA's Euthanasia Guidelines (American Veterinary Medical Association 2007)), may have their Assurance Statement restricted, which in turn can limit access to PHS funding for research. Sustained non-compliance with the PHS Policy can result in withdrawing the approval of the assurance and cessation of all PHS funding for animal-based activities.

The awardee institution must also submit an annual report. Institutions that are reviewed by an outside accrediting body, such as AAALAC International (Category 1 institutions), must indicate in the annual report if that accreditation status has been removed. Institutions that are not accredited by an external review group (Category 2) must provide the most recent copy of their IACUC's semi-annual programme review and facility inspection with the Assurance. The role of the IACUC in providing local oversight of animal care and use is a key element of the PHS Policy. Although the required composition of the IACUC for the PHS differs slightly from USDA requirements, due to a Memorandum of Understanding concerning laboratory animal welfare among APHIS/USDA, the Food and Drug Administration (FDA) and the NIH that sets forth proce-

dures for co-operation among the three agencies in their oversight of animal care and use programmes, the general functions and responsibilities of the IACUC are similar.

OLAW conducts site visits of awardee institutions both 'for cause' and 'not for cause'. In addition, an ongoing significant mission of OLAW is the educational outreach it performs in collaboration with awardee institutions. Jointly sponsored workshops focus on information of value to Institutional Officials and IACUCs to provide appropriate oversight of animal care and use. OLAW also provides guidance through articles in journals, commentary on other articles, NIH Guide Notices and a listserve.

#### *Other laws, regulations and policies*

In 1978 the FDA initially promulgated regulations for the conduct of animal research on new or existing pharmaceutical agents, food additives or other chemicals. These regulations, known as the Good Laboratory Practice (GLP) regulations (which have been subsequently revised), specify appropriate diagnosis, treatment and control of Disease in animals used in the work (see 21 CFR Part 58<sup>3</sup> (Code of Federal Regulation 1998)). The Environmental Protection Agency (EPA) has issued companion regulations (Code of Federal Regulation 1997) for conducting research pertaining to health effects, environmental effects and chemical fate testing in a separate set of GLP regulations<sup>4</sup>. Both the FDA and EPA GLP regulations rely heavily on adequate and detailed record keeping. Records must include standard operating procedures, animal identification, food and water analysis, documentation that any pesticides or chemicals used near the animals do not interfere with the study, and documentation of any disease and treatments animals experience. On-site inspections are conducted to ensure compliance with GLP standards.

The Department of Defense (DoD) developed a 'Policy on Experimental Animals' in 1961 to ensure that all research at DoD facilities involving animals was conducted in accord with certain principles of animal care (Rozmiarek 2007). Later versions of this policy included overseas sites. Subsequently a joint regulation, entitled 'The Use of Animals in DoD Program', from the Army, Navy, Air Force, Defense Nuclear Agency and Uniformed Services University required all DoD facilities to 'seek accreditation by AAALAC' and to establish local institutional animal care and use committees (Department of Defense 1995).

State laws to protect animals have a long history, with the first anti-cruelty law passed in 1641 in the Massachusetts Bay Colony to prevent riding or driving farm animals beyond established limits (US Congress Office of Technology Assessment 1986). All 50 states and the District of Columbia have enacted anti-cruelty laws. The overarching goals of these laws are to protect animals from cruel treatment, require that animals have access to suitable food and water and require that animals have shelter from extreme weather. Some state laws define 'animal' and some do not. In common

<sup>3</sup>[http://edocket.access.gpo.gov/cfr\\_2004/apr/qtr/pdf/21cfr58.1.pdf](http://edocket.access.gpo.gov/cfr_2004/apr/qtr/pdf/21cfr58.1.pdf)

<sup>4</sup><http://ecfr.gpoaccess.gov/cgi/t/text/text-idx?c=ecfr&sid=cd55b9ce1e35880245e76f6ba16ab76d&rgn=div5&view=text&node=40:23.0.1.1.11&idno=40>

among the state laws is the diversity of approaches to providing protection to animals. Some states have additional provisions for animals used in research, and many states prohibit the sale of pound animals into the research stream. In general, criminal penalties are imposed for offences. On occasion, state anti-cruelty laws have been used against research facilities. In recent years, state and federal laws have been used by private citizens or citizen groups claiming 'standing to sue' on behalf of animals. The issue of 'standing' has undergone a long litigation process and a chronology of court decisions on this issue has been compiled by the National Association for Biomedical Research (1999).

Because animal research can involve a variety of different species, several other federal acts, laws and treaties have bearing on animal use. These include the US Endangered Species Act, which restricts the research conducted on these animals to those studies that would directly benefit the species under investigation; the Marine Mammal Protection Act, which provides authority for scientific research on marine mammals by special permit; the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), which requires signatory countries to obtain a permit for the import or export of certain species; the Lacey Act, which governs import, export and interstate commerce of foreign wildlife; and the Migratory Bird Treaty Act, which makes it unlawful to take or possess any protected bird except by permit.

## Asia

### Japan

Effective 1st June 2006, the Science Council of Japan (SCJ) issued 'Guidelines for Proper Conduct of Animal Experiments' as a result of the amended Law for the Humane Treatment and Management of Animals (amended 2005) and at the request of the Ministry of Education, Culture, Sports, Science and Technology (MEXT) and the Ministry of Health, Labour and Welfare (MHLW). Of particular note, the amended law and SCJ Guidelines requires attention to the Three Rs in the planning and conduct of research, though in practice, particular emphasis is placed on refinement. The detailed guidelines promulgated by the SCJ build upon the more basic guidelines, 'Fundamental guidelines for proper conduct of animal experiment and related activities in academic research institutions under the jurisdiction of the Ministry of Education, Culture, Sports, Science and Technology', 'Basic policies for the conduct of animal experimentation in the Ministry of Health, Labour and Welfare' and 'Standards Relating to the Care and Management of Laboratory Animals and Relief of Pain (Ministry of Environment, 2006)'.

The SCJ Guidelines encourage each institution to develop and implement its own policies for the conduct of animal-based research. The SCJ guidelines place ultimate responsibility for all experiments with the director of the institution, but also encourage the formation of an IACUC. Therefore, the IACUC's role is to provide the institutional director with a report on the committee's deliberations regarding a pro-

posed study, and then the director approves or disapproves the protocol. The number of IACUC members may vary with the size and complexity of the institution, but the committee should include researchers who conduct animal experiments, laboratory animal specialists and '*other persons of knowledge and experience*' (Science Council of Japan 2006). The primary role of the IACUC is to evaluate the scientific merit of the proposed study, taking into consideration the aforementioned law, standards and policies. The IACUC is also charged with reviewing the education and training of the investigator and to make recommendations to the director of the institution as necessary.

The SCJ Guidelines provide general recommendations regarding items for the IACUC to consider when reviewing a protocol, items that should be contained on the protocol form, facility and equipment considerations, animal restraint, food and water restriction, surgical procedures, analgesics and anaesthetics, humane endpoints, euthanasia, safety considerations and reporting of experimental results. This latter item suggests that the investigator report to the director of the institution the number of animals used, whether any changes were made to the protocol and the results of the experiment. Other topics covered include laboratory animal selection and receipt, the care and management of laboratory animals, laboratory animal health management, as well as education and training. Under the topic of laboratory animal care and management, cage space is discussed. The Guidelines recommend considering the animal's characteristics (species, age, etc) and its behaviour when determining appropriate cage size, or alternatively to use the *Guide* (NRC 1996). The Standards provide additional guidance on environmental conditions and other related animal care and use programme information. Although a government inspection system does not validate conformity with these standards and guidelines, a third party audit system is encouraged, which may be met by a relatively new national audit system or through assessments and accreditation provided by AAALAC International.

### Korea

The first Korean Animal Protection Law was passed in 1991 that formally permitted the use of animals for teaching, research, '*or other scientific study*'. The law was amended in January 2007 with a 1-year period for institutions to come into compliance (Korean Animal Protection Law 2007). The amended law addresses several key principles, including consideration of harm/benefit, alternatives, using the minimum number of animals necessary to achieve the scientific goal, ensuring appropriate training and experience of the investigator, pain mitigation and euthanasia. Importantly, the amended law requires the establishment of an Animal Experimentation Ethics Committee to '*oversee the protection and ethical treatment*' of research animals. The composition of the committee is specified as a chair and 3–15 members, one third of whom must be independent of the institution. The committee must have a veterinarian; a person who represents animal welfare and is recommended by a private organization; a lawyer; and a professor that is in charge of animal protection and welfare at an institution of '*higher education*'. The committee is appointed by the head

of the facility and the chair is elected from among the committee members. A fine may be levied against the head of an animal facility who has not appointed an Animal Experimentation Ethics Committee. Under the terms of the amended law, an annual report must be submitted to the Minister of Agriculture and Forestry regarding animal experimentation activities.

### People's Republic of China

The 'Regulations for Administration of Laboratory Animals' was approved by the State Council in 1988 (State Science and Technology Commission 1988). The Ministry of Health subsequently published Implementing Detailed Rules of Medical Laboratory Animal Administration. In general, these regulations are designed to ensure high-quality animals for research. The standards, 'Laboratory animal – Requirements of environment and housing facilities' (GB 14925-2001) were revised in 2001. Standards are described regarding construction of the animal housing areas; separation of animals by source, species, strain, experiment and pathogen status; quality of food, water and bedding provided to the animals; quarantine procedures; preventive medicine; and animal transportation. In 2006, the Ministry of Science and Technology (MOST) issued guidelines for the humane treatment of laboratory animals. This was the first state policy-related document which directs administrators and technicians to attend to the welfare of laboratory animals. In this manner, concepts such as the Three Rs and scientific merit have begun to be included in Chinese regulations.

The Beijing Municipality has additional regulations regarding the Administration of Laboratory Animals (Beijing Municipal Science and Technology Commission 1997). These regulations are specific to '*artificially raised and bred animals with control of microbes and parasites carried by them and definite genetic background and clear sources that are used for scientific researches, teaching, production, examinations and other scientific experiments*'. The Beijing regulations require a license be obtained from the Beijing Municipal Science and Technology Commission for the use of laboratory animals in breeding, research or testing. The municipal regulations require personnel training, and technical staff must complete a technical competency assessment. Proper care, handling and treatment of the animals are emphasised throughout the regulations. Similar approaches are established in other cities where scientific research is important, such as Shanghai.

### Taiwan, ROC

In Taiwan, the Animal Protection Law (Taiwan Animal Protection Law 1998), under the auspices of the Council of Agriculture (COA), has provisions that address animals used for commercial purposes (eg, meat, milk, fur, etc), science (teaching and research) and animals kept as pets. Chapter II, Article 12 of the Animal Protection Law precludes the killing of animals, with certain exceptions such as killing for scientific purposes. Chapter III, Articles 15–18 specify the conditions for the '*scientific utilization of animals*'. Included in this chapter is the mandate that the minimum

number of animals necessary will be used in ways that cause the minimum amount of pain or injury. Article 16 requires that the institution that is using animals form an '*animal experimentation management unit*' to oversee the scientific utilization of the laboratory animals. In addition, the institution must establish an ethics committee, which must include a veterinarian and one representative of a private '*animal protection group*'. Under this law, the institution is entitled to employ an '*animal protection inspector*' or use voluntary '*animal protectors*' to assist with the supervision of animal use, including inspection of locations where animals are housed and used. In 2001 the COA announced regulations for establishing Laboratory Animal Care and Use Panels for institutions using vertebrate animals. Training sessions were provided for the panel members and the COA developed a Guideline for the Care and Use of Laboratory Animals for use by the panels.

### India

The Animal Welfare Board of India was set up in accordance with Section 4 of the Prevention of Cruelty to Animals Act 1960 (No. 59 of 1960). The Ministry of Food and Agriculture constituted the Animal Welfare Board of India in 1962. Since 1998, oversight of the Animal Welfare Board is the purview of the Ministry of Social Justice and Empowerment. Among the functions of the Board are: to advise the government on promulgating rules with a view to preventing unnecessary pain or suffering of captive animals and on potential amendments to the law. Chapter 4 of the Prevention of Cruelty to Animals Act addresses experimentation on animals. Included in the act is the authority for the government to appoint a Committee for the Purpose of Control and Supervision of Experiments on Animals (CPCSEA). The committee must ensure that animals are not subjected to unnecessary pain or suffering before, during or after the performance of experiments on them. To achieve this, the committee may, subsequent to notification in the Gazette of India, develop rules regarding the conduct of experiments. In general, the rules for animal experimentation pertain to appropriate qualifications of individuals conducting the experiment, minimisation of animal pain by the use of anaesthetics, euthanasia, consideration of alternatives to animal experimentation, that pre- and post-procedural care be provided to the animal, and that suitable records are maintained. The committee can authorise inspection of the location of the experiment and can suspend animal work by an individual or an institution.

The Indian National Science Academy is responsible for the development of guidelines for the operation of Institutional Animal Ethics Committees (IAEC). For example, protocols must be provided to the IAEC 30 days in advance of the committee meeting. The IAEC's principal responsibility is the review and authorisation of proposed animal experimentation. Each IAEC includes a member of the Committee for the Purpose of Control and Supervision of Experiments on Animals. Most experimentation is conducted on small laboratory animals (eg, mice, rats, guinea pigs, rabbits); permission must be obtained from a subcommittee of the CPCSEA to conduct research on larger animals.

## Singapore

Singapore recently established Guidelines on the Care and Use of Animals for Scientific Purposes (National Advisory Committee for Laboratory Animal Research 2004). These cover animal care and use for scientific purposes based on ethical, legal and scientific considerations, Institutional Animal Care and Use Committees and training of personnel involved in the care and use of animals for scientific purposes. Implementation is institution based, and they draw heavily on US, Australian and Canadian standards for husbandry, care and protocol authorisation, and on European standards for training guidelines.

## Australia and New Zealand

### Australia

The Australian Code of Practice for the Care and Use of Animals for Scientific Purposes (National Health and Medical Research Council 2004) provides a national standard for the use of animals in research, testing and teaching and since it is integrated into state-based animal welfare legislation, it is legally binding in each jurisdiction. Now in its seventh edition, the Code of Practice began in 1969 as an initiative of the scientific community aimed at establishing ethical and welfare standards for animal research. It is published by the National Health and Medical Research Council (NHMRC) which is Australia's peak statutory health body and whose responsibilities include the promotion of ethical behaviour in the conduct of research. Periodic revisions to the code are conducted with public consultation through a Code Liaison Group which includes representation from animal welfare groups in addition to government research bodies and academia. This process of periodic revision and the legally binding status of the code means that the regulatory framework can respond to changes in the biological sciences and community attitudes more readily than is usually possible through the formal legislative process. The NHMRC supports the enhancement of laboratory animal welfare in other ways too including through its Animal Welfare Committee, which provides advice to the Council on the conduct and ethics of animal experimentation. The Animal Welfare Committee participates in the revision of the Code of Practice and has developed numerous policies, guidelines and publications on topics such as advice for independent members of AECs, the care of genetically modified animals, monoclonal antibody production and the training of surgeons using animals.

The Code of Practice covers all live non-human vertebrates and also cephalopods. It emphasises the responsibilities of investigators, teachers and institutions to:

- ensure that the use of animals is justified, taking into consideration the scientific or educational benefits and the potential effects on the welfare of animals;
- ensure that the welfare of animals is always considered;
- promote the development and use of techniques that replace the use of animals in scientific and teaching activities;
- minimize the number of animals used in projects; and
- refine methods and procedures to avoid pain or distress in animals used in scientific and teaching activities

The Code of Practice endorses the principles of the Three Rs and also provides practical guidance by setting out general principles for the care, housing and humane use of animals. Importantly, it also requires the establishment of AECs for each research institution. Membership of an AEC must include a veterinarian, a scientist, a person with a demonstrable commitment to animal welfare but who is not employed by the institution, and a person viewed by the wider community as bringing a completely independent view and who is both independent of the institution and who has never been involved with the scientific use of animals. In addition, the AEC should appoint to its membership a person responsible for the routine care of animals from within the institution. AECs must have terms of reference that are publicly available and must include provision for oversight of all aspects of the animal care and use programme, assessment of animal use proposals, withdrawing approval of a project, authorising emergency treatment or euthanasia of animals and making recommendations to the institution to ensure compliance with the Code of Practice.

To assist with regulatory oversight, the Code of Practice provides guidance for the external review of animal research institutions and their AECs although details of the implementation varies between states according to legislation. In the state of New South Wales, for example, the legislation requires the establishment of a 12-member panel constituted by representatives from animal welfare organisations, the research sector and government. The panel has broad responsibilities that include serving as a conduit for community input to policy development, advising on the resolution of complaints and oversight of institutional self-regulation through on-site inspections and audits in collaboration with government veterinary inspectors. It has also published guidelines on practical aspects of laboratory animal care with an emphasis on evidence-based approaches.

In addition to state and territory laws dealing specifically with animal welfare, other laws at both the state and federal levels extend into the regulatory environment of animal research in Australia. These include laws relating to quarantine, wildlife management, genetic manipulation and occupational health and safety.

Recently, the Federal Government released the Australian Animal Welfare Strategy (Commonwealth of Australia 2005). This comprehensive strategy covers not only laboratory animals but all use of animals in Australia. In common with the Code of Practice, however, broad consultation was prominent in its development with input being sought from animal welfare groups, government, industry and the general public. The goals of the Strategy include the enhancement of existing animal welfare arrangements and development of nationally consistent policies which will, among other things, take into account scientific evidence and social considerations. At present, the prospect of federal legislation governing animal research seems unlikely since the Australian Constitution is usually interpreted as delegating animal welfare matters to the state governments. However, the integration of the Code of Practice into state animal research legislation, does, in effect, achieve the Strategy's goal of a consistent national policy in this area.

Another recent publication has been the NHMRC's 'Guidelines to promote the wellbeing of animals used for

scientific purposes: The assessment and alleviation of pain and distress in research animals' (National Health and Medical Research Council 2008). The guidelines offer definitions of animal welfare and well-being and contain 'Factsheets' addressing a diversity of topics relevant to research proposal review, including food and water restriction, tumour induction, polyclonal antibody production and several others.

### New Zealand

Animal use in New Zealand was initially regulated by the Animals Protection Act 1960 and, in particular, its 1983 amendment which stipulated conformance with a code of ethical practices when using animals for research or testing. The Act covered all vertebrate animals kept in captivity or which are dependent upon humans for care. The 1983 amendment also established a National Animal Ethics Advisory Committee (NAEAC).

The Animal Welfare Act of 1999 (Ministry of Agriculture and Forestry (MAF) 1999) replaced the Animals Protection Act of 1960 to meet changing societal views toward the use of animals. It also expanded the types of animals covered under law to include most of those that can feel pain, excluding shellfish and insects due to the lack of evidence that would support their ability to feel pain. Part 6 of the Animal Welfare Act requires that an institution hold a Code of Ethical Conduct (CEC) approved by the Director-General of the MAF before research, testing or teaching with animals can be done. Organisations and individuals who wish to engage in research, testing or teaching may, however, use another organisation's code and animal ethics committee. The goal of the CEC is to ensure that the applicant's staff have the 'appropriate qualifications and expertise' to carry out the proposed procedures on animals (Ministry of Agriculture and Forestry 2006). The CEC describes the policies and procedures implemented by the code holder to ensure that the use of animals in research, testing and teaching complies with the Animal Welfare Act. Specifically, a system of record keeping and monitoring of all animal activities is required. Subsequent to the CEC's initial approval, it must be reviewed and renewed after a maximum of 5 years. This role has been assumed by NAEAC. The 1999 Animal Welfare Act also calls for an independent, periodic review of the programme to ensure it conforms to the CEC, the Act, and other relevant regulations.

As noted, the holder of a CEC must form an animal ethics committee (AEC). The committee is appointed by the code holder who may be the chief executive of the institution or his/her nominee. The AEC must be comprised of at least four members and have a minimum of three external members, including a senior member of the organisation; an outside veterinarian; a person representing animal welfare groups who is not affiliated with the institution and is not involved with animal research, testing or teaching; and a person to represent the public (lay member). The NAEAC has published a guide to assist the lay member in his/her role on the AEC (National Animal Ethics Advisory Committee 2007). The AEC is responsible for overseeing conduct of research at the institution, including reviewing proposed projects, monitoring the conduct of the project,

reviewing project renewals, monitoring management practices and facilities to ensure conformance with the CEC, suspending or revoking project approval and recommending to the code holder changes to the CEC. Each proposed project must include a harm/benefit analysis and must address reduction, replacement and refinement (the Three Rs) of animal use. If the animal(s) is euthanased at the end of a manipulation, Part 6 does not require that the AEC consider the ethical question of killing the animals. Rather, the harm/benefit analysis that must be considered with each proposal is limited to the pain and/or distress that the animal may experience. Part 6 of the Animal Welfare Act provides for circumstances where pain, distress, and 'compromised care' of the animals may be allowed such that the researcher cannot be prosecuted for not conforming with Parts 1 or 2 of the Act.

The Animal Welfare Act stipulates that the physical, health and behavioural needs of animals used in research, testing and teaching are met in a manner that conforms with good practice and available scientific knowledge. To that end, the NAEAC and MAF published a 'Good practice guide for the use of animals in research, testing and teaching' (National Animal Ethics Advisory Committee 2002) with the stated purpose of promoting 'the humane and responsible use of animals for scientific purposes' by describing guidelines for good practice. The guide addresses the acquisition of animals, facility construction and operation, management of animals in breeding and holding areas, responsibilities of investigators and responsibilities of teachers. Of particular note is the Animal Welfare Score Sheet provided as an appendix.

Finally, the Animal Welfare Act requires that all code holders submit to MAF annual animal use statistics. These data are made available to the general public. These reports contain data regarding animal source, the purpose of the experiment, a grading of the animal procedure severity and other related information.

### Examples of oversight elsewhere in the world

#### Mexico

Technical specifications for the production, care, and use of laboratory animals (Norma Oficial Mexicana para la Producción, Cuidado y Uso de los Animales de Laboratorio) are contained in the federal Mexican law, NOM-062-ZOO-1999. The law covers dogs, cats, pigs and non-human primates. In addition, Mexico City has enacted a law in 1981 for the prevention of cruelty to animals (Ley del Distrito Federal para la Prevención de la Crueldad a los Animales).

#### Russia

Russian regulations (Sanitary Regulations for the Organization, Equipment and Maintenance of Animal Facilities for Experimental Biology (Vivaria) 1973), describe the location and design of animal facilities; sanitation requirements of animal facilities; housing and husbandry requirements; acquisition and quarantine of animals; standards for personal hygiene; and standards for the humane

treatment of animals. Included in the latter section is the requirement to minimise pain experienced by the animal through the use of anaesthetics and analgesics.

### Israel

The Israeli Animal Welfare Law (Experiments with Animals) 1994 establishes a review system and standards that are very similar to the US institutional based system. However, oversight of contentious procedures is performed directly by a National Council for Experiments in Animals, whose composition includes scientists, animal welfare representatives and non-affiliated members. The Council may withhold permission to conduct animal research if a reasonable alternative is available. The Council also visits animal facilities.

### South America

In Brazil, animal welfare is encompassed in the Constitution (Article 225) and the Federal Decree on Anti-Cruelty (1934). The Brazilian Environmental Crimes Law (1998) supplements the Constitution to include cruelty crimes against animals. Article 32 of the Environmental Crimes Law specifically addresses the use of animals in research. This Article encourages the use of alternatives and requires the use of anaesthesia for painful procedures. Various states and municipalities have additional animal laws in place. In Peru, the protection of Domestic Animals Law (2000) covers the use of cats and dogs used in research.

### South Africa

The South African National Standard, 'The care and use of animals for scientific purposes' (SANS 10386:2008 (South African Bureau of Standards 2008)) encompasses all aspects of the care and use of animals for medicine, biology, agriculture, veterinary and other animal science, as well as industry and teaching. These standards define an animal as 'live, sentient non-human vertebrate, including eggs, fetuses and embryos, that is fish, amphibians, reptiles, birds and mammals ... and higher invertebrates such as the advanced members from the Cephalopoda and Decapoda'.

### Acknowledgements

The authors wish to express their gratitude to Dr. Gilly Griffin, Guidelines Program Director, Canadian Council on Animal Care and for her contribution to ensuring the accuracy of some of the information presented in this chapter.

# 9 Planning, design and construction of efficient animal facilities

Barbara Holgate

## Introduction

Research animal facilities are complex and highly technical buildings which need to be planned to address the need to provide for the health and welfare of the animals, as well as the health and safety of the people working within the facility. In view of this, the planning and design process for a new or refurbished facility needs to be carefully thought through and to involve all those with an interest in the final functioning of the facility.

The key groups to involve at the planning stage include:

- the scientists who will plan and conduct studies within the facility;
- the animal technicians who will service the facility and care for animals within it;
- the engineering and other support staff who maintain the fabric of the building;
- health and safety advisors;
- regulators.

This is also the point at which to consider how the animals' needs can best be met.

The objectives and critical success factors for the new facility need to be specified very clearly. These are likely to include:

- capacity to meet research objectives by reducing environmental variability in animal studies and maximising the capacity to capture data;
- maximising animal welfare;
- providing a pleasant and safe environment for people to work in;
- maximising the future flexibility and adaptability of the facility;
- minimising the total lifetime cost of the facility;
- completing the project on time and within budget;
- building a state-of-the-art facility in order to attract and retain talented researchers.

Establishing the detailed objectives may not be easy: reviewing past and current volumes and types of research and scientific procedures involving animals is necessary, but may not give a clear indication of future needs. Departmental plans, including recruitment patterns and future plans, are important to consider in establishing trends. There is a clear benefit in trying to make facilities as future-proof as possible, by designing with flexibility and adaptability in mind

and, if possible, allowing for expansion. One or two examples of recent shifts in trends may help illustrate the need for flexibility. In many countries, total animal usage was fairly steady or declining until the rapid expansion in recent years of the use and breeding of genetically altered animals (especially mice). An even more recent trend is the expansion in use of zebrafish. UK Home Office statistics for 2008 (Home Office 2009) summarise recent trends for the UK, and may be useful in helping to predict trends elsewhere also. Over many years, the use of mice has increased, and the use of rats has decreased. The number of animals used in breeding has increased steadily, as has the proportion of those animals which are genetically altered – this had reached 37% in 2008. The overall percentages for different species used in the UK in 2008 are shown in Table 9.1.

## The design process and design team

For a successful project, a large amount of thorough preparation is needed before the first pile is driven. This should start many years before the facility is required, and one of the first steps is gaining recognition and acceptance of the fact that a new or refurbished facility is required. This may require collation of large amounts of data on occupancy of existing facilities, and predictions of future work, both in terms of volume and type.

A useful activity at this early stage is process mapping (Bicheno 2004). This is a formal way of capturing existing activities, and also allows the opportunity to identify scope for improvement, either within the existing facility or in the future facility that is to be designed. In some cases, the additional efficiencies that may be identified might postpone the need to build or extend facilities; if not, then the results of the exercise are useful confirmation that a new facility is indeed necessary.

Once there is some commitment to build a new facility, a design team should be assembled. In the early stages, this should include, at minimum, representatives of the future users of the facility (typically researchers, animal technicians and laboratory animal veterinarians), a project manager, an architect and engineering representatives. Although a small design team can usually make progress more rapidly, it is essential that the user population is adequately represented. Failure to consult widely and appropriately may well result in a design which is at worst unsuitable for the proposed

**Table 9.1** UK Home Office statistics for species used in scientific procedures in 2008.

Species	Percentage of total
Mice	66%
Rats	10%
Fish	17%
Birds	3%
Other mammals	3%
Reptiles and amphibians	1%

use, or at best very unpopular, leading to multiple complaints and dissatisfaction.

There is a significant advantage in engaging architects and engineers that have prior experience of the design and construction of animal facilities. This shortens the education process that otherwise is required to inform these individuals about the detailed requirements of such facilities. It also allows visits to existing facilities where they have been engaged previously, to learn from the relative successes and failures (Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC) 1998). If possible, several such visits should be arranged and discussions should take place with the current users of those facilities to seek their views.

Traditionally, the design goes through several iterations, from initial concept, to the development of a brief, and then of the detailed tender documents which are used to engage contractors to build the building. More recently, an approach known as 'alliance contracting' has gained popularity, where contractors are engaged at an early stage, involved in development of the design, and then share in the risks and benefits that develop through the project. This approach has arisen mainly because of cases in the past, in which contractors have taken on too much risk in accepting contracts and have either gone out of business or ended up in lengthy legal disputes with the contracting parties (Egan 1998).

## Key information required in early planning

### Species

While the full range of species that may be kept in a facility can be difficult to predict, a facility designed to house rodents can generally be adapted to house the majority of small species that might be considered. This could even be extended to include some aquatic or amphibious species such as fish and toads. Among the points to consider here are to ensure that the load-bearing capacity of the floor of the facility will cope with the additional weight of containers filled with water, that there is a means of dealing with water from spillage or leaks, either through drainage or vacuuming, and that the ventilation system can deal with high relative humidity within the area.

Facilities intended for large animals (eg, dogs, farm animals, macaques) are rather different, and it can be very difficult to adapt the functions of a facility designed for large animals to suit smaller ones, and *vice versa*. Larger animals

such as dogs, pigs and primates will normally be kept in large enclosures rather than in racks of cages within a room, and these animals are much more capable of causing damage to fixtures and finishes, therefore the choice of materials must be much more durable than is necessary with rodents and other small animals. Large-animal facilities also require more extensive consideration of noise reduction and the means of dealing with the larger volumes of bedding and other waste. Again, flexibility is desirable, and several establishments have designed accommodation that is adaptable to the needs of both pigs and dogs.

### Capacity

Calculating the required capacity for a new facility is often a process of educated guesswork. Information that may be available to help the calculations will include historical data and future estimates of the number of animals used annually, the duration of typical studies or, most usefully, the number of each type of animal that may be held at any given time. Another critical factor is whether or not animals are held individually, or group housed, and what provisions are made for environmental enrichment. Space allowances must, of course, at minimum, comply with local legislation for a particular type of animals involved (Home Office 1989, 1995; Institute of Laboratory Animal Resources (ILAR) 1996; Council of Europe 2006), but more generous provision allows for a wider range of enrichment approaches.

### Capacity for breeding and supply of animals

The majority of research facilities now source many of the animals that they use from commercial suppliers and breeders. In general, these suppliers can provide animals more efficiently than on-site breeding facilities. There may be exceptions, such as the creation and breeding of genetically altered animals, where the breeding is in essence an experiment in its own right, and the researcher may wish to keep the various steps of the breeding programme under their direct control. There can also be exceptions where, because of long transport routes, or concerns over security, the decision may be taken to undertake in-house breeding of key species and strains. However, it can usually be assumed that space should be provided for the holding, acclimatisation and conduct of procedures on animals, but not for their breeding and supply.

### Holding capacity

The information required to inform estimation of the necessary holding capacity includes:

- The number of each animal to be housed at any time. If possible, it is useful to have an estimate of the average population, the minimum and the maximum, as, depending on the urgency of the work, it may be possible to smooth out the peaks and troughs in population rather than provide capacity for the worst-case scenario.
- The range of ages and weights of animals to be kept, and the effect this may have on stocking density.

- Whether any animals will need to be housed singly, or whether they can be group housed, taking into account legislation on stocking densities.
- It is also helpful to find out whether animals awaiting procedures can be housed in accommodation with those of other investigators, or whether they need to be segregated from other groups. This may be affected by factors such as health and immune status, and susceptibility to disturbance.
- Cage and rack design. There is considerable variation in the stocking densities that can be accommodated within a given footprint, depending on the style of caging that is chosen. Many of the cage manufacturers have developed higher stocking density systems, by reducing the space between cages in a rack, increasing the height of racks or introducing so-called 'library' systems, where racks are rolled to and fro to open up working space when required, rather than providing a permanent space between racks. Increasing stocking density in these ways will have a significant effect on ventilation needs. It is also wise to consider the impact on ergonomics; placing and managing cages on the top and/or bottom row of racks can involve uncomfortable stretching and may be injurious to staff over time.

#### Capacity for procedures

It is important to try to gain estimates from the researchers that will be using the facility on the number of animals they foresee undergoing experimental procedures at any given time, and the duration of those procedures. In general, it can be difficult for research groups to share either procedure rooms or rooms for holding animals under study. However, in order to achieve efficient use of space, such sharing should be encouraged whenever possible.

There is a trend to gather more information from each animal than was possible in the past (which, as a general principle, is to be encouraged). This means that more measuring and observational equipment is required, and hence the proportion of procedure to holding space is increasing. As a rule of thumb, 10 years ago, the proportion of procedure space to holding space was around one third to two thirds. However, that is changing and many newer facilities are designed to provide two thirds procedure space and one third holding space. If one includes some of the highly complex imaging facilities that are now being built, that proportion seems set to shift even further. It is essential to obtain as much information as possible about the experimental procedures that are planned and to build in flexibility to accommodate those which may not yet have been anticipated.

#### Health status and barrier requirements

The health status of most research animals has improved considerably over the last 10–15 years, and suppliers can generally provide common rodent strains to a reliable specific pathogen free (SPF) status. Hence some of the historical concerns over segregation, containment and quarantine of groups of animals have diminished. This may not apply to

genetically altered animals (GAA) obtained from other research establishments rather than commercial suppliers. In addition, many GAA strains have altered immune status and are more susceptible to infections. Research may involve the use of infectious agents (including those that have been genetically modified), and an understanding will be required of the hazard categories to which they belong and the necessary containment requirements. For many reasons, then, it is very important to develop an understanding of the health and immune status of the animals to be used, and the work to be conducted, in defining the required barrier structures, systems and procedures. In a multi-user research facility, it is usual to have to provide for groups of animals with different health or immune status, and so a single, facility-level barrier system is unlikely to be satisfactory. It is more likely that a local barrier system that allows protection or containment at room, isolator or cage level will be required. Components of barrier systems are outlined in Table 9.2.

#### Site

Ideally, the chosen site would be large enough to allow an ideal footprint size and to minimise disturbance to neighbouring facilities, would have good access to utilities, be accessible for the researchers and be secure. Very often, there is little choice of site, where the proposed new animal facility is to be located within an existing research establishment; and this will mean that conflicts and compromises will need to be carefully managed.

Points to consider in selecting a suitable site include:

- Access – both during construction and operation of the building. Management of the construction issues is a specific engineering discipline (construction design and management – CDM) and will require an early study to confirm that the building can indeed be constructed on the site proposed.
- Planning restrictions. These can often include restrictions on the height of the building and on visual appearance. Early consultation with planning authorities is advisable, in order to identify and address potential concerns.
- Scope for future expansion. This is an ideal – often the site is only just large enough for the current requirement. But if extension at a later date is a possibility, then care must be taken not to 'sterilise' the site for further expansion by the positioning of the current development.
- Access to utilities. It must be possible to supply all the required utilities and services to the site, and not to disrupt existing services.
- Access to outside space for large-animal enclosures. This may introduce security concerns and can also mean noise disturbance to nearby buildings.
- Relationship with other nearby buildings. This can include a range of issues, from ensuring researchers can access the animal facility without undue travel time from other laboratories, to assessing the prevailing wind direction, as occupants of buildings downwind of the facility may be affected by smells.

- Geographical and physical hazards (such as the likelihood of floods or major storms).

### Costs

Animal facilities have always been relatively expensive and the situation is only likely to worsen, as the work becomes more equipment-intensive. As the rate of change in scientific procedures increases, it becomes harder to prevent obsolescence of facility designs, and therefore the lifespan of buildings (ie, time before their refurbishment, modification or replacement) is tending to decrease. Quoting sample costs here is of little value, as they are not comparable between countries, nor will they remain static over time. However, it may be useful to make some brief comparisons with other types of buildings. A modern, well equipped, rodent research facility (eg, with automated cage-wash and imaging facilities) would be at the top end of building costs, comparable with highly automated laboratory buildings. On the other hand, in the design and construction of a recently completed dog breeding facility, using simple but robust materials, final costs were comparable with those for standard office accommodation on a per square metre basis.

Another worthwhile comparison is to benchmark areas of usable space versus circulation space and plant room space (Clough 1999).

The lifetime costs of the facility should also be considered. One issue that can arise in the design and construction of new facilities is that the project capital costs are considered separately from the revenue costs of running a building. Project managers are often under extreme pressure to ensure that their building project is completed within or below budget. To this end, they may be tempted to cut costs in construction and fit-out that would actually result in reduced running costs. Examples of finishing and equipping that may impact on running costs include:

- Quality of finishes. High-quality floor finishes can be extremely expensive per square metre. However, economising in this area can result in a poor finish which wears badly, is hard to clean and maintain, and needs replacing within a short space of time. This increases the total running costs and is also very disruptive.
- Automation. Automated cage wash areas require a very high capital investment. However, fewer staff are required to carry out the cage cleaning operation, so over the lifetime of the building the initial investment

**Table 9.2** Components of barrier systems.

<i>Item</i>	<i>Comment</i>
Separation of building from hazards (other research facilities, wild rodents)	Although this is a good method of preventing spread of infections, the cost of constructing multiple small facilities makes it difficult to achieve
Exclusion of wild rodents and insects from facility	Rodent-proof doors, or rodent barriers, are recommended at all entrances into the facility. Insecto-cutors are required inside all external doorways
Staff changing routines, protective clothing	Not essential if the barrier is at cage or isolator level, but important if at facility or similar level. May require shower and full change to be really effective. Common sources of infection include hands and respiratory system
Air pressure regimes	Keeping animal holding rooms at positive pressure can help exclude pathogens, but also pushes allergens out of the animal rooms into staff areas, which can increase the risk of development of laboratory animal allergy (LAA)
Air filtration	High-efficiency particulate air (HEPA) filtration is required for maximum protection. This can be at facility level or below (isolator, cage). Lower levels of filtration may be appropriate in conventional facilities. HEPA filtration of extract may also be required if containment of infections is required
Sterilisation and disinfection	All items entering a fully barriered area require treatment (eg, autoclaving, irradiation and/or surface disinfection by spraying, fogging or immersion) to minimise the potential of carrying infections into the area
Isolators	Isolators (usually flexible film isolators) represent the maximum barrier possible, as all items entering the isolator are sterilised or disinfected, and people do not enter the working area
Individually ventilated cages (IVCs)	IVCs can represent an effective barrier, if air is HEPA filtered into the cages, other materials are sterilised before use and all operations requiring opening of the IVC are carried out in a biological safety cabinet. Strict compliance with operating procedures is essential to maintain these systems effectively
Quarantine	An important procedure when adding animals from a less trusted source to animals of a known health status, allowing time for health screening of the new population before they are added to the existing animals
'Clean to dirty' flow of operations	Theoretically, people and materials moving from a 'dirty' area may carry pathogens with them, so ensuring work flows in the opposite direction should reduce the risks
Restricted access	Restricting access to the minimum number of staff, and ensuring they are all trained in correct procedures, should minimise the risks of introduction of new infections

can result in significant savings. As an additional benefit, automation can also minimise the exposure of staff to laboratory animal allergens.

- Ventilation of safety cabinets. Once-through, non-recirculating Class II cabinets can be more expensive to install than other systems, because of the ductwork required. However, because fewer fans and filters are required in the immediate working area, there may be efficiency gains because staff can adopt a more ergonomic working position, and maintenance may be easier and cheaper.

## Design considerations

### Structure

Modern buildings are commonly constructed with a steel frame. It is important to be aware at an early stage of the spacing between components of the steel frame and to attempt to lay out a grid which is both structurally strong but also reduces interference with room layouts (for example, avoid positioning columns in the centre of rooms). Larger grid spacing requires bigger steel columns and beams, which can add costs and reduce ceiling headroom for distribution of services. Typical grid spacing is around 6–8m, which allows for room widths of 3–4m. This is in line with typical animal room widths.

### Single or multi-storey?

Single storey facilities are undoubtedly easier to construct and operate. Typically, they would involve a single storey of animal facility, with plant room above. However, the size of site available may often dictate that a multi-storey facility is constructed, or there may be a requirement to build an animal facility as a single floor within a multi-storey research facility. The issues that can arise with multi-storey facilities include:

- movement of people, animals and materials around the facility and, in particular, the need for lifts;
- floor loading by heavy equipment (eg, autoclaves, MRI and PET scanners);
- potential leakage from cage wash facilities or other 'wet' facilities if these are not placed on the lowest floor;
- distribution routes for ventilation, access for maintenance.

### Services

Animal facilities will typically need good supplies of electricity, steam, water (including chilled water for cooling) and drainage. Often these will be taken from existing site supplies, but it is essential to ensure that there is adequate supply capacity, and that there are backup systems in case of any interruption. Enquiries should be made about the quality of steam – wet or 'dirty' steam can cause problems with autoclaves and cage washers, as can a lack of steam

**Table 9.3** Checklist of typical service requirements.

Service	Comment
Electricity	Required for the majority of equipment, and for lighting. Back-up supply likely to be required for some equipment, especially IVCs and isolators, where failure to supply fresh air to the animals can result in mortality after short periods of time. Electrical power requirements need to be carefully planned in relation to the equipment to be run
Water	Required for hygiene procedures, animal drinking water, staff facilities and cooling
Heat	May be locally generated (in which case fuel such as gas or oil is required) or site supply (eg, hot water, steam)
Laboratory gases	Commonly oxygen, carbon dioxide. Other specialist gases may be needed. Scavenging of waste anaesthetic gases is likely also to require consideration
Drainage	Drainage from sinks and toilets definitely required. Floor drains only essential for large species. Where installed in large animal facilities, floor drains must be designed to prevent blocking with bedding and similar materials

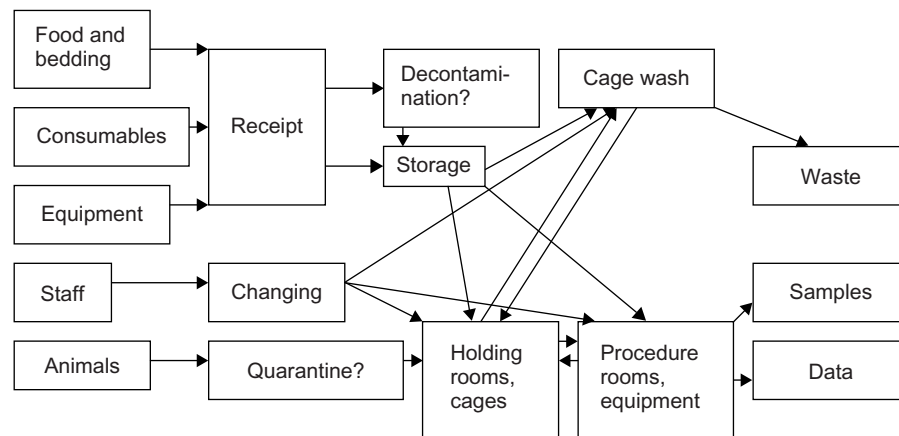

pressure. Table 9.3 outlines some of the service requirements.

### Functional relationships

The layout of an animal facility is critical to its success. Animals, people and materials will need to enter the facility and be moved around within it, then people and waste materials will need to exit (see Figure 9.1). All these different categories of inputs and outputs will need to be handled safely and efficiently, with the minimum of crossing of movement routes (especially for 'clean' versus 'dirty' items). In addition, movement into or near animal holding areas should be minimised to avoid disturbance. Single-corridor versus dual-corridor systems need to be considered: dual-corridor systems make segregation of clean and dirty materials much easier, but are costly in terms of space. Clough (1999) outlines common functions and their relationships and a range of single- or dual-corridor layouts.

### Storage

Most facility managers claim that they do not have enough storage space, and this is generally a commodity that is under pressure during the design of a building. To a degree, this is inevitable, as space in animal facilities is expensive and priority tends to be given to the absolutely essential functions such as animal holding, procedures and plant. Some potential solutions to solve the issue include:

**Figure 9.1** Simple process map for planning purposes.

- Working with suppliers to develop 'just-in-time' methods.
- Use of lower specification, cheaper storage space outside the main facility, in conjunction with smaller storage spaces within the facility for immediate use. Several facilities have adopted this approach for bulky items (such as food and bedding), or for equipment that is used infrequently.
- Use of efficient storage and retrieval methods, such as automated 'Kardex'-type systems. Even if not used for automatic re-stocking, these systems make good use of vertical space and reduce corridor space needed to access all parts of the storage system.

## Corridors

Corridors are essential but take up a lot of space. They need to be wide enough to allow easy flow of people and materials around the building. The NIH recommendation for single-corridor buildings is 2.1m clear width (National Institutes of Health (NIH), 1999). In dual-corridor systems, corridors can be narrower as there is less two-way traffic.

## Doors

Doors will generally need to be 1.1–1.2m wide to enable movement of people and materials into rooms. Vision panels can be very useful, but on doors into animal holding rooms these should be provided with a light tight cover or blind.

For safety reasons, doors should normally open into rooms (not out of them into corridors). Alternatively, sliding doors may be used (though these are usually more expensive). Doors should be constructed in such a way as to resist the ingress of moisture into the structure or fabric. Doorways may need to be designed to contain or exclude rodents. This can be achieved with rodent-proof doors or by the use of rodent barriers. Where rodent barriers are used, they can potentially pose a trip hazard: this may be reduced by ensuring either the barrier or the slots which hold it are flexible and safely collapse if a person knocks into the barrier.

## Lifts

Animal facilities on a single floor are undoubtedly easier to design and manage than multi-floor facilities. However, limited land space may drive the need for multi-floor facilities. In these cases, dual lifts are strongly recommended, with separation of clean and dirty functions. The shaft of the dirty lift should generally be at negative pressure to the rest of the facility (NIH 1999).

## Windows

Traditionally, few if any windows have been built into animal facilities, for two main reasons. Firstly, there have been concerns that windows are a weak point in security, and secondly, they can make controlling photoperiods more difficult. However, more recently, there has been a desire to make the working conditions for people inside animal facilities more pleasant, and it seems that access to daylight can be very positive in this respect. It can also create the impression of a more open facility. Careful placement of windows in administrative areas, or on outside corridor walls, can achieve these positive gains without significant adverse impact. Skylights and light tubes can be useful alternatives. In large-animal facilities (for example, housing dogs or primates), access to daylight can be seen as a positive enrichment and recommendations to this effect are now starting to appear in some national and international guidelines (Council of Europe 2006).

## Floors and floor drains

Floors should be made from robust and durable materials, capable of physical cleaning and disinfection.

Drains are essential for large-animal facilities, where large volumes of water may be used in cleaning. However, difficulties are commonly experienced in achieving an adequate floor fall towards floor drains, resulting in pooling of fluids. For this reason, where drains are not essential, it is suggested they may be best avoided.

As well as choosing an appropriate flooring material, it is essential to make sure that the contractors laying the floor

are skilled and experienced. Poor-quality workmanship is a frequent cause of problems in this area.

Where drains are provided, the drain traps should be kept filled with water and additional means of preventing the ingress of wild rodents may be necessary. If floor drains are used in rodent facilities, the design should also prevent the escape of the animals housed. Drains in large-animal facilities will need to be of adequate diameter and it is highly likely that stainless steel mesh baskets will need to be provided in the drains to catch sawdust bedding and prevent clogging further down.

The load-bearing capacity of floors will need to be taken into account; especially as very large items of equipment are increasingly being used. For example, MRI and PET facilities involve very heavy equipment and may be best placed on ground or basement floors.

## Walls

Walls need to have smooth, moisture resistant finishes, capable of withstanding regular fogging or disinfection. It is not always necessary to have heavy-duty construction (eg, plastered block walls). Lightweight construction of stud and plasterboard, with an appropriate finish (eg, Vinyl sheet), can be satisfactory in small animal facilities. The advantage of this type of construction is that it is relatively flexible, and removal of a wall, or creation of a new one, can be done with the minimum of disruption. Prefabricated panel systems may also be appropriate – there are several systems in use in hospitals which may be worthy of consideration. The key point to be covered in the building brief is that the walls, along with the floors, must be capable of regular cleaning and disinfection. Attention to sealing joints and coving angles, where appropriate, is very important.

## Bumpers and guards

Due to the relatively heavy traffic within animal facilities, walls, doors and lifts will require bump rails and corner protection to avoid damage. These must be positioned at the correct height to prevent sharp corners on trolleys and cage racks from making contact with the finishes to be protected, and should be robust and firmly fixed. Bump rails must be deep enough to protect surface-mounted items such as electrical sockets.

## Ceilings

Ceilings should be smooth, to avoid the creation of dust-traps. Depending on the function of the particular room, they should be moisture resistant and capable of cleaning. However, where ceilings are not going to be subject to contact with a lot of water or disinfectants, there may be an opportunity to use sound-absorptive materials to reduce sound levels within the room. As far as possible, the design of the facility should avoid the need to access above ceilings to conduct maintenance on, for example, ventilation and lights.

## Drinking water for animals

Animals should be supplied with uncontaminated drinking water. The precise quality of water, and the treatment required to achieve this quality, will usually depend on the health and immune status of the animals concerned. For example, in a barriered breeding unit, it might be appropriate to filter, chlorinate and irradiate the water with UV light. On the other hand, water supplies to a conventional dog unit could be taken straight from the municipal supply. Water supplied to immunocompromised animals within isolators may well need to be completely sterile. Acidification may need to be considered – it has been used as a means of controlling infection with organisms such as *Pseudomonas aeruginosa*. Hard water may need to be treated to avoid deposits within delivery systems. Reverse osmosis appears to be the method of choice for this purpose, as it requires no addition of chemicals.

The water delivery systems for animals need to be considered. Traditionally there have been two choices: either automatic water systems or bottles. More recently, suppliers have been offering the option of supplying water in plastic pouches (similar to pouches used for sterile intravenous fluids). Attributes of different water delivery systems are summarised in Table 9.4.

## Procedure rooms

General procedure space will be required in research facilities, in which to conduct routine and common activities such as dosing animals, collecting samples and making observations. This space can be suitable for diverse activities – typical requirements are that it is quiet, close to the holding area, well lit and sufficiently spacious to allow for equipment. Typically, such rooms will contain laboratory benching and cupboards, a sink, plentiful electrical sockets and data sockets, and little else in the way of fixed equipment; researchers will bring equipment to the room as and when required. Cantilever benching is often favoured, as it allows easy floor cleaning.

More specialised space is required for surgical procedures and for *post-mortem* examinations.

Increasingly, in all procedure areas, provision is required for engineering controls to reduce exposure to laboratory animal allergens. Options include Class II cabinets, down-flow tables and laminar air flow (LAF) booths. Operator protection and ease of use varies, with Class II cabinets being hardest to use from an ergonomic perspective, but offering best protection, while downflow tables and LAF booths offer less protection but greater ease of use.

## Cage wash facilities

It has been recognised in recent years that cage changing and cleaning is one of the activities that may lead to the highest exposure to laboratory animal allergens. Various approaches have been taken in order to try to reduce this exposure. Mobile bedding disposal stations are available, which draw air from the front of the cabinet to the back,

**Table 9.4** Attributes of different animal drinking water systems.

<i>Automatic system</i>	<i>Bottles</i>	<i>Pouches</i>
Expensive initial outlay	Bottles relatively cheap. Bottle washing equipment can be expensive (especially if largely automated)	Capital outlay depends on system: pouch-making machine can be expensive; ready-made pouches require no machine but increase revenue costs
Low labour requirement	Can be labour intensive, especially if washing process not automated	Low labour requirement
Constant supply of water (but system still needs regular checking to detect failures)	Water levels require frequent checking	Water levels need checking, but, depending on volume of pouch, less often than with bottles
Failures may not be obvious	Failures generally obvious	Failures generally obvious
Difficult to avoid flooding in conjunction with solid-floored cages	Flooding limited to volume within bottle	Flooding limited to volume within pouch
Impossible to measure water consumption	Easy to measure water consumption	Easy to measure water consumption
Difficult to administer treatments in water to small groups of animals	Easy to administer treatments in water to animals within an individual cage	Easy to administer treatments in water to animals within an individual cage

filter and recirculate it, thus protecting the operator from the allergen-laden dust which would otherwise enter their breathing zone during cage changing. However, these stations tend to be somewhat restricted in size, and can lead to ergonomic issues whilst handling cages within them. This has led to the development of large, walk-in, down-flow booths, where there is much greater access to the actual point of bedding disposal. These are much better ergonomically, but still rely on much repetitive manual work. The most sophisticated cage change and cage wash facilities now incorporate robots to empty cages of waste material and place them on the conveyor of tunnel washers. When the cleaned and dried cages have reached the far side of the tunnel wash, further robots take them off the conveyor, and add clean sawdust and stack them ready for use. These systems are very expensive to install, but capable of high throughput and almost continuous operation, and clearly offer the maximum protection from exposure to laboratory animal allergens. They are, however, only likely to provide an appropriate economic pay-back in large facilities.

Another recent development in cage washing equipment has been the possibility of using cage washers for fumigation, when connected to vaporised hydrogen peroxide (VHP) generators. VHP is an effective surface sterilant and is becoming popular for room and building fumigation. Connected to a cage washer in this way, it can be used to sterilise large items of equipment or bagged consumables.

### Autoclaves

If the barrier requirements necessitate an autoclave for sterilisation, then key considerations include:

- ensuring the chamber is large enough to take the largest item requiring sterilisation;
- ensuring the different cycles available are suitable for all the types of materials to be sterilised;
- ensuring the cycle time is short enough to avoid bottlenecks in the operation of the facility; the barrier system

will break down if the capacity of the autoclave is insufficient to supply enough sterile materials.

It is also wise to plan how maintenance, repairs and replacement will be carried out without having to cease operation of the facility.

### Data handling

Research is a data-intensive process, and it is important to provide sufficient capacity in the facility for collection and transfer of data. High-speed network links and multiple computers allow data to be collected directly, without transcription. Many recording devices (weighing balances, measuring callipers, for example) can be directly linked to computers. Wireless networks may allow the computer to be taken cage-side for immediate recording of observations.

### Environmental specifications

This is a key area in the design and construction of an animal facility, and generally represents a high percentage of the overall building cost. National guidelines usually specify performance requirements and may require proof that these are met before the building can be used, hence achieving compliance is a critical success factor for a building project. It must be noted that the majority of guidelines specify the *macro* environment for keeping various species (ie, the room environment), and were probably, partly, empirically derived from environmental parameters that were found to provide comfortable working conditions for staff. The immediate environment around the animals (ie, the micro environment within the cage) can be significantly different. From a functional perspective, as well as meeting compliance requirements for the macro environment, the building design should also ensure the micro environment will support the satisfactory health and welfare of the animals.

## Temperature

Theoretically, it seems logical to keep animals within their thermo-neutral zone (TNZ); coping with more extreme ranges may be physiologically possible, but requires considerable energy expenditure and adaptation, and there is evidence of altered experimental results at different temperature ranges (Romanovsky *et al.* 2002). However, Romanovsky and colleagues also explain that the TNZ can vary across different experimental set-ups, even for the same animal. They describe TNZ values from the literature that vary widely, including values for the rat that vary from 18–34°C. Much of this variation may be a result of the micro environment and the behavioural responses of the animals. Gordon *et al.* (1998) describe the concept of the 'operative' ambient temperature by modelling heat loss in different circumstances. In an acrylic cage with a wire top and no bedding, the 'operative' temperature was more than 10°C cooler than a similar cage with wood shavings and a filter top. This probably explains why rodents which 'choose' an ambient temperature of up to 30°C do not appear to suffer cold stress when kept in cages with bedding within a room where the ambient temperature is around 22°C. One can envisage a future where the performance criteria for the animal facility will be to prove that animals are within their TNZ in whatever caging system is provided. In the current circumstances, while it is necessary to achieve compliance with guidelines and codes of practice, it is also wise to be aware of the potential effects of temperature variations and instability on the research to be conducted in the facility.

In designing a facility, decisions will need to be taken on the range of temperatures which can be set for animal rooms, and whether they are controlled at the level of the individual room, at the level of the whole facility or somewhere in between. Individual room control will add significantly to the costs, while increasing the flexibility to hold species with different temperature ranges, as set out in legislation or codes of practice.

## Relative humidity (RH)

Published guidelines recommend RH ranges which avoid extremes (Home Office 1989; ILAR 1996). Low humidity can cause increased heat loss, and 'ringtail' in some strains of rats. High humidity can reduce the ability to lose heat, and has been associated with rapidly increasing levels of ammonia within cages. A set point of 50%, with variation of 15% around the set point, is achievable and avoids likely problems. The ventilation system must be designed to meet these limits within the range of external relative humidity experienced at the location of the facility.

## Sound, noise and vibration

There are some circumstances where it is possible that noise within an animal facility will cause physical damage to an animal – loud barking by dogs has been raised as a concern in terms of damage to their own and their handlers' hearing (Sales *et al.* 1997). However, there is a growing body of evi-

dence that noise and vibration can disrupt studies in animals through disturbance and stress effects (Faith 2007). Sudden impact noises may be more of a concern than high but constant background noise levels, as they are more likely to induce a startle response in the animals. It is thus difficult to define acceptable noise levels, but experience suggests that noise levels quoted in the UK Home Office Codes of Practice appear to avoid major disruption (Home Office 1989). Where it is known that planned research is particularly susceptible to noise disruption (such as telemetry or behaviour studies), additional measures, such as sound insulation between rooms or the use of subdivisions within rooms (eg, mobile cabinets with built-in ventilation), may be necessary. The use of such cabinets has been reported to reduce noise levels within the containers by 30dB in comparison with the surrounding room (Mayers 2007).

It is well understood that rodents have a different hearing range to humans, and so sources of ultrasound as a cause of disturbance to the animals must also be considered (Sales *et al.* 1988).

## Light

The aim of the lighting system should be to meet the following functions:

- to provide sufficient light to inspect animals and ensure they are healthy;
- to provide sufficient light to conduct procedures (which might include surgery);
- to ensure light levels in the animal's immediate environment are low enough to avoid retinal degeneration or aversiveness;
- to provide a means of controlling photoperiod (including reverse light cycles, which allow the study of animals during their active phase);
- to assist in the provision of a pleasant working environment.

The first two requirements can be contradictory, as high light levels may be aversive to albino rats (Blom *et al.* 1995) but are required to allow intricate work by people. This contradiction can be resolved by positioning of lights, use of tinted or opaque cage material and switching off 'task' lights when not required. Modern building regulations in many countries also require that thought is given to the energy efficiency of lighting. This can include tactics such as linking lights in administrative areas to passive infrared detectors, so that the lights only switch on when people enter the rooms. Energy-efficient light bulbs may be used and these have the added benefit that they last longer and require less maintenance. Light emitting diode (LED) technology is showing significant promise in this area. Energy-efficiency requirements may drive the need to consider the use of daylight where possible: this can also make for a more pleasant working environment, but it is important to ensure animal holding areas can be made lightproof, so as not to interfere with photoperiods.

A wide variety of research programmes may require the use of reverse light cycles. Traditionally, this has been achieved by the use of red sleeves around fluorescent strip

lights. However the colour density of these sleeves can be variable, and there has been some interest in looking at sodium lights, as a more reliable means of providing a wavelength that is not visible to rodents (McLennan & Taylor-Jeffs 2004). Aside from this, there is little strong evidence about the effects of different light colours, and standard fluorescent or incandescent lights have been used for many years without apparent issues (Clough 1999).

## Heating, ventilation and air conditioning systems

The main objectives of a ventilation system should be to supply adequate oxygen, to remove excess heat generated by animals, people and equipment, to extract waste gases and particulates, and to maintain an appropriate relative humidity. Additionally, the ventilation system may be designed to maintain pressure differences between different parts of the facility. The ventilation system should do all this without creating draughts which may be uncomfortable for the occupants. AAALAC reports that inadequacies of ventilation systems are one of the commonest reasons for failing inspections (AAALAC 2007), and that this was, typically, because specifications for temperature, humidity or air change rates were not being met. Given that these performance data are specified at an early stage in most projects, and have been relatively constant for many years, it is somewhat surprising that such failures are so common.

The key driver for designing the system is usually the removal of heat generated by animals, humans and equipment. Hence a good estimate of stocking density is an important starting point in calculations. Air change rates sufficient to achieve this aim will also deal successfully with waste gases and smells in most cases.

Distribution of the air in the rooms is critical in achieving appropriate delivery of fresh air and removal of waste gases. Clough (1999) describes common positions for supply and extract vents to achieve good distribution of air, and the design of systems can now also be informed by computer modelling. Prior to this, physical mock-ups were often used, either using live animals, or simulations with small heat-generating objects such as light bulbs.

A very useful summary of details from guidelines, and data such as heat production from different species, is provided at the Phoenix website (Phoenix 2003).

There is a number of approaches that can be taken to the distribution of HVAC (heating, ventilation and air conditioning) ducting within a building. Broadly, these are either horizontal (walk-on ceilings or parallel interstitial space) or vertical (vertical risers). Vertical distribution takes up horizontal space within rooms, but allows the overall building height to be lower. It can be more energy efficient than horizontal distribution. Horizontal distribution generally provides better access for maintenance.

The HVAC system should be designed to provide some degree of surplus capacity or redundancy. For example, it may be possible to supply the facility from two air handling units, both sized to run at 60% capacity during normal operation. In case of failure of one unit, the other can be ramped up to deliver around 80% of the normal requirements of the facility.

The HVAC system must be designed to help achieve the target noise levels for the facility. Air flow velocity, duct and diffuser size, turbulence due to changes of duct direction and vibrating fans are just some examples of sources of noise in these systems, which need to be minimised if the recommended levels are to be achieved.

## Individually ventilated cage systems and integration with HVAC

The IVC system has become a common means of keeping rodents in recent years. The technology evolved from the simple filter cage (Kraft 1958) to systems which have delivery and extraction of air from each cage, and in which HEPA filtration can be provided on both supply and extract if required. Supply and extract can be balanced to provide positive or negative pressure with respect to the surrounding room. If combined with an appropriate transfer station (eg, microbiological safety cabinet or similar) for all manipulations involving opening of the cage, good containment of or protection from pathogens can be provided, as well as good micro-environmental conditions (Lipman 1999). Details of specific systems are best discussed with the various manufacturers, who can provide details and performance features of their current models. However, some general points on whether and how to integrate IVC systems with HVAC systems are provided here. Early IVC systems were self-contained, with fan units for supply and extract normally standing next to, or fixed on top of, the cage rack. More recently, manufacturers and ventilation engineers have considered integration of the cage ventilation with the building HVAC systems. The pros and cons of the various options have been reviewed (Stakutis 2003) and can be briefly summarised as follows:

- Independent supply and exhaust fans. These are easy to fit into existing facilities, but can be noisy, cause vibrations and generate extra heat, which is retained in the room as the extracted air is recirculated. The space requirements are larger. Control systems are simpler and only small numbers of racks are affected by any failures.
- Independent supply and exhaust fans with thimble or capture hood for exhaust. In theory, this has the advantage that exhaust gas is extracted from the room, rather than recirculated within it. However, it is expensive (all the costs of the first system, plus the cost of thimbles) and can be very difficult to balance satisfactorily.
- Independent supply fan, exhaust ducted into building ventilation system. Here the supply fan is as in the previous two options, but the exhaust gas is extracted purely by the building ventilation system. This approach removes heat and waste gases more reliably, and is potentially less expensive than individual extract fans on each cage rack. Valves connecting into the ventilation extract need to be flow-independent, which can add cost and complexity. Consideration also needs to be given to whether the extract needs to be HEPA filtered, and if so, at what level (at cage level, or more centrally within the building extract ventilation ducting, for example).

- Supply and extract provided by building ventilation system. Here the rack has no independent fans, but relies on the building system for all air movement. In theory, this system will give least noise and vibration locally, and generate no extra heat within the room. No independent power supply is needed within the room. However, there are disadvantages – the valves connecting to the ventilation system all need to be variable flow, which adds cost to the HVAC system. The positioning of the racks within the rooms becomes somewhat less flexible, as the connections to the ventilation system have to be fixed during construction.

As indicated by some of these considerations, integration of an IVC system with the HVAC system is not a trivial undertaking, and if felt desirable, it should be planned at a very early stage of the building design, with close co-operation between the IVC manufacturers and the HVAC designers.

### Sustainability

Concerns about global warming and carbon footprints mean that new and refurbished buildings need to take account of energy efficiency and sustainability. Local regulations may require individual electricity metering of different areas of the animal facility in order to record consumption.

HVAC systems are major consumers of energy, and a critical consideration is whether or not air can be recirculated. Recirculation may involve the risk of cross-contamination with pathogens. Whilst in some cases this may be overcome with filtration of air, in others the risk might be considered too great (for example, biohazard areas or areas where non-human primates are housed (ILAR 1996)).

While windows may make the facility more pleasant to work in, and reduce the amount of artificial lighting required, they can also increase solar gain in the facility and increase the need for cooling (which can add significantly to the energy consumption).

More radical approaches might include use of solar panels or wind production of electricity, or novel approaches to insulation (such as the use of grass or moss roof coverings).

### Commissioning

Snagging and commissioning are important phases at the end of a project, before the building is handed over for operation. Clear performance targets should have been set during design, and it is essential to make sure these have been met before accepting handover of the building. Sufficient time must be left for commissioning – a period of several months to complete this and get the building running fully is not unusual.

### Concluding remarks

Animal facilities are complex, costly and time consuming to build. Such projects require a multidisciplinary team

approach, with a strong supportive but challenging team ethos in order to make good progress and deliver a satisfactory result which will meet the objectives. As time progresses, the technical solutions available for tackling the various challenges of maintaining the animal house environment increase but, at the same time, the standards to be met also advance (whether they are standards for animal welfare, human safety or environmental impact). Recent trends (eg, increasing use of imaging, genetically modified animals and fish) show how rapidly requirements can change – this is likely to remain the case, and hence the key challenge for those planning future facilities is likely to be how to build in the maximum flexibility and adaptability.

# 10 Enrichment: animal welfare and experimental outcomes

Robert Hubrecht

*'The need for designing animal facilities that provide the basic needs of shelter, food, water and a degree of environmental stability has long been appreciated. Currently, however, it is recognized that science also has an ethical responsibility to house animals according to their species specific needs, and that responsibility invokes the concept of behavioural and environmental enrichment.'* (Wolfle 2005)

## Introduction

It is now almost 50 years since Russell and Burch pointed to the need to refine animal experiments by reducing 'to an absolute minimum the amount of stress imposed on those animals that are still used' (Russell & Burch 1959, reprinted 1992, p. 134). More recently Buchanan-Smith *et al.* (2005) clarified the definition of refinement as: 'any approach which avoids or minimises the actual or potential pain, distress and other adverse effects experienced at any time during the life of the animals involved, and which enhances their well-being'. Enrichment having any of these effects is a refinement, which should be implemented wherever possible.

For many years unenriched housing was the norm, but over the last 20 years or so, there has been remarkable growth in the provision of enriched housing conditions for animals used in research. There is a number of factors that are likely to have contributed to this change, not least the development of enrichment in other areas of animal husbandry. Zoos were relatively early adopters of enrichment in the 1970s (Markowitz 1982); included: concerns about the occurrence of abnormal behaviour (eg, Hediger 1950); a better understanding of natural animal behaviour and of the effect of environmental variables on the behaviour, better understanding and physiology of captive animals (Shepherdson 1998, 2003). Within agricultural practice, the Brambell report on farm animal welfare of 1965 stimulated welfare research, calling for studies in the fields of veterinary medicine, stress physiology, animal science and animal behaviour (Fraser 2008). Moreover, the Brambell committee chairman suggested that animal welfare might be advanced by studies of motivation and preference: an early call for studies that have since become a major component of enrichment research. Animal welfare science has, since then, developed rapidly; its research influencing current practice with respect to enrichment provision in laboratory animal

housing, as well as the newer regulations and codes of practice governing laboratory animals (see Chapter 8). However, it is important to recognise that the impetus for improvements in housing and husbandry has not just come from legislators and animal welfare researchers but also from those directly involved in using and caring for animals in research. Many institutions, even facilities carrying out regulatory work, have developed innovative enrichment strategies as a means to achieving high welfare standards (Dean 1999; Johnson *et al.* 2003).

Nonetheless, experience shows that implementation of enrichment varies between institutions and countries and that some species are either more likely to be provided with enrichment, or are provided with more varied enrichment than others. Moreover, on some occasions researchers or others may resist the use of enrichment. Reasons for these differences in implementation may include concerns about: cost; standardisation; bias of experiments; increase in variation; potential risk to the animal; or a lack of understanding of the welfare impact of enrichment. In order to assess, and perhaps be able to address these concerns, it is important that animal care staff understand the implications of enrichment for welfare and experimental outcomes. The aim of this chapter is to provide a short introduction to the subject by discussing: what enrichment is; why and when it is needed; how it might interact with research requirements; and the practicalities of providing environments that meet animals' needs.

## Terminology

As others have noted, enrichment is not a term that has always been used consistently (Bayne 2005; Benefiel *et al.* 2005; Würbel & Garner 2007). As a paradigm in neurobiological research, where it is used to investigate the plasticity of the neural system, it has been defined as 'a combination of complex inanimate and social stimulation' (Rosenzweig *et al.* 1978, cited in Praag *et al.* 2000). In these neurobiological studies, various modifications are made to standard housing and husbandry practices. Standard unenriched conditions for rodents used in such studies typically comprise socially housed animals in a relatively small enclosure fitted either with a grid floor, or a solid floor with a substrate to absorb waste. Enriched conditions have included: social housing in large groups; larger than normal enclosure sizes; and the

provision of various physical items such as tunnels, nesting material, running wheels, etc. Food locations are often also frequently changed (Praag *et al.* 2000).

The purpose of such studies is not to inform animal husbandry decisions, although in some cases the enrichment used in these studies might incidentally have improved welfare. However, for those concerned about animal husbandry, the purpose of enrichment is that it should be beneficial to the animals. Hence, Shepherdson (1998) defines enrichment as *'an husbandry principle that seeks to enhance the quality of captive animal care by identifying and providing the environmental stimuli necessary for optimal psychological and physiological well-being'*. Newberry (1995) defined environmental enrichment as *'an improvement in the biological functioning of captive animals resulting from modifications in their environment'*, and Olsson and Dahlborn (2002) suggest that changes to the environment should only be considered as enrichment when their use results in an improvement in animal welfare.

Not surprisingly, welfare legislation and codes of practice for animals used in research also link enrichment with welfare. So, for example, the Library of Congress defines enrichment as *'enhancing the environment of confined animals in order to encourage natural behaviors and improve their quality of life'* (Kreger 1999). Similarly, a US report on the psychological well being of non-human primates, says that environmental enrichment *'is an independent variable that refers to manipulations to improve the environments of captive primates to enhance psychological well-being'* where *'enrichment is used in the sense of providing for species-appropriate activities in an otherwise restricted and limited environment'* (National Research Council (NRC) 1998, p. 10). In Europe, an amendment to *The European Convention for the Protection of Vertebrate Animals used for Experimental and other Scientific Purposes* (ETS 123) states that *'special relevance should be given to the enrichment of the environment of the respective species according to their needs'*<sup>1</sup> and the recently revised Appendix A to the Convention (Council of Europe 2006) refers to environmental enrichment as being *'an important factor for the welfare of the animals'*. Although the ultimate aim of enrichment in these documents is to have a beneficial impact on the animals, there are differences between them regarding the specific outcome expected (eg, to encourage natural behaviour, enhance psychological well-being, etc). This probably reflects different underlying assumptions regarding the nature of animal welfare. Various definitions of welfare have included concepts such as the ability to perform natural or normal behaviour, evolutionary fitness, feelings, etc (Fraser *et al.* 1997); see also Chapter 6.

The terms behavioural enrichment and environmental enrichment have sometimes been used in rather different ways. Behavioural enrichment has been used to refer to strategies likely to elicit certain species-specific behaviours, whilst environmental enrichment referred to attempts to provide a sufficiently complex environment that would stimulate a wide range of species-typical behaviours

(Markowitz 1998). These days, environmental enrichment is more often used in animal welfare science to refer to all attempts to provide a more suitable social and physical environment for captive animals. Approaches to achieve this have included: modifications of the enclosure structure or its surrounds; changes to social structure or opportunities for social interaction; the provision of objects within the enclosure to increase complexity and choice; increased opportunities for sensory stimulation; changes to feeding methods; and strategies to occupy the animals (Bloomsmith *et al.* 1991; Young 2003). To help focus attention on the diversity of enrichment needed, some authors have subdivided the term into subcategories. For example, Bloomsmith *et al.* (1991) lists five subcategories: social, occupational, physical, sensory and nutritional. Divisions such as these should be used with care as the categories can overlap. A cage mate (social enrichment) might also be thought to be a form of occupational or sensory enrichment.

The use of the term enrichment to describe a wide variety of changes to a range of husbandry conditions leads to difficulties in using the term in a way that is generally understood. Because enrichment is used by some branches of science in a welfare-neutral way, and because not all attempts at welfare-based enrichment are successful or biologically relevant, Würbel and Garner (2007) have proposed using sub-categories. This subdivision into: pseudo-enrichment (enrichment that does not benefit the animal), conditionally beneficial enrichment (enrichment that is beneficial for some animals or under some circumstances) and beneficial enrichment, seems a very useful way forward.

## Why is enrichment needed?

### Enrichment and evolutionary niches

Traditional standard laboratory housing provides a very limited environment compared to the natural environments in which animals evolved, which are usually complex and rich in stimuli. Therefore, enrichment has been described as more of a reversal of the impoverishment normally found in the laboratory setting than an enrichment over a natural setting (Praag *et al.* 2000). There is, as will be discussed in the following sections, a considerable body of evidence from both deprivation studies and studies of environmental enrichment (which are fundamentally similar except for the reversal of the experimental and control groups (Fuller 1967)), that barren environments, or housing designed without taking into account the natural history of the animal, can result in abnormal development, physiology and behaviour.

Animals are complex organisms with behaviour and physiology adapted towards their natural ecosystems. The evolutionary process works so that organisms tend to behave and function in ways that maximise their chances of reproduction and reduce their chances of dying before achieving their reproductive potential. This does not, of course, mean that animals in natural environments always experience good welfare. All environments, including natural ones, are likely to include some stressors (defined as

<sup>1</sup>[http://www.coe.int/t/e/legal\\_affairs/legal\\_co%20operation/biological\\_safety%2C\\_use\\_of\\_animals/laboratory\\_animals/Res%20accommodation.asp#TopOfPage](http://www.coe.int/t/e/legal_affairs/legal_co%20operation/biological_safety%2C_use_of_animals/laboratory_animals/Res%20accommodation.asp#TopOfPage)

real or perceived perturbations to an organism's physiological homeostasis or psychological well-being (NRC 2008, p. 2)). However, animals have evolved to respond to a range of natural stressors with coping mechanisms that may include behavioural, hormonal or immune function changes. In captivity, problems can arise if the environment does not allow an appropriate coping response or if the coping response is overloaded, leading to a breakdown of homeostasis and a state of distress.

It is generally accepted that some degree of predictability and control are important in reducing the likelihood that stress will tip into distress, and that control over the environment requires that the environment possesses a certain degree of complexity (Wiepkema & Koolhaas 1993; Rennie & Buchanan-Smith 2006; NRC 2008). There is, however, a balance to be struck between too much and too little predictability (Sambrook & Buchanan-Smith 1997).

Enrichment can allow more opportunities for animals to make choices that allow them to maintain homeostasis or to control social interactions. Mice are commonly housed at 20–24 °C which is outside their thermoneutral zone of 26–34 °C, and given the choice prefer warmer temperatures (Gaskill *et al.* 2009). Nesting material can allow them to create an area with a microclimate and express such choice. Similarly, visual barriers, that allow animals to move out of sight of other animals, may allow them to cope with the ups and downs of social life and to maintain harmonious social groupings.

While the proximate aims of providing enrichment for welfare reasons may be to reduce abnormal behaviour, stimulate normal behaviour, allow the animal to exercise choices etc; for many, the ultimate goal is to improve the animal's affective state. This, sometimes referred to as the animal's emotions or feelings, is part of the mechanism by which animals make choices so as to maximise their chances of survival and reproduction. Hence, environments that frustrate strongly motivated behaviour or that tip the balance of adverse stimuli towards the negative result in poor welfare. It is becoming increasingly accepted that we should not simply be concerned about animals' negative experiences but should also try to promote positive ones (Yeates & Main 2008). To paraphrase Fraser (2008, p. 69), for animals' welfare to be satisfactory, they should experience a minimum of suffering and they should be allowed the normal pleasures of life. As discussed in the sections below, there is a growing body of research indicating that animals' affective states can be adversely affected by traditional standard housing and that they are motivated to attain certain enriched environments.

### Motivation for enrichment

If it can be shown that animals really value a particular enrichment, that is, that they are strongly motivated to use it, then that provides a powerful, although not compelling, argument, for its implementation to improve the animals' welfare. Conversely, it is likely that an animal's welfare will be poor if it is strongly motivated to do something but cannot do so because of an inadequate environment. Animal welfare scientists have developed a range of study tech-

niques that provide different types of information on animals' motivation for various resources (see also Chapter 6). The simplest of these are observational studies that report on the animals' use of various enrichment options when they are added to an existing enclosure. Such studies have shown that primates, for example, will use various types of enrichment including foraging devices, toys/manipulanda and mirrors (Lutz & Novak 2005). Dogs make extensive use of platforms and chews when given the opportunity (Hubrecht 1993, 1995a; Joint Working Group on Refinement (JWGR) 2004), and if not provided with chews may chew inappropriate pen materials such as plaster or steel cord. A somewhat more complicated type of study which allows the researcher to rank animals' motivation for resources is the choice or preference test. Such studies have shown that mice, for example, prefer nesting material to a nest box and prefer effective nesting materials to less easily used materials (Olsson & Dahlborn 2002); there are many other examples.

However, neither observational studies nor choice tests provide much indication regarding the extent to which an animal wants a resource. To address this issue, operant studies have been used to assess the strength of animals' motivation for resources (Patterson-Kane *et al.* 2008). In these studies, sometimes known as demand studies, the animals may have to push a lever a number of times in order to obtain a resource, or might have to travel or cross an aversive substrate. By changing the cost that the animal has to pay to access the resource, the experimenter can gain an estimate of the value of that resource to the animal. Such studies have shown that mice are strongly motivated to explore and patrol all accessible areas of their environment (Sherwin & Nicol 1996) and will work for access to resources such as a larger cage and running wheels, enrichment items and deep sawdust (Sherwin 1996). Moreover, the mice worked as hard to maintain access to these resources as for food, giving some idea of the importance of these resources to these animals. Other studies have shown that rats work harder for social contact than for an empty home cage (Patterson-Kane *et al.* 2002), and will lift substantial weights to gain access to a novel environment or a resting place with a solid floor (Manser *et al.* 1996).

These studies have an obvious appeal and have provided extremely useful data on the features that should be provided for various species. However, their interpretation is not always straightforward, demand studies have their limitations (Kirkden & Pajor 2006) and there is ongoing scientific debate on these studies regarding appropriate experimental design and choice of measures. Animals' preferences and choices may be affected by context, experience, time of presentation and the options that are offered to the animal. Moreover, animals' short-term choices may not always be in their best long-term interests; for example, an animal might work hard for a high-calorie treat but eating too many might have long-term health consequences. It is also the case that demand studies on larger species used in research such as dogs and primates are lacking, probably because of the practical and financial difficulties involved in constructing large test apparatus. Despite the difficulties outlined above there is a need to extend demand-study research to these species.

## Abnormal behaviour in unenriched or standard housing

Abnormal behaviour is a sign that, at some point, conditions for the animal have not been adequate, and seems to be relatively common in some species used in research. It has been estimated that around 50% of mice, the animals most commonly used in research, stereotype, performing repetitive behaviours such as bar biting, jumping and looping around the cage (Würbel & Stauffacher 1994, reported in Würbel 2006). The prevalence of the behaviour may come as a surprise to some animal care staff, but this is because much of the behaviour is performed at night. Extrapolating from the figures above, Mason and Latham (2004) estimated that the numbers of laboratory housed mice exhibiting abnormal behaviour may amount to a total of 7.5 million worldwide. Gerbils are also prone to develop stereotypies in standard laboratory housing (Wiedenmayer 1997). Similarly for primates, 89% of individually housed rhesus monkeys at a research centre showed abnormal behaviour, with pacing occurring in 78% and self-injurious behaviour occurring in 11% (Novak *et al.* 2006). In carnivores, home range size is linked to their propensity to develop stereotypies (Clubb & Mason 2003). As dogs can range over substantial areas (Hubrecht 1995b) it is, perhaps, not surprising that they also develop stereotypies when kept in restricted social or environmental conditions. In one study, 13% of single-housed laboratory dogs spent more than 10% of their time in repetitive behaviour patterns (Hubrecht *et al.* 1992), and some dogs spent up to 51% of their time performing these behaviours.

It is well known that inadequate social environments during development can lead to abnormal behaviour in the adult. Harlow and his followers in the 1960s demonstrated the importance of a normal social environment for macaques during their development (Novak *et al.* 2006; NRC 2008, Chapter 3). Similarly, Fuller (1967) showed that dogs reared under a partial social isolation regimen became less social and interacted less with their environment; early weaning of mice can lead to increased anxiety, as tested in an elevated plus maze, and poorer maternal behaviour (Kikusui *et al.* 2005). Separation of animals after they have developed social ties can also cause problems. Self-injurious behaviour is much more common in individually housed than socially housed rhesus macaques (Novak *et al.* 2006) while Fox and Stelzner (1966, 1967) found that isolating dogs from conspecifics led to later deficits even if human social contact was provided.

## Stimulation of normal behaviour and reduction of abnormal behaviour in enriched environments

Enrichment of barren environments can stimulate an increase in behaviours that are deemed to be normal within the caged environment, typical of behaviour in the wild or simply thought of as desirable behaviour. Young (2003) reviews the literature for this on farm, zoo and laboratory animals. Lutz and Novak (2005) and Honess and Marin (2006) provide extensive reviews of the effects of various

types of enrichment on non-human primate behaviour. Enrichment can be used to stimulate desirable behaviours, such as chewing of toy items, as an alternative to the cage or walls by dogs (Hubrecht 1993), and play (marmosets, Ventura & Buchanan-Smith 2003). It may also be used to reduce undesirable behaviours such as aggression in rodents (mice, van Loo *et al.* 2002; rats, Johnson *et al.* 2004) or primates (Honess & Marin 2006).

However, it is important to consider what is meant by normal and to interpret these studies with care. Normal behaviour, as seen in the wild, is not necessarily closely linked with good welfare (see Chapter 6). Behaviour such as aggression is normal, although it may be undesirable in the research environment depending on the context, level and duration of aggression. Similarly, anti-predator behaviour is undoubtedly normal behaviour but its expression is unlikely to be linked to a state of good welfare. When considering how much time is spent in various behaviours, there can be difficulties in determining what would be a normal time-budget for the behavioural repertoire for a species (Veasey *et al.* 1996). It is also necessary to take into account the full spectrum of behaviour elicited by a particular enrichment. For example, Marashi *et al.* (2003) found that enriching male mouse cages increased play (an indicator of good welfare) but also found that aggression, possibly linked to territoriality, was increased.

Enrichment can not only promote normal behaviour, but also reduce abnormal behaviour. Shyne (2006) carried out a meta-analysis of zoo animal enrichment studies, showing that attempts to enrich housing have generally been effective in reducing stereotypies, but to have their best effect, animals should be exposed to an enriched social and physical environment throughout their development. Enrichment later in the animal's life can still be beneficial, but may not undo the damage caused by an inadequate environment during development (squirrel monkeys, Fekete *et al.* 2000; deermice, Hadley *et al.* 2006). Social enrichment, rather than physical items such as toys or foraging devices, seems to be more likely to result in improvements for non-human primates (Lutz & Novak 2005). Nonetheless, some improvement can occur; for example, mealworm feeders decreased marmoset stereotyped pacing (Vignes *et al.* 2001), and Würbel *et al.* (1998) showed that the provision of a tube for mice reduced wire-gnawing by 40%. It has been asserted that because there is little evidence that enrichment of rodents' cage environments reverses abnormal behaviour, it has no effect on their well-being (Benefiel & Greenough 1998). However, stereotypies resulting from chronic exposure to a sub-optimal environment can be thought of as a behavioural scar (Mason 1991). Hence, stereotypies are not necessarily a good indicator of current welfare status (see Chapter 6) and they can be resistant to improvements in housing condition. Failure to eradicate established stereotypies, therefore, does not necessarily indicate that the enrichment is a failure.

## Enrichment and stress

Animals used in research are inevitably exposed to stressors, both during husbandry and during experimental pro-

cedures. Enrichment that improves their ability to cope and reduces fear and stress will improve their welfare.

There is evidence for a range of species that enrichment can produce less fearful, more confident and adaptable animals than those kept in barren conditions (Chamove 1989; Prior & Sachser 1994; Larsson *et al.* 2002; van de Weerd *et al.* 2002; Young 2003, p. 34; van Loo *et al.* 2004). A study carried out by Sherwin and Olsson (2004) in which mice were allowed to self dose with an anxiolytic, indicated that mice housed in enriched cages may be less anxious than those housed in standard cages. Environmental complexity can decrease stress reactivity as shown by behaviour in the elevated plus maze, defaecation in a novel environment, defensive responses to a predator and open-field exploration (Lewis 2004). Young (2003, p. 40) cites evidence for the beneficial effects of certain enriched environments on a range of physiological indicators of stress on a variety of species. More recent studies include those by: Benaroya-Milshtein *et al.* (2004) in which enrichment such as ladders, tunnels and running wheels attenuated behavioural and physiological responses to an electrical shock; and van Loo *et al.* (2004) who showed that provision of nesting material reduced corticosterone levels in male Balb/c and CD-1 mice. Changes in stress responses can lead to different disease outcomes, most of which are beneficial (Praag *et al.* 2000); and it has been suggested that the beneficial effects of enrichment observed in mouse models of Huntington's disease and Alzheimer's disease could lead to new avenues of research for effective treatment of humans (Hockly *et al.* 2002; Jankowsky *et al.* 2005).

Reductions in stress responses such as these suggest that enrichment not only has the potential to improve the animals' welfare during husbandry but could also help to refine procedures. For example, Meijer *et al.* (2006) found that enrichment and frequent handling of mice reduced their temperature and heart rate following procedures such as injection or restraint.

Those implementing enrichment programmes should be aware that some common forms of enrichment may not work for a specific gender or strain, resulting in increased stress rather than a reduction. For instance, it can be counter-productive to provide shelters for some strains of male mice, as the enrichment is associated with increases in testosterone, aggression and corticosterone that are probably linked to increases in territoriality (Haemisch *et al.* 1994; Haemisch & Gartner 1994; Nevison *et al.* 1999; van Loo *et al.* 2002).

### Enrichment and quality of science

Researchers may be concerned that enrichment could affect their results (Benefiel *et al.* 2005). There is a number of potential issues wrapped up in this concern. These are: that enrichment might affect validity by biasing results by producing abnormal animals; that it might decrease reliability by increasing between-subject variation thus reducing test sensitivity; or it might decrease replicability by increasing between-laboratory variation (Garner 2005; Würbel & Garner 2007). These issues are addressed in the following sections.

### Bias

Enrichment (as defined by Rosenzweig *et al.* 1978) certainly has the potential to affect experimental outcomes (Federation of European Laboratory Animal Science Associations (FELASA) 2006). Enrichment can result in: increased neurogenesis; increased capillary development; the formation and changes to the efficiency of synapses; and changes to neurotransmitter activity (reviewed in Healy & Tovée 1999; Praag *et al.* 2000; Lewis 2004). Rats kept in an enriched environment (ie, with a selection of toys/chews and conspecifics) increase brain size by about 5% with the largest changes occurring in the cortex. Similar effects have been found for other mammalian and avian species, including cats, monkeys and even humans (Healy & Tovée 1999).

Animals kept in enriched environments often show improved memory, learning and behavioural plasticity (Lewis 2004) which may well be related to changes to structures such as the cortex, hippocampus and thalamus (Nithianantharajah *et al.* 2004). It is interesting to note here that, while enrichment does promote neurogenesis, the changes produced by enrichment on spatial learning and habituation are not dependent on this but may result from synaptic changes (Meshi *et al.* 2006).

Enrichment can affect the senses and their development as visual acuity of enriched mice was 18% greater than those of mice kept in standard conditions (Prusky *et al.* 2000). Cortical sensory maps can also be affected. When rats are kept in a naturalistic environment, complete with conspecifics, subterranean tunnels and opportunities for foraging, the cortical representations of the rats' sensory whiskers become refined and more focused, contracting by up to 46% compared to rats housed in standard cages (Poley *et al.* 2004).

So, can enrichment bias experimental outcomes? Benefiel *et al.* (2005) list a range of effects of various types of enrichment on experimental variables that include a range of ameliorative, and sometimes negative, effects on animals used as disease models. Olsson and Dahlborn (2002) provide a detailed review of the effects of enrichment on mice (see also FELASA 2006) and Bayne (2005) lists effects on primates, rabbits and rodents. Some of these effects may be modulated by stress responses, which, as we have seen, can be affected by enrichment. Moreover, changes in anxiety and stress responses can persist for some time after the enrichment is ended (Larsson *et al.* 2002).

At first glance this literature might suggest that, at least for studies where stress responses are measured or might influence the variable in question, enrichment should be avoided. However, it is important to note that the reviews included studies where the aim was not always to improve welfare and the enrichment was more elaborate than would normally be used for animals under study (Olsson & Dahlborn 2002; Benefiel *et al.* 2005). Moreover, the enrichment used in studies where negative effects occurred was clearly not beneficial and thus these studies are irrelevant to considerations of the impact of beneficial enrichment. It is also important to consider whether animals kept in a beneficially enriched environment are more likely to deliver externally valid data. As described earlier, enriched environments are closer to the environments in which animals evolved. It seems likely, therefore, that standard laboratory conditions lead to reduc-

tions in size and capabilities of the brains of laboratory animals, which raises questions about the validity of learning and memory research carried out on animals housed in these conditions (Healy & Tovée 1999). Moreover, mismatches between evolved behaviours and the captive environment provided by standard housing (Würbel 2001) are, as already discussed, likely to lead to stressed animals and increased incidence of abnormal behaviour, which could affect the quality of science (see review by Sherwin 2004). Conversely, as Garner (2005) suggests, beneficial enrichment should result in animals that are more like the natural animal in terms of their neural development, physiology and behaviour; and in most cases these should be better experimental models with improved external validity. To summarise, beneficial enrichment should help to avoid bias caused by housing conditions rather than create it.

Despite the arguments outlined above, the situation might arise where there are data indicating that beneficial enrichment has an effect on the experimental variable in question, and the researcher is unconvinced that there is a scientific need for a more normal animal. To answer this, the ethical imperative is to provide, if possible, an environment that meets the animals' needs and it is worth considering the following discussion points: It may be that, as enrichment would be provided to both treatment and control groups, there would be no effect on any difference between the groups. Consider whether the magnitude of any effect produced by enrichment would be trivial compared to the experimental effect. The importance of an enrichment effect should also be judged in context with other factors such as: strain differences (Kim *et al.* 2002); normal husbandry routines (Duke *et al.* 2001); site differences, etc.

Finally, while there is a growing body of literature on the value of many types of enrichment and this has helped to inform guidance given in this volume and elsewhere, it remains true, as pointed out by Würbel and Garner (2007), that further work is needed to clarify the relationship between housing conditions, external validity and welfare, and work of this sort would help inform decisions regarding optimal enrichment.

### Replicability and variation

Researchers may be concerned that variable implementation of enrichment will reduce standardisation between sites leading to reduced replicability. However, so-called standard housing is, itself, not particularly standardised, with variation between sites and between countries in cage design, materials and husbandry. Some sites use grid floor cages whilst others use solid-bottomed cages; cages may be made from different materials or ventilated in different ways. Moreover, even when conditions between laboratories are rigorously standardised, systematic differences between the laboratories still remain (Crabbe *et al.* 1999). Further, Würbel (2000) and Würbel and Garner (2007) have argued that institutional standardisation leads to poor external validity, and that it can actually reduce between-laboratory replicability as different laboratories adopt different standards. They suggest that a better approach would be to design factorial experiments with

subject animals exposed to a variety of husbandry and environmental conditions including various types of enriched environments.

A related issue is replicability over time. Researchers may be concerned that the introduction of enrichment will impair comparison of current results with those from previous studies (historical data). However, this problem should only be a temporary one; as once an enrichment programme is in place new historical data will rapidly be generated.

With respect to within-study variation, there have been a number of studies reporting variously that enrichment increases variation (Eskola *et al.* 1999; Mering *et al.* 2001; Tsai *et al.* 2002, 2003), reduces it (Eskola *et al.* 1999; van de Weerd *et al.* 2002) or has no effect (Eskola *et al.* 1999; Augustsson *et al.* 2003). Taken together, these studies seem to indicate that there is no obvious effect on variation. Moreover, the enrichments used in these studies were not always those that are commonly used in laboratory facilities to improve welfare and not all may have been beneficial. Only one study, published in the journal *Nature*, has explicitly tested the effects of enrichment on variation and replicability (Wolfer *et al.* 2004). In this study, three laboratories raised three batches of female mice of two strains and their hybrids. The mice were housed in small standard cages or large enriched cages, and the results indicated that enrichment neither increased individual variability in behavioural tests nor the risk of obtaining conflicting data in replicate studies. The authors conclude that, at least for female mice, environmental enrichment should '*improve the animals well-being without reducing the precision and reproducibility of the data derived from them, while attenuating abnormal brain function and anxiety – both of which are possible confounds in animal experiments*'.

### Factors to consider when choosing enrichment

What are the benefits of the proposed enrichment?

The aim of enrichment in laboratory animal husbandry is to improve welfare. However, what does this mean in practice? Young (2003, p. 2) provides the following list of goals, which should help to focus planning and to assess success:

Goals of enrichment are to:

1. increase behavioural diversity;
2. reduce the frequencies of abnormal behaviour;
3. increase the range or number of normal behaviour patterns;
4. increase positive utilisation of the environment;
5. increase the ability to cope with challenges in a more normal way.

As discussed earlier, some so-called enrichments may turn out to have no or negative effects on the animals' welfare. Therefore, it is important to avoid filling the animals' enclosure with a random selection of items in the hope that the animal will make use of them. Instead, enrichment choices should be based on a sound understanding of the animal's biology and preferably on experimental research. A good example of enrichment that combines these features is the provision of refuges with tunnels for gerbils.

Gerbils commonly develop stereotyped behaviour in the laboratory. The reason for this was not understood until Wiedenmayer (1997) showed that gerbils not only need a refuge, but also a tunnel of a certain length leading to that refuge to avoid the development of stereotyped digging behaviour. It is likely that this is because gerbils, in the wild, dig burrows that are connected to the surface by tunnels of a sufficient length to reduce the risk of predation and to protect them from other hazards (Chapter 23). As a result, it seems that they are strongly motivated to keep digging if they are not able to achieve this goal in captivity. Those implementing behavioural strategies should therefore review the literature to familiarise themselves with the natural history of the species and to identify any proven beneficial enrichments.

While enrichment should be biologically relevant (Garner 2005) it need not be naturalistic (ie, designed to mimic features of the wild environment). However, non-naturalistic objects such as bells, marbles, metal manipulanda, etc, should be evaluated to ensure that they really are a beneficial enrichment and that they are not harmful or distressing to the animals. Even if animals do make use of, or manipulate, enrichment items, it is important to consider whether they are doing so for positive reasons and not, perhaps just trying to remove them from their living areas. The answers to these questions lie in carefully designed behavioural experiments, which, if the enrichment is a commercially marketed one, should be the responsibility of the manufacturer. To help encourage manufacturers to carry out this research, customers of companies selling enrichment should ask to see the scientific data that supports their claims.

### Enrichment and animal safety

As the aim of enrichment in laboratory animal husbandry is to improve animal welfare only beneficial, or conditionally beneficial, enrichments should be used. However, the addition of any novel item to an animal's environment carries some risks. It is therefore necessary to attempt to identify these and to weigh them against the likely benefits arising from the enrichment before using a new enrichment. This assessment is likely to require considerable input from care staff, which includes veterinary care staff (Nelson & Mandrell 2005). A good example of the costs and benefits of enrichment is social housing. It is increasingly accepted that social animals should be housed in harmonious social groups (eg, European Commission 2007). Social housing allows animals to interact with each other, thus permitting the expression of species-specific behaviours and keeping them occupied. It may also have other less obvious benefits. For example, Schapiro and Bushong (1994) found that incidences of diarrhoea and dehydration were reduced in socially housed macaques. On the other hand, it is not possible to guarantee that groups will continue to be socially harmonious and social housing carries risks. Bayne (2005) reviews literature for non-human primates where social housing resulted in deaths or increases in self-injurious behaviour. Dogs housed socially also may fight, and in some cases the injuries may be severe, perhaps even resulting in death. For animals at the losing end of these encounters, social housing as enrichment will have failed. Generally,

however, although some animals may need to be housed singly, experience shows that aggression can be minimised with good management practices. This is an ethical issue where the consensus is that the benefits to the majority outweigh the risks to the few (Hubrecht & Buckwell 2004; Joint Working Group on Refinement (JWGR) 2004, 2009).

Physical items can also result in injury, either directly, or by increasing aggression. Bayne (2005) reviews harms (as well as benefits) arising from attempts to provide enrichment for non-human primates as well as rodents and rabbits. Animals can become entangled in objects. Murchison (1993), for example, described a case of a pig-tailed macaque becoming entangled in a ring toy. Items placed into a cage may be ingested, even if that is not the specific aim of the enrichment, so there may be risks of choking or obstruction. It is possible that certain types of food enrichment, if not properly controlled, may lead to obesity or tooth decay. Moreover, commonly used enrichments may result in problems for particular strains, eg, nesting material for nude mice (Bazille *et al.* 2001). Enrichment may result in increased aggression either because the items may be desirable resources in themselves, or because they allow the animals to divide the enclosure into territorial units as previously described for male mice. Enrichment within the animals' environment can make cleaning more difficult, and the enrichment items themselves could act as fomites (Bayne *et al.* 1993). To help put these risks into context it is worth considering that no environment is entirely safe, that incidences of disease related to enrichment items seem to be very rare, that enrichment can also reduce aggression (Honest & Marin 2006) and that injuries can occur even in an unenriched environment. Marmosets have been known to entangle their arms in the mesh of their cages; dogs without chews may chew through the steel cable holding up pop holes or even at the walls, with consequent tooth damage. The increased risk of injury from most physical enrichment options is likely to be small, and there are few published reports of enrichment devices resulting in injury (Young 2003; Nelson & Mandrell 2005). This lack of data may not be surprising, given its sensitive nature, but there are obvious benefits that could arise if both failures and successes were published. While the increased risk of injury or disease when using well established enrichment items is small, it is best to avoid problems. The checklist of safety considerations provided by Young (2003) is a useful starting point in carrying out a risk assessment. As Young points out, safety assessment should be an ongoing process, as animals may use enrichment in new and unexpected ways.

### Enrichment and human safety

Enrichment strategies must meet the needs of staff and researchers as well as the animals. Clearly any enrichment must be practical and cost effective, and any health and safety issues for the staff must also be addressed. Concerns may include trip hazards, increased weight of enclosures, increased exposure to allergens, exposure to sharp objects (eg, after animals have gnawed or broken them). Some species such as primates or apes may cause injury by throwing enrichment items. Excessive enrichment might also

compromise the ability of staff to avoid potentially dangerous animals. Again, an attempt should be made to identify risks to human safety before introducing the enrichment and to find ways of ameliorating these by reconsidering housing and management regimens.

### Enrichment and the experiment

Previous sections have discussed the issues of enrichment and experimental outcomes, but it goes without saying that before introducing enrichment both scientists and care staff must be content that it will not adversely affect the outcomes of experiments in which the animals or their offspring might be used. Where there are concerns that a proposed enrichment might have such effects, it is important to carefully assess the validity of these concerns, bearing in mind that enrichment programmes have been successfully adopted in many experimental protocols. It is also important to consider whether the procedures carried out on the animals might impact on the way in which they interact with the enrichment. If, for example, the research involves damage to the animals' motor or sensory function, then this might necessitate changes to enrichment regimens to avoid safety issues.

### Validating new enrichment

Ensuring that enrichment is beneficial is an important component of any programme. This issue is discussed in detail in a FELASA working group document (FELASA 2006), which points out that the techniques used to demonstrate a welfare benefit (eg, preference/choice tests, demand studies, physiological measurements) can be difficult to use and to interpret. As previously discussed, choice tests, for example, can provide some indication of the relative value that an animal attaches to a resource, but they do not tell how much an animal either likes or dislikes a resource, or why the animal has made the choice. The test might therefore reflect the animal's motivation to minimise deprivation, maximise pleasure or monitor unwanted problems; and the value of the enrichment in question would be very dependent on which of these was the underlying motivation. Past experience of the animal can also strongly affect preference test outcomes, and in some cases animals may make short-term choices that result in a long-term reduction in welfare or health, such as through diet choices that ultimately result in obesity or dental caries. Finally, the enrichment needs of animals can vary between strain, by gender and with age.

The requirement for validation of enrichment will depend to a great extent on the novelty of the enrichment being introduced. For the reasons outlined above, the initial determination of the types of enrichment required by a species will normally best be carried out either by, or in collaboration with, specialist animal welfare scientists who will be aware of the pitfalls of these studies and will have the necessary experience to choose appropriate measures and study designs.

Once an enrichment has been validated as beneficial it would normally be a waste of time and resources for indi-

vidual laboratories to repeat this process. For example, it is well known that foraging enrichment is beneficial for primates and further research to corroborate this is unnecessary. Nonetheless, there may be local variations in the implementation of categories of enrichment, and these details may need to be evaluated to ensure that they function as expected, there are no safety concerns and that the enrichment will not compromise the study.

### Managing an enrichment programme

Successful enrichment strategies depend on good communication and management. Research institutions should be committed from top management down to providing a high quality of housing for their animals; and animal care staff, veterinarians and research scientists should have bought into this concept. Enrichment should not be introduced piece-meal, but should be properly planned and discussed, particularly with the scientists who will be using the animals.

It may be helpful to have a committee charged with implementing the programme; even if this is not the case, enrichment should be the subject of regular review to ensure that it is being implemented, that there are no problems and to assess its efficacy against current knowledge. For some research programmes, the normal enrichment and housing conditions may not be compatible with the aims of the research, but requests to keep animals without enrichment should always be carefully examined to determine whether an alternative enrichment programme, perhaps using different materials, is possible.

Management should ensure that there is a reasonable and sufficient budget to meet enrichment needs and to fund any research necessary to validate the programme. However, simple enrichments can be as effective as more complex and expensive options (Schapiro *et al.* 1997). Enrichment items need not be expensive, and have been made from everyday items such as old water bottles, cardboard rolls, etc. Nonetheless, such items should be used with care as they may contain undesirable substances, and their composition may not remain consistent. Commercial enrichment products have the advantage that they can often be obtained with a certificate of analysis, which is necessary for regulatory studies. Further advice on implementing enrichment within a GLP framework is available from FELASA (2006).

The extra costs arising from an enrichment programme should not impact adversely on research. For commercial establishments, the costs of enrichment are usually trivial compared to overall budgets. Moreover, as enrichment becomes more widely accepted, competitive disadvantages between commercial organisations adopting enrichment should decrease. For academic establishments it may be harder to find the extra funds but, at least within the UK, the major funding bodies emphasise the importance of the Three Rs, and of housing animals in a complex and varied physical environment in appropriate social groupings, with the aim of promoting exercise and performance of species-typical behaviours (Medical Research Council (MRC) 2008). Moreover, funding bodies have indicated that they would consider offering funding to enable establishments to

achieve high standards (Animal Procedures Committee (APC) 2005).

Within the animal house, records should be kept of the enrichment used and of any rotation of enrichment items. As part of continuing professional development, staff should keep up-to-date with the literature on enrichment, should visit other research sites and attend conferences at which enrichment is discussed. It is also useful to invite experts on various species to visit and comment on the enrichment programmes in place. When animals are bought in from outside institutions, it is important to determine the husbandry and enrichment systems of the supplying institution. This is partly to minimise adverse effects resulting from a change of husbandry, and also to encourage the worldwide spread of high standards (APC 2007). Finally, institutions should make efforts to disseminate information on the successes or failures of their enrichment programmes.

## Special housing arrangements

Mike Dennis

### Introduction

Whilst it is desirable to maintain laboratory animals in accommodation that is as close as possible (excluding harmful aspects) to their natural habitats, there are several reasons why special housing arrangements are required in some cases in order to meet more exacting experimental requirements than are provided by conventional caging or penning systems.

Special housing arrangements may be required to achieve any of the following:

- to prevent contamination of germ-free animals;
- to protect animals that are particularly sensitive to infection, for example genetically immunocompromised animals such as severe combined immunodeficient (SCID) or nude (athymic) mice;
- to protect animal handlers from allergens or infections that are deemed to be a potential risk (eg, from animals of unknown health provenance or that have been administered an infectious agent).

Many approaches and systems have been developed over the years to address these issues but the main principles involve a physical barrier, a directional/laminar airflow or a combination of both.

Physical barriers may be provided by:

- protective clothing;
- animal rooms;
- plastic film isolators;
- filter-top boxes;
- independently ventilated cages;
- laminar flow hoods;
- isolation booths;
- rigid cabinets.

All barriers, even one as simple as protective clothing, can have an impact upon the welfare of the animals. This chapter will first describe the types of containment systems currently in use and then address their use with individual species. It will not cover highly specialised housing situations such as tethering or metabolic cages as their use is generally short term and the welfare issues associated with their use are generally covered by a project licence or other equivalent experimental permission/justification.

### Types of containment

#### Protective clothing

This is probably the most common physical barrier used in animal facilities. Personal protective equipment (PPE) may be as simple as a gown over normal clothing and a pair of gloves, but may also include hats and masks. For higher levels of operator protection it may be necessary for a complete change of clothes and the use of respiratory protective equipment (RPE) (Figure 11.1). Other protection strategies may require the use of powered respirators or suits with their own integral air supplies, depending on the danger presented by the infectious agent that is being used (Figures 11.2, 11.3).

#### Welfare considerations

Protective clothing may impact on animal welfare in a number of ways. This impact may be accentuated if a sudden change in regime is adopted, for example after an experimental challenge (ie, a sudden change in appearance and practices may well have an influence on the dynamics of the relationship between the animal, its handler and even its cage mates). Animals that have become habituated to their care staff may be affected by any of the following changes:

- Odours: the use of PPE may remove smells that have become familiar to the animals; or PPE equipment may have a distinctive odour of its own that is not pleasant to the animals.
- Colours: a change in the colour of protective apparel from the previous everyday laboratory gown may affect some species.
- Noise from powered air supplies: these may disturb animals and even if they may seem quiet to the wearer, there may be sub- or super-sonic noise that can be disturbing to certain species.
- Visibility: the profile of an individual may be changed by protective wear such that they can no longer be recognised. Face masks or other RPE hide usual visual signals that may be used by some species.
- Startling sudden appearance without the usual clues of approach (eg, if emerging from a changing room, rather than directly from a corridor).

- Gloves: the wearing of gloves has been shown to affect dexterity and this may result in clumsier, more stressful handling of smaller species.

**Figure 11.1** The use of RPE plus down-draught table to protect the operators during procedures on infected animals. (Courtesy of Health Protection Agency.)

**Figure 11.2** A Martindale-type suit with a filtered, powered air supply. (Courtesy of Health Protection Agency.)

#### Welfare aspects of higher levels of PPE (eg, suits, half suits, powered RPE with full clothing change)

The use of specialised apparel with higher levels of PPE usually involves strict changing and showering regimes that are time consuming and reduce the number of visits that can be made per day. In addition, protective equipment can restrict movement, hearing and dexterity, and its use has an inherent level of discomfort that reduces the amount of time that can be safely spent on any one visit. A further problem

**Figure 11.3** A one-piece full suit that might be required for work with dangerous pathogens. (Courtesy of the Canadian Science Centre for Human & Animal Health.)

with this equipment is the lack of facial signals to animals because of reduced clarity or reflectivity of visors or other head-gear.

#### The animal room

In some cases the boundaries of the animal room itself may be considered as the primary barrier between the animals and the rest of the facility. This type of barrier system is likely to be required where the work involves species that cannot be housed with any degree of practicability in other containment systems. Examples may include adult farm animals such as cattle, pigs or sheep. In such cases and where high-level containment is required, the room might need to be modified and this may impact upon animal welfare in ways that are not immediately obvious. Containment of pathogens dangerous to humans or to other animals may require the provision of *en suite* changing rooms, showers, fumigation chambers and autoclaves. The supply air, extracted air, or both may require high-efficiency particulate air (HEPA) filtration and the room may need to be maintained at negative pressure, depending on the defined biosafety level.

#### Welfare considerations

Practices within the room may be affected by the containment level specified for the room: for example if effluent

treatment is part of the containment strategy, then the use of water for cleaning down may be restricted. In addition, the type of bedding that can be used may be restricted to avoid blocking the drains that lead to the treatment plant. Due consideration needs to be given to where procedures and necropsies are to be performed, bearing in mind both the welfare of other animals and any safety requirement to prevent release of any pathogens. It is highly likely where the confines of the room itself are used as the primary barrier, that protocols will also prescribe some level of protective clothing for animal care and scientific staff, as described in the section on clothing above. The needs of high-level biocontainment may dictate the use of sealable submarine-type doors to prevent escape of pathogens, to enhance air pressure cascades and to allow regular fumigation. Current biosecurity requirements often demand that facilities using certain agents should have robust physical security, such as coded locks or swipe access, to limit access. As layers of mechanical or procedural strategies are built up to address safety issues or to ensure the integrity of the experiment, then more attention needs to be paid to the impact upon the welfare of the animals as they become more isolated from the rest of the facility and its day-to-day activities. Table 11.1 provides a summary of potential welfare issues and solutions relating to using rooms as a barrier.

### Flexible film isolators

Flexible film isolators are used extensively for the microbial isolation of experimental animals. The original flexible film isolators were developed by Trexler and Reynolds (1957),

and designed specifically to maintain germ-free (animals with no detectable microbial flora) or gnotobiotic animals (derived germ-free but having a defined, given microbial agent) and to prevent contamination of these animals by environmental microbes. Germ-free animals are derived free of microbial contamination by removal directly from the uterus under sterile conditions either by hysterotomy or hysterectomy in the case of mammals (decontamination of newborn has also been reported) or by decontamination of eggs in the case of birds.

Flexible film technology has proved to be extremely effective and adaptable as a microbiological barrier and a wide range of species, from rodents to farm animals such as pigs, sheep and calves, have been maintained under gnotobiotic conditions (Tavernor *et al.* 1971; Alexander *et al.* 1973; Dennis *et al.* 1976). Microbial isolation is achieved by the physical barrier of the flexible film canopy, enhanced by positive pressure and HEPA filtration of both incoming and outgoing air.

Germ-free or gnotobiotic animals are used in research for various reasons: to investigate the role of commensal bacteria in development of the immune system (Butler *et al.* 2005; Hope *et al.* 2005); in studies of gene expression (Chowdhury *et al.* 2007); or to provide an insight into diseases of unknown aetiology (Wyatt *et al.* 1979; Bridger *et al.* 1984).

### Welfare and handling considerations

The use of isolators can impact upon animal handling with potential knock-on welfare consequences in various ways:

- If the operator's vision is reduced or restricted this may impact upon animal observations and checks on well-

**Table 11.1** Potential welfare issues of the room as a containment barrier.

Parameter	Potential welfare issue	Solution
HEPA filtration	Room reliant on air handling system for adequate ventilation/environmental control. Failure of fans could lead to inability to control temperature, humidity and build-up of waste gases	Build in redundancy on air handling equipment and have reliable emergency power with automatic cut in
Negative (or positive) air pressure	Needs to be well controlled. Sudden changes in pressure can be distressing	Have feedback between supply and extract, build in a delay in variable fan speed to allow for door opening
Limited access due to time-consuming changing and showering regimes	Reduced time and frequency of observation and interaction with animals	Consider CCTV and environmental enrichment appropriate for species. Consider practices that reduce the time taken to enter/exit (eg, is showering necessary? Could air showers be used?)
En-suite autoclave/fumigation chamber	Exposure to noise, heat, noxious fumes	Ensure good sound and heat insulation, use an ante-room if possible, have local ventilation that will cope with steam or leakage of fumigant
Procedures and necropsies	Requirement for biocontainment may preclude separate procedures room or use of a shared postmortem room	Have, as a minimum, a screened-off area that is well ventilated. Use a cascade pressure regime away from the animal accommodation to the procedures area
Effluent treatment	Capacity issues or fear of blockage may restrict use of water and certain types of bedding. This may impact on natural behaviours such as foraging for food	Consider using a system of screen filters for the drains and have separated areas where deep litter can be used and then bagged for disposal
Use of PPE/RPE	Stress may be caused by unfamiliar suits/respirators and lack of usual facial and olfactory signals	Acclimatise animals by wearing apparel on occasions before study start or by hanging suits in room

**Figure 11.4** A flexible film isolator used to house infected mice or guinea pigs. (Courtesy of Health Protection Agency.)

being. Plastic canopies, even if of clear PVC, will reduce optical clarity, although clearer panels can be introduced to enhance visibility in key areas of the canopy.

- Reduced dexterity may affect the handling of smaller species and hinder sampling or administration procedures. Access to cages and to the animals will be via glove sleeves built into the walls of the isolator (Figure 11.4) or by the use of integral half suits (Figure 11.5). These gloves will normally be fixed in place and will thus have to be of a size to accommodate all users.
- The length and position of glove sleeves may mean that there are certain areas within the isolator that cannot be reached. There needs to be a contingency plan in place to deal with animals that have escaped from cages within the isolator so that this will not compromise the experiment (eg, by chewing through the isolator wall or a glove) or stress the animals during attempts at recapture.
- The reduced or absent gut microflora of gnotobiotic animals may affect their digestion or utilisation of nutrients that are usually made available by commensal organisms. In addition, the normal microflora may act as a barrier to pathogenic or opportunist organisms, and animals in which this flora is absent or restricted may be more susceptible to infection.
- Some species may be colostrum-deprived in order to maintain germ-free status and so be deficient in protective maternal antibodies, resulting in greater susceptibility to disease by opportunist organisms, or to any pathogens given experimentally.

The environment within isolators is dependent upon a constant adequate airflow through the isolator to prevent high temperature, high humidity or build up of ammonia and welfare will be at risk if these systems should fail. The removal of waste is time consuming and is a risk to the integrity of the system.

The introduction of food, water, bedding and other materials into isolators requires strict decontamination protocols. Usually, these materials are pre-sterilised by autoclaving,

**Figure 11.5** The interior of a half-suit isolator used to house infected guinea pigs. (Courtesy of Health Protection Agency.)

filtration or irradiation and sealed into plastic bags or other containers that can then be introduced to the isolator via a transfer port after surface decontamination. The use of chemical disinfection may potentially expose animals to unpleasant or toxic fumes. It is important to select non-toxic disinfectants, those that break down rapidly to non-toxic components (eg, peracetic acid breaks down to water, carbon dioxide and oxygen) or to design isolators to have some sort of ventilation system to remove unpleasant or toxic fumes.

It is important to check that treating food by autoclaving or irradiation will not result in loss of essential trace elements or nutritional value.

**Table 11.2** Potential welfare issues of isolators.

Parameter	Potential welfare issue	Solution
Air supply	Restricted space requires constant airflow to be maintained to avoid build up of humidity, temperature or waste gases (eg, ammonia). Failure of power or fans will rapidly cause problems	Have over-capacity for fans. Have reserve fan or twin-motored fan. Emergency generator is essential and battery back-up to power fans is recommended
Use of supply ports	Potential route for contamination. Potential for exposure to chemical disinfectants	Minimise frequency of use of entry ports by use of supply isolators and/or extended waste bags. Choose disinfectants that will decompose into non-toxic components or ventilate the port
Sterilisation of food	This may affect nutritional value	Select least drastic sterilisation technique. When specifying diet composition allow for decay of essential vitamins or trace elements
Interaction with staff	Reduced visibility, dexterity and ergonomics may limit observation of animals, precision for handling or procedures and may reduce the time staff can spend at one session	Consider lighting levels, glove positions, number of cages per isolator and positioning. Consider half suits for improved ergonomics. Environmental enrichment and group housing can be the same as for conventional rooms
Procedures and necropsies	Confined space and biosafety requirements may lead to procedures and necropsies being performed in close proximity to other animals	Where possible have a separate isolator or cabinet attached for conduct of procedures/necropsies. For more intricate procedures removal to a draught table may be required
Natural microflora	May affect ability to utilise food	Consider supplementation of diet or possibility of introducing a balanced microflora
Escape from cage	Escaped animals may damage canopy or sleeves and this may compromise the experiment There may be areas in the isolator that cannot be reached due to restrictions of glove sleeves	A strict regime of checking cage security is required. Caps can be used to prevent access to glove sleeves Design out any dead spaces or ensure that some form of humane capture such as netting can be used successfully

More recently, isolator technology has been adapted as a strategy for primary containment of infected animals and, in this scenario, the isolator is maintained under negative pressure to enhance operator protection. The same points listed apply regarding potential impact on animal welfare. Flexible canopies need robust support to prevent collapse on to the animals' cages due to the negative pressure (UK Health and Safety Executive guidelines (Guidance on the use, testing and maintenance of laboratory and animal isolators for the containment of biological agents<sup>1</sup>) recommend a minimum operating pressure of 30 Pa below laboratory pressure). In order to safeguard animals' welfare, isolators need to be equipped with alarms that indicate out-of-range pressure changes and air supply failure. They also need to be linked to standby generators and to emergency battery back-up that will cut in to maintain the air supply, allowing sufficient operating time to allow any remedial action to be completed.

### Rigid isolators

Rigid isolators operate in the same way as flexible film isolators, but their walls are made of rigid plastic. This makes them more resistant to physical damage, but the rigid nature of the walls limits the access reach of glove sleeves: this normally necessitates the use of integral half suits to improve access and user ergonomics. The other disadvantage of these isolators is that they are less able to absorb sudden pressure

fluctuations such as those that occur when entering the glove sleeves or half suit and this could potentially compromise the protective efficacy of a negative- or positive-pressure regime unless carefully managed. Rigid isolators have been used where a more robust structure is required such as for housing infected marmosets (Brown & Hearson 2008) or poultry (Timms *et al.* 1979). Table 11.2 provides a summary of potential welfare issues and solutions relating to using isolators.

### Individually ventilated cages

The principle of the individually ventilated cage (IVC) is for each to be a mini containment system (Figure 11.6). Each cage has a removable lid that, for effective containment purposes, is clamped and sealed to the top rim of the cage. Ventilation for the occupants is provided by plugging each cage into a dedicated rack system that has either an integrated air supply/extract or which, less frequently, plumbs into the room air-handling system in some way. The supply and extract air can be balanced to provide either positive or negative pressure within the cage, depending upon the experimental requirements. For effective high-level biocontainment the integrity of these air penetrations is managed by the use of small in-line HEPA filters or by snap-shut valve systems or a combination of both. IVCs are often used as the preferred option for protecting staff from exposure to animal allergens (Renström *et al.* 2001) or, in older facilities, as a less expensive method of meeting recommended air change rates, in place of total refurbishment.

<sup>1</sup> <http://www.hse.gov.uk>

**Figure 11.6** A rack of IVCs used to house mice. (Courtesy of Arrowmicht.)

### Welfare considerations in the use of IVCs

Individually ventilated cages are capable of providing good air change rates and environmental conditions when working well (Clough *et al.* 1995; Höglund & Renström 2001). However, dust clogging of filters may affect performance (Höglund & Renström 2001). They can provide protection from external disease or cross-contamination from experimental infection (Lipman *et al.* 1993; Morrell 1997), but there is reduced visibility of the occupants. Kallnik *et al.* (2007) found that for some inbred mouse strains, housing in IVCs reduced activity and increased anxiety-related behaviour. To improve visibility, the food hopper can be moved to the rear of the cage.

These cages are labour-intensive to service: a change of bedding requires transfer of each cage to cabinet prior to removal of lid and strict disinfection regimes to prevent cross-contamination (Figure 11.7) (Höglund & Renström 2001). There is a risk of uneven distribution of air throughout cages depending on their position on the rack. Other potential disadvantages or problems include:

- There is a risk of suffocation if the air supply fails (therefore, they need good back-up support and visible evidence of airflows for each cage on the rack, plus good alarm systems) (Krohn & Hansen 2002). An uninterruptible power supply (UPS) is essential to guarantee the well-being of the occupants.
- Care must be taken that the noise and vibration of air handling units is not transferred to the cages. This should include any frequencies beyond the normal human range. Noise level considerations should also extend to the cabinet where cage changes or procedures may be conducted.
- Disturbance during cage changes may affect breeding performance (Reeb-Whitaker *et al.* 2001). In the most recent systems, the improved level of ventilation means that cages need cleaning out at fortnightly rather than weekly intervals.
- Reduced frequency of cleaning may mean that welfare problems may go unnoticed unless a strict discipline of

**Figure 11.7** An IVC being serviced in a Class II type cabinet. (Courtesy of Tecniplast UK.)

observation by animal care staff is enforced. This practice may also require the use of large food hoppers and drinking bottles that may intrude upon and reduce the amount of three-dimensional cage space available to the occupants.

- A drive towards more efficient use of room space may lead to the deployment of cage racks that are too tall for direct observation of all animals. Similarly, library racking systems may present a tempting economy of room usage, but working practices must be in place to ensure that cages are observed at least once per day by a competent individual.

Table 11.3 provides a summary of potential welfare issues and solutions relating to using IVCs.

**Table 11.3** Potential welfare issues of IVCs.

Parameter	Potential welfare issue	Solution
Air supply	Sealed lids and small volume of airspace requires constant airflow to be maintained to avoid build up of humidity, temperature or waste gases (eg, ammonia) Failure of power or fans will rapidly cause problems and may lead to suffocation if prolonged	Have a system that ensures even distribution of air to all cages. Have reserve fan or twin-motored fan. Emergency generator is essential and battery back-up to power fans is recommended (UPS). A schedule of regular servicing should be in place to ensure optimum performance
Filtration	Effective biocontainment will involve filtration of air. Filters will become clogged with dust and dander and this will affect performance	Either change filters frequently (expensive) or have a disposable pre-filter that can be discarded Have a monitoring system that will warn of reduction in performance (preferably for each cage)
Cage cleaning/changing	Every event such as addition of food and water, changing bedding, close inspection of animals, will require removal to a cabinet	Reduce change requirements to a minimum by optimising air change rates
Interaction with staff	Reduced visibility and ergonomics may limit observation of animals Requirement to move to cabinet before removing lid may reduce the time staff can spend at one session	Organise cages to allow maximum visibility of occupants (eg, move food hopper from front of cage) Have strict daily observation regime in place Mobile transportation units are available to move batches of cages whilst maintaining air supply
Procedures	Cages need to be transferred to a cabinet or downdraught table to conduct experimental procedures. This will be time-consuming and may lead to fatigue	Design experiments so that groups of animals can be dealt with in a tolerable time period. Do not be over-ambitious with the types of procedures that can be conducted, bearing in mind group sizes and the limitations of cabinet work
Cross-contamination	The use of a cabinet for husbandry or procedures means that there is a risk of cross-contamination between groups of animals	Strict operating procedures are required to schedule the order in which groups of cages are opened and to define disinfection regimes for exposed surfaces

### Filter-top cages

Filter-top cages provide a simple method of preventing cross-contamination between cages by providing a physical barrier to larger particles (Figure 11.8). Typically they consist of a shoebox-type cage with a lid consisting of a polycarbonate frame fitted with a piece of filter media. Such systems have been shown to protect the cage occupants from exposure to pathogens in adjacent cages (Lipman *et al.* 1993). Whilst they can be used successfully to prevent cross-contamination between groups of infected animals such as hamsters infected with *Clostridium difficile* (Shone personal communication), they are not recommended for use with pathogens dangerous to humans without the additional use of some other, more robust form of containment.

#### Welfare considerations in the use of filter-top cages

The presence of a filter lid reduces visibility of the occupants and of food and water levels. Also, the presence of a filter without a forced air supply reduces ventilation and can lead to a build up of waste gases. Reviews of the environmental conditions within such cages indicate that the reduced airflow observed within these cages could lead to a build-up of gaseous pollutants that may adversely affect the animals' health (Keller *et al.* 1989) and that the high relative humidity, ammonia and carbon dioxide levels result in lower body weight gain and lower water consumption (Corning & Lipman 1991; Memarzadeh *et al.* 2004).

**Figure 11.8** A filter-top box housing hamsters infected with *Clostridium difficile*. (Courtesy of Health Protection Agency.)

However, if due consideration is given to the number of animals housed per cage, the provision of bedding that will absorb waste effectively and to the frequency of bedding change (Reeb *et al.* 1998), then these cages provide a simple and effective means of preventing cross-contamination.

The filter lid should only be removed in a contained environment such as a safety cabinet, otherwise the benefits of using the lid will be lost and the resultant cross-contamination may invalidate the experiment. A strict working prac-

tice regime, including disinfection, placing only similarly infected groups of cages in the cabinet at the same time, and working from the lowest dose upward, is required for this system to work effectively.

### Ventilated cabinets

Ventilated cabinets are cabinets with sets of shelves on which the animal cages are placed. They can provide low-grade protection or isolation (Figure 11.9). There are usually one or two doors at the front to allow access to the cages, and air is supplied either by an integral air-handling system or by plumbing into the room air system. The air handling can usually be switched between supply or extraction so that the cabinet can be operated at either negative or positive pressure. The shelves may be perforated to allow better distribution of air. Ventilated cabinets are frequently used in combination with filter-top cages, as any protective efficacy is lost as soon as a cabinet door is opened. Ventilated cabinets can be fitted with a range of optional extras to suit user requirements, such as building in a variable circadian rhythm with light/dark time control or fitting temperature control to allow post-operative recovery.

#### Welfare considerations in the use of ventilated cabinets

Ventilated cabinets limit the observation of occupants, especially if used in combination with filter-top boxes. Ventilation is limited in the event of a power failure. As with other ventilated systems due consideration should be given to the transfer of noise and vibration from air handling systems. There may be a temptation to conduct more than one experiment in a room as the cabinets appear very self-contained. For such a strategy to succeed there need to be strict proto-

**Figure 11.9** A typical ventilated cabinet containing mouse cages. (Courtesy of Tecniplast UK.)

cols in place for removal of cages for husbandry or experimental procedures.

### Laminar flow booths or cubicles

Laminar flow booths are essentially miniature rooms with their own air handling systems and they are used to subdivide an animal room into several independent units. Their main advantage is that this subdivision of a room can enable more efficient use of space where this is at a premium by allowing several different experiments to be conducted simultaneously (Figure 11.10).

Typical isolation booths include: a wall system, a ceiling containing controls and an air handling system and a vertically telescoping front access door with transparent windows. They can be operated at either positive pressure, to protect the occupants, or at negative pressure, to protect staff. They can be custom built to fit any particular space and are usually accessed from the front by upward-opening sectioned doors. As with ventilated cabinets, any protective efficacy afforded by the pressure differential or direction of airflow is considerably reduced when the doors are opened to access the occupants of the booth. The use of upwardly telescoping, rather than outward-opening doors reduces this effect and allows the air handling system to cope more efficiently with the breach in the barrier that is created. The vulnerability of the occupants of such systems to power or fan failure is very much dependent on the size of the booth.

For smaller booths, animals will need to be removed to a separate area or cabinet to perform daily husbandry or procedures, but larger booths can incorporate a section to allow such functions.

#### Welfare considerations in the use of laminar flow booths

These booths can provide a degree of microbiological separation but they permit only poor observation of occu-

**Figure 11.10** A typical containment booth with upwardly telescoping sectioned doors. (Courtesy of Britz & Co., USA.)

pants from outside the booth. Other potential problems include:

- limited ventilation in the event of power failure;
- as with other ventilated systems, there is the potential for transfer of noise from air handling equipment or generated by the flow of air.

The environment of a booth can be easier to control in terms of air changes, temperature and humidity than that of an entire room. A controlled light–dark system can also be incorporated if required. A strict regime of daily practice is required for staff to prevent cross-contamination between booths and where smaller booths are sharing an area or cabinet for procedures, robust protocols must be in place to prevent cross-contamination between separate experiments. As with any enclosed system a reliable UPS is essential.

### Bespoke systems

For some species, no systems that offer acceptable levels of operator protection are commercially available and bespoke systems have to be developed according to need. An example of this is the directional flow containment system developed at the UK Centre for Emergency Preparedness and Response (CEPR) to enable group housing of macaques that have been challenged with infectious agents (Figure 11.11a,b). Here, operator protection depends upon a directional flow of air that is maintained to a minimum velocity of 0.7m/s at all times, even when accessing the animals. The room air-handling system is used to provide the ventilation for the system. The primates are physically isolated from the general room area by a solid transparent plastic barrier fixed to the front of the cage system. This barrier serves to enhance the directional airflow and to provide a physical barrier to

potentially contaminated material generated by coughing, urination or defecation.

The risks associated with the husbandry of infected primates are controlled by strict discipline with regard to feeding, watering and waste removal regimes. The risks associated with handling of the primates are controlled by a strict regime whereby animals are sedated by injection before any handling or removal from the cage. Injection for sedation is accomplished by the use of a winding mechanism that gently brings the animal to the front of the cage and a strategically placed access door to allow injection. Sedated animals are removed from the cage into a carrying box that will be used at all times for transportation to and from a separate procedures area. All procedures are conducted on validated downdraught tables.

### Welfare considerations of bespoke systems

Access to the animals is restricted compared to the situation when using an open cage system. It is essential that all systems are designed so that animals can be accessed and isolated without causing undue stress for sedation or for remedial treatment in case of injury. In these systems, observations of animals can be limited by reflection of the plastic barrier. Overhead lighting needs to be positioned carefully to avoid this. Observation periods are also limited due to the demanding entry and exit procedures that require the use of protective clothing and strict disinfection regimes. Solid barriers inevitably alter the relationship between the care staff and the animals. This is no great problem if the animals are housed in social groups. Such systems can change the ergonomics of husbandry procedures and consideration needs to be given at the design stage to the potential for fatigue or strain in staff conducting day-to-day husbandry procedures.

## Species

### Mice

IVCs are now in common usage for mice for containment of infection, for reduction of animal allergens or to protect susceptible animals from outside contamination. The ability to 'quarantine' animals of unknown health status in such systems has led to increased usage linked to the increasing traffic of transgenic strains of mice between research groups in different countries.

The other obvious attraction of these systems is that more efficient use can be made of animal accommodation, whilst not compromising health status (increases in stocking density of up to 50% are claimed). Thus, IVC systems are seen as a preferred option to improve standards of environmental health for both staff (allergen containment) and animals (cross-contamination, environmental control) without investing heavily in facility refurbishment or in new facilities.

Ventilation is provided by plugging individual cages into an air-handling system that is either integral to the cage rack or is plumbed in to the room air supply. Protection is afforded by maintaining either a positive or negative pressure within each cage. This works well whilst the cages are attached within the rack but the challenge to bio-containment status comes when the cages have to be removed in order to change bedding, food and water, or to handle the animals. Containment integrity after removal from the rack can be maintained, to some extent, by an airtight seal between the lid and the box. This airtight seal presents a potential threat to the welfare of the occupants should the air system fail or should the box not be replaced accurately on the rack. Manufacturers have overcome this problem by placing an additional filter on the lid of the box that will allow passive exchange of gases and by adding pressure alarms and emergency battery power that will allow continued operation for a finite time until power is restored and by engineering in accurate locating systems. The effect of various ventilation rates from 30–100 air changes per hour (ACH) has been evaluated (Reeb *et al.* 1998) and whilst all rates kept ammonia levels below 3 parts per million (ppm), carbon dioxide levels, relative humidity and temperature were found to vary according to air change rate. The authors concluded that ventilation rates of 30ACH were adequate if bedding was changed weekly, but this needed to be increased to 60ACH in case of a fortnightly change frequency.

Removal of the lid for any husbandry or procedural functions is generally performed within a safety cabinet (usually Class II) but strict working protocols must be put in place to prevent cross-contamination between groups of animals. Any assessment of working practice should include the likelihood of contamination when handling the animals for operations such as cage changing or procedures: this is usually addressed either by changing gloves between each cage (very time consuming) or using disposable forceps to pick up the mice (this requires careful choice of implement and of experienced staff to avoid injury to the animals).

Other containment systems used for mice include:

- isolators;
- filter-top cages;
- ventilated cabinets;
- ventilated booths;
- suited laboratories.

### Welfare considerations with the use of containment systems for mice

Mice should be kept in groups wherever possible. Bedding and nesting materials should be provided; this includes the consideration of the importance of location of nest boxes as described by Kostomitsopoulos *et al.* (2007). Plastic, autoclavable nest boxes are available specifically for containment systems and treats, disposable tunnels and mouse refuges are readily available.

Containment strategies should be selected that allow maximum observation of animals but minimise laborious clothing change procedures. Where ventilated containment systems are used due consideration must be given to avoid exposing mice to excessive air change rates or air velocities (see also Chapter 21). All aspects of ergonomics should be considered so that staff are not reluctant to observe and care for animals. The preventative maintenance implications to keep containment systems running efficiently and safely for animal welfare should be considered.

### Rats

IVCs are now manufactured at an appropriate size to maintain rats. Other suitable containment systems for rats include:

- isolators;
- ventilated cabinets;
- ventilated booths;
- suited laboratories.

### Welfare issues with the use of containment systems for rats

As with mice, rats should be housed in social groups of three to five (Patterson-Kane *et al.* 2001) wherever possible. Cage height may be important to allow rats to stand erect. It has been noted that rats prefer a lower air change rate, below 80ACH (Krohn *et al.* 2003). Rats are also affected by ammonia build-up (Gamble & Clough 1976) compared to mice, who are thought to be more ammonia tolerant (Smith *et al.* 2004), so an optimal ventilation rate needs to be established. Provision of refuge and shredded nesting materials are thought to provide the best environmental enrichment for rats but they do not show any preference for tunnels or pipes (Bradshaw & Poling 1991).

### Hamsters

Suitable containment systems for hamsters include:

- filter-top boxes;
- isolators;
- ventilated cabinets;

- ventilated booths;
- suited laboratories.

#### **Welfare considerations with the use of containment systems for hamsters**

Hamsters are more solitary than rats and mice and care is needed when housing them in social groups unless they are put together at an early age. They have a need to burrow or hide in shelters, so deep litter and appropriate nesting materials are of great benefit. It should be borne in mind that hamsters are very adept at chewing through cages.

#### **Guinea pigs**

Suitable containment systems for guinea pigs include:

- isolators;
- ventilated cabinets;
- ventilated booths;
- suited laboratories.

#### **Welfare considerations with the use of containment systems for guinea pigs**

Animals should be housed in groups or pairs with deep litter if possible. Sudden noises or movements should be avoided during husbandry or experimental procedures. Guinea pigs do well with a set routine and adapt poorly to changes, especially more mature animals. They may be upset by changes in the type of food hopper, water bottle or the type of food (Wolfensohn & Lloyd 1998) and they may be upset by a sudden move from conventional to contained housing.

#### **Rabbits**

Suitable containment systems for rabbits include:

- isolators;
- ventilated cabinets;
- ventilated booths;
- directional flow systems;
- suited laboratories.

#### **Welfare considerations with the use of containment systems for rabbits**

The use of senses such as smell or hearing may be impeded by the enclosure, by directional airflow or the use of protective clothing. A risk assessment taking into account the infectious agent may allow group housing in floor pens or large cages with deep litter if this results in no increased biological risk to handlers. This type of housing may be accommodated in a bespoke directional-flow system and will have the potential benefit of reducing stereotypic behaviours. Boxes or tubes should be provided as refuges from aggression. Cages should be of a size to allow the animals to stand on their hindlegs, or climb on ledges to get a better view. The housing should allow animals to get an early warning rather than be startled by the sudden appearance of an operator (as might happen if they were housed in an isolator system similar to those shown in Figures 11.12 or 11.13).

#### **Ferrets**

Ferrets are considered to be good models for several human respiratory infections, including influenza, to which they are

**Figure 11.12** The interior of a containment isolator for piglets. (Courtesy of Bell Isolation Systems Ltd.)

**Figure 11.13** An isolator for gnotobiotic calves. (Courtesy of Bell Isolation Systems Ltd.)

**Figure 11.14** A ventilated unit for use with ferrets infected with a high-level pathogen. (Courtesy of Tecniplast UK.)

naturally susceptible; they have been shown to respond to infection in the same way as humans.

Suitable containment systems for ferrets include:

- ventilated cages (Figure 11.14);
- ventilated booths;
- directional flow systems;
- suited laboratories.

#### **Welfare considerations with the use of containment systems for ferrets**

Ferrets should be housed in social groups or pairs where possible. Risk assessment should be undertaken to give consideration to allowing floor pens with deep litter, tunnels and disposable boxes if there is no increased risk to handlers. Consideration should be given to a bespoke system

that will allow this whilst satisfying the experimental requirements for safe access to the animals for husbandry and procedures. Sullivan and Reardon (2008) report that ferrets used as a model for H5N1 influenza, requiring high-level containment, can be given the same level of enrichment as that provided prior to infection.

#### **Non-human primates**

Suitable containment systems for non-human primates include:

- rigid isolators (New World only);
- directional flow systems: see Figure 11.11;
- negative pressure rooms plus RPE;
- suited laboratories.

### Welfare considerations with the use of containment systems for non-human primates

Primates should be housed in social groups wherever possible. Marmosets are usually pair-housed for experimental work as a vasectomised male and female, whereas tamarins and Old World primates such as macaques can be successfully housed in single-sex social groups. After social groups have been established, sufficient time should be allowed before the start of a study to ensure that the groupings are compatible and stable.

Provide foraging in deep litter or foraging tray/box if not possible, vary the diet, add toys, puzzle feeders, mirrors, etc, and alternate these to maintain interest. The author has found that providing a TV can be useful enrichment. The TV should be visible for all individuals, with a range of DVDs. Duration and content should be varied to avoid losing the novelty value.

CCTV with a view of all animals and a zoom facility can be used to study abnormal behaviour or overt clinical signs without disturbing the animals. Far more subtle information about well-being can be acquired if the animals are not reacting to human presence. CCTV can also be used to record, so that any missed time periods can be reviewed (Figure 11.15).

Staff familiar with individual animals should be those that assess clinical or behavioural signs. Humane endpoints with clear definition of criteria that are unambiguous and easy to evaluate should be used.

Animals should be acclimatised to the containment system or to protective clothing, using staff who are familiar to the animals. Where possible, train the animals to come to the front of cage or to the area where sedation will be given.

**Figure 11.15** Animals being observed by CCTV. (Courtesy of Health Protection Agency.)

Train them to take oral dose, use target training for groups, and use positive reinforcement. Train animals to allow them to be weighed by, for example, entering a detachable weighing box.

In addition to the above:

- Provide a nest box or bucket for marmosets or tamarins to sleep in and hammocks for macaques.
- Maintain the same social groups throughout and plan experimental groups to allow same partners. Plan for eventuality of when humane endpoints are met. Plan necropsy schedules so that animals are not left alone, if at all possible.
- Remote telemetry allows continuous data capture (temperature, blood pressure, ECG, respiration rate, mobility), without repeated sedation. It provides improved experimental data and may assist in establishing early humane endpoints; but choose a system that allows group housing where possible and balance the harms to the animals in terms of surgical implantation, against the benefits (Figure 11.16).
- Ensure that staff are fully trained to understand animals' behaviour and the impact of their own behaviour so as to minimise aggression.
- Design cages so that animals can be separated if aggressive, or isolated for sedation or veterinary treatment if injured. It is of little value having vast cages if animals cannot be captured/sedated without prolonged stress to the animals and staff. Brown and Hearson (2008) describe a humane way of restraining marmosets without stress or injury, using a netting cassette.
- Make cages as complex as possible, using partitions and shelves, or perches for smaller species. This makes the environment more interesting and allows refuge from peers or more dominant animals.
- Feed in an appropriate manner, so that all members of the group can access adequate food: this avoids disrupting groups by minimising aggressive incidents at feeding.

**Figure 11.16** Real-time display of cardiac and respiratory data from a telemetry implant. (Courtesy of Health Protection Agency.)

## Pigs

Young piglets can be housed in flexible film isolators, but will outgrow such limited accommodation within a few months (Figure 11.12). Other suitable containment systems for pigs include:

- directional flow systems;
- negative pressure rooms plus RPE, or suited laboratories.

### Welfare considerations with the use of containment systems for pigs

A deep substrate should be provided to permit natural behaviours such as rooting for food. Enrichment, such as toys, plastic bottles, boxes and play chains, should also be provided. Interactions with handlers are important, so consider how high-quality interaction can be achieved. It is important that there is a system to enable restraint for examination or sampling without causing stress.

## Ruminants

Young calves and lambs have been reared in modified flexible film isolators either as germ-free animals or to contain an experimental infection (Figure 11.13). However, like piglets, they will outgrow this type of accommodation within a few months. Adult animals require negative pressure rooms plus RPE, or suited laboratories.

### Welfare considerations with the use of containment systems for ruminants

From a welfare point it is preferable to house animals in isolators in pairs rather than as individuals as this type of containment gives a high degree of isolation from outside stimuli. The plastic canopy insulates from noise and the height of the base container limits vision of the external environment.

For containment of larger juveniles and adult ruminants, the most practicable alternative is the use of negative pressure rooms with staff wearing PPE (and RPE if necessary). In such accommodation, it is essential that consideration is given to providing more than just a concrete floor. Rubber matting, or straw or other bedding if at all possible, should be provided. It is important to ensure that systems are in place that allow the animals to be restrained for examination or sampling without stress. It is important also to ensure that a diet containing suitable fibre to prevent digestive problems can be provided without compromising any drainage/effluent treatment systems. In most cases these problems can be addressed by the use of high-fibre, pelleted rations supplemented with mineral blocks and cubed hay.

## Birds

Suitable containment systems for birds include:

- isolators (Figure 11.17);
- negative pressure rooms plus RPE or suited laboratories.

**Figure 11.17** An isolator designed for use with poultry. (Courtesy of Bell Isolation Systems Ltd.)

### Welfare considerations with the use of containment systems for birds

Environmental enrichment, such as sand baths, artificial turf, provision of perches, has been shown to improve the condition of domestic hens (Abrahamsson *et al.* 1996). Enrichment objects reduce aggression between birds (Gvoryahu *et al.* 1994). Ventilation systems will be required in enclosed systems to prevent ammonia build-up. The filters can be affected by rapid clogging with dust.

### Check list for containment

The check list below is designed to help avoid overlooking any important aspects when planning to use containment facilities.

- Is a containment system really necessary? Is its use going to decrease the risks associated with your experiment (are the animals shedding infectious particles, are they infectious by aerosol or by direct contact) or could you actually be increasing risks (eg, needle-stick or bites due to decreased dexterity)?
- Does it do what it is supposed to do (contain or protect)?
- Does it still contain/protect during associated practices (eg, feeding, watering, cage changing, experimental procedures) and does any ancillary equipment offer the same level of protection?
- Can you demonstrate/quantify the effectiveness of operator protection?
- Is it practical to use (ergonomics, dexterity)?
- Can you actually perform all the experimental requirements?
- Can the animals be housed in social groups?

- Can they be accessed easily for food, water, health checks or handling?
- Can the animals be restrained or sedated without undue stress?
- Can they be readily observed for abnormal clinical signs, behaviour?
- Is rapid intervention practicable (eg, humane killing at endpoint, separation if aggression observed, remedial veterinary care)?
- Can they escape and if so can they be retrieved?
- Is air supply optimised for air changes, temperature and humidity?
- Can these conditions be sustained over an extended period?
- Are noise levels acceptable at all times?
- What measures are necessary against power failures?

### Legislative requirements

Each country will have its own legislative requirements but there is general consistency especially in assigning containment levels to specific pathogens. In general, biological agents are assigned to a hierarchical grouping according to the perceived threat to human health. These are normally called biocontainment or biosafety levels or the hierarchy may be named after the national body that assigns these 'risk' or 'hazard' groups. Thus for a particular infectious agent you will encounter a number of risk assessment phrases such as biocontainment level (eg, BCL3), biosafety level (eg, BSL3) in the US (Centers for Disease Control and Prevention and National Institutes for Health 2007) or, in the UK, Advisory Committee on Dangerous Pathogens level (eg, ACDP3; Advisory Committee on Dangerous Pathogens (1995)). Criteria that affect this categorisation include: the ability of the pathogen to infect humans; the seriousness of disease; the ability to spread from person to person; and whether prophylaxis (eg, a vaccine) or therapy is readily available. A good general outline of guidance on biohazard categories and the equipment and facilities required to operate safely is given in World Health Organization (2004).

To further complicate matters, many countries have assigned a similar hierarchical system to pathogens that may threaten the environment or agricultural species of economic importance. In this case the hierarchy is based more upon the potential to infect farm animals, the likelihood of escape into the environment and the consequences of infection, rather than the risk to human health. Here you will encounter categorisation of microbes under regulations such as Specified Animal Pathogen Order (eg, SAPO3) or BSL-3 Ag in the US (USDA Agricultural Research Service, Heckert & Kozlovac 2007). In some cases, eg, anthrax, the pathogen may come under both human and animal pathogen legislation and the containment strategy will need to take both into account.

Yet more legislation applies to genetically modified organisms and yet another hierarchy is applied based on the nature of the genetic alteration, whether this has enhanced or diminished the ability to infect or cause disease, whether the altered organism can survive outside the laboratory and whether the altered genes can be passed on to organisms in the outside environment. Be aware that this legislation will

apply to genetically altered animals as well as microbes, so containment protocols and risk assessments will need to address the issue of escaped animals and how these might interact genetically with the wild population.

### The future

As long as there is a requirement for animal models of infectious diseases there will be a need to use containment strategies to protect the operators. The principles underpinning current containment systems have changed little over the years, relying on some sort of physical barrier supplemented by a differential pressure regime: the main changes that have been seen relate mainly to improving the engineering associated with filtration, pressure and temperature control, alarm systems and emergency back-up capabilities. Thus, the use of isolators, IVCs and cabinets will continue to expand as the expectations of health and safety regulators increase. Furthermore, there is currently an explosion of investment worldwide in high-containment laboratories, driven in part by the perceived threats of bioterrorism, emerging diseases (eg, H5N1 influenza, severe acute respiratory syndrome (SARS)) and changing patterns in disease prevalence due to climate change and population mobility (eg, vector-borne diseases). The main driver for improving these systems is always going to be minimising risk to the operators and will thus be focused on ergonomics and infection hazards. Many of these agents cause serious disease or death and there are some that have an infectious dose for humans of one organism. Thus, potentially lethal needle-stick injuries, bites or scratches must be prevented at all costs. Inevitably, any disease-containment strategy will add to the time taken to perform a given task. Copps (2005) gives an example of a single blood sample from one pig that will take 15 minutes at BCL-2, 30 minutes at BCL-3 and 60 minutes at BCL-4, taking into account the time taken to don and doff protective clothing, check all systems, restrain the animal, disinfect and shower out. The challenge will be to optimise animals' welfare within these parameters.

The value of giving animals the ability to manipulate their environment and express preferences, even in a small way, should not be underestimated as it allows them to cope better with the housing conditions necessitated by the procedures.

Given the range of materials available for the construction of cages and enrichment equipment there is little excuse for not addressing the welfare needs of all species of laboratory animals even under the most stringent biocontainment regimes. If animal-friendly materials are not sterilisable for re-use then they should be considered as disposable and destroyed or made safe in the most appropriate manner. Several laboratories that specialise in high containment have demonstrated that cage sizes can be maximised, that materials such as plastics and wood can replace stainless steel and that group housing is possible. Biotelemetry can be especially useful in the context of biocontainment, where human presence is kept to a minimum, as it allows continuous monitoring of physiological parameters that can be used to inform on humane endpoints or to indicate a point in the disease progression when extra monitoring or care will be

required. Telemetric systems are now being developed that allow concurrent monitoring from multiple animals within group housing (Williamson *et al.* 2007) and it is hoped that these will evolve to be applicable to more species and to be minimally invasive, whilst still providing meaningful physiological data. In addition, the creative use of CCTV can enable continuous monitoring of animals and can even be advantageous in observing natural behaviour that cannot be seen during human presence.

# 12 Refinements in in-house animal production and breeding

Roger Francis

## Introduction

From time to time all animal house managers, whether in academic institutes or research laboratories, are likely to be asked to breed animals in-house rather than obtaining them from commercial breeders. Scientists often consider that it would be far easier and cheaper for them to have their own colonies of animals, bred in-house and under their control. While this chapter is aimed primarily at the scientist who wishes to have animals bred in-house, and it does not apply directly to commercial breeding establishments, many of the issues raised may also apply when purchasing from commercial breeders. For example, it is just as important for users to provide the commercial breeder with precise information on numbers required and when they are required so as to minimise wastage.

The resource implications of breeding in-house should not be under-estimated. Laboratory animal housing is expensive to provide and maintain. The requirements necessary to protect both the animals (eg, in the UK, Home Office 1989, 1995) and the personnel working within the animal unit (eg, Health and Safety Executive 2002; European Agency for Safety and Health at Work<sup>1</sup>) have led to the development of very specialised environmental needs. The maintenance of laboratory animals within specialist animal units requires: regulated relative humidity; precise temperature ranges; controlled rates of change of high-quality air (HEPA-filtered); dual lighting systems (a normal lower level for the animals and a higher level for humans to work in); dawn and dusk lighting and photoperiod control etc. Depending upon the nature of the work undertaken, specialist drainage systems with catchment containment systems for sterilisation of effluent prior to discharge may be required. In addition to these specialist environmental controls, animal accommodation must also have high-quality, easily cleaned finishes. Infrastructure and running costs make animal accommodation extremely expensive per square metre to maintain, and users have to judge the costs and benefits of using available space for breeding or for research animals.

It is just as important to have the resources to maintain high-quality breeding animals as it is to have adequate infra-

structure. Questions to consider before breeding in-house include: Are there adequate trained staff for the species to be bred? Are staff familiar with the species, and with the type of housing required? Will they need specific training in order to work with new housing systems such as containment systems? Is veterinary advice available to develop and run the necessary programmes for screening, routine treatments, vaccinations etc? Are the animal care technicians fully conversant with the information technology required to maintain and monitor the breeding colonies and to facilitate regular communication between the animal unit and the scientist?

## The Three Rs in animal production

The topic of animal breeding and production, as opposed to the use of animals in research, may not be one that immediately springs to mind when considering the Three Rs (Russell & Burch 1959, see also Chapter 2). However, two of the Three Rs, reduction and refinement, are very relevant to the ethical production of laboratory animals.

Proper planning of production and usage should be undertaken in pursuit of reduction, to minimise the chances of any overproduction. Centralising animal production within multiple-user establishments can lead to reductions by reducing the replication of strains within the same establishment. Challenging assumptions about the need to use only one sex of animal, or animals at very precise weights or ages may also help to reduce the size of the colony required.

When establishing new colonies, the user groups and animal technicians should meet prior to starting the colony to discuss special needs and how these can be addressed. They should meet regularly to review progress and discuss whether the initial discussions were appropriate and effective. Senior technicians should produce reports on production, usage and wastage at regular intervals for users and the animal house committee, to enable trends to be monitored.

Where several animal units are spread across a campus or site there should be a central register of strains kept, their usage and surpluses or tissue availability.

Refinement is very important in the management of breeding colonies. Well trained animal technicians, who are specifically aware of the care and needs of breeding stock, are integral to keeping healthy animals to good welfare

<sup>1</sup>[http://osha.europa.eu/en/legislation/directives/index\\_html/@@legislation\\_overview](http://osha.europa.eu/en/legislation/directives/index_html/@@legislation_overview)

standards. The maintenance of high health status is essential but has considerable cost implications.

Refinement includes reducing suffering due to disease or morbidity. Good record systems (see the section on communication) can be used to monitor the efficiency of the colony, and can provide early indicators of problems, such as an increase in, or high levels of, pre-weaning mortality. Any problems must be investigated. For example, is an elevated incidence of pre-weaning mortality because nervous or stressed dams are killing their offspring? Would giving more nesting material reduce the loss? Or could it be caused by an underlying disease problem? If the latter is suspected, then health screening should take place and veterinary advice should be sought. For genetically altered (GA) animals, does a passport (a description of the animal the way in which it has been altered and the consequences of the alteration (Figure 12.1, see also RSPCA booklet GA Passports: *The key to consistent animal care*, In Press)) exist for the line? If so get a copy and continue to update it with your own findings. For all species research the literature for up-to-date advice on enclosure design and enrichment (see species-specific chapters).

### Making the decision

Despite all the disadvantages, there is a number of reasons why it may be necessary to produce animals in-house. It may be that the species, strain or animals of an appropriate health status are not readily available from commercial establishments within the same country. The animals may be required at a stage that is not readily available from commercial suppliers or which would result in, for example, undue stress during transport, eg, timed pregnancy, timed lactation, animals prior to normal weaning age, aged animals.

### Establishing user requirements

When a research worker or a research group asks for animals to be bred in-house, the first question has to be what species/strains are required? If these are readily available commercially, the next question is what is the case for producing the animal in-house? If the requirement is for a commonly available species or strain after the normal weaning age then this it is likely to be more efficient and cost-effective to purchase the animals from a commercial animal producer. However, if the requirement is for species, strains or developmental/life cycle stages that are not readily available then in-house breeding will need to be explored and discussed.

Before establishing in-house breeding colonies, animal unit managers should insist on written confirmation of what is required: species, strain, numbers, age, sex, special requirements, dates or times when required, and including details of endpoints, financial arrangements, start and finish dates, and legal requirements (legal authority may be needed for production of some strains). It should be made clear that only the principle investigator can make changes to these specifications and that any changes must be in

writing. This is so that requirements are carefully planned and costly changes avoided. Much of this information is relevant also when sourcing animals from commercial suppliers. Do not forget to agree a contingency plan (see later in this chapter).

## Breeding facilities and health status

Having decided on species and/or strain, there are many issues to address relating to health status. For example: Is the unit able to maintain the required animals at an appropriate health status? Does the animal unit have barrier systems, equipment and sufficient trained staff to maintain the animals appropriately? Can regular health screening be carried out (Laboratory Animal Breeders Association (LABA) 2002)? Are there legal constraints on transporting animals that are part of a scientific study? The method of housing must also be considered in conjunction with the users' needs. Are the users prepared to comply with the biosecurity arrangements (barriers etc) required to maintain the health status of their animals, and do they understand the terminology relating to this (see below)? In establishments with multiple user groups, it may be that some groups (eg, immunologists) require animals of different status than other users. Nonetheless, unless the research topic is the animal disease there can be no justification for keeping animals with compromised health status.

Because of modern requirements for high health status animals, the breeding of animals using conventional methods has become much rarer. As a minimum, most will need to be maintained in a barrier system producing specific pathogen free (SPF) animals. This places restrictions on the amount of access that user groups will have to their animals and may necessitate the scientist handing over the daily running of the colony to the animal house technicians, who then issue the animals as required. It may be necessary to maintain animals within individually ventilated cages, racks, or container systems, or negative- or positive-pressure isolators, all of which require highly developed standard operating procedures (SOPs) and place considerable restrictions on access and usage. One option may be to house nucleus or pedigree lines separately in higher containment systems while expansion colonies could be housed in simpler containment systems. Considerable care must always be taken when buying in animals to establish new colonies, and a period of quarantine and health screening is necessary to ensure that the new animals are of the appropriate health status.

## Predicting usage

Users must appreciate that the supply of animals cannot be simply switched on or off. Depending on the stage of development/life cycle that is required, it may be several months before an in-house colony is in a position to supply animals on a regular basis. For some species (primates, cats and dogs), it could be several years before a breeding colony could supply animals. Even when colonies of animals are in full production, users must appreciate the need to communicate their requirements. For instance, if the user requires 8-week-old mice then the production of those mice needs to be set up some 11–12 weeks before the user's required date.

If animals must be produced in-house then, wherever possible, the user should be required to provide a reasonable usage plan. There will be peaks and troughs in usage, for instance there is normally a drop in use around and

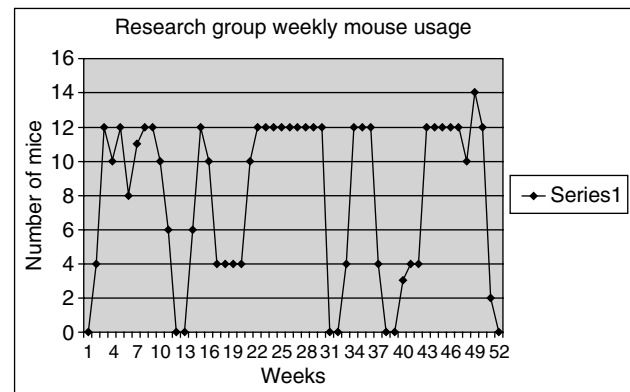

Figure 12.2 Weekly usage of mouse pups by a research group.

during holidays. Experience in academia shows that there may be a surge in use at the start of each academic term and then again when students have departed in early summer. Therefore, to minimise wastage, it is important to know when the research groups are planning to take annual holidays, or when they are attending conferences. Figure 12.2 shows the usage by a research group of 10–12-day-old mouse pups each week, with zero use in weeks 52 and 1 coinciding with the Christmas/New Year holiday, another break at weeks 13–14 (the Easter holiday), a drop to only 4 animals per week for a 4-week period, 2 weeks' annual holiday with no usage during weeks 30–31 followed by no usage in weeks 38–39 when the research group was away at a conference. Such changes should be predicted and planned for so as to minimise wastage.

Research workers may not appreciate the size of colonies needed to produce the numbers of animals that they require each week. The smaller the numbers required the more difficult it is to keep the colony viable. Colonies consist of current breeders, replacement breeders, growing stock and within most colonies there will be animals that may already have already been used, unless there are clear instructions regarding culling. A colony to supply six male mice a week at 8 weeks of age could consist of between 60–80 animals.

If a colony is to successfully produce the required animals over a number of years it will need to be robust, and the management required to achieve this will depend on colony type. If the colony is to have an inbred status, then there will have to be sufficient animals to maintain pedigree lines and, where appropriate, to maintain expansion colonies. If the colony is outbred, then the population must be large enough to maintain a gene pool so as to allow unrelated pairings and to prevent inbreeding (see also Chapter 4).

## Communicating with the users

Good communications between the animal producer and the user are essential and with the use of electronic transfer of information, records can be regularly updated, on a weekly basis or more frequently if desired. Indeed, if the animal technicians update computer records of animal production and usage on a daily basis, then this information can

also be sent daily to users. Simple spreadsheets can be used to report on the number of animals produced, used, culled etc. Much of this information may already have been collected and collated to enable accurate charging for the full cost recovery of running the colony. The information can be distributed to user groups at the same time as to the animal unit administrator. Besides the day-to-day information on the production and running of the colony, health information (eg, health screening results), any unexpected problems with the animals and changes in environmental conditions etc should also be reported.

The communication needs to be two way. The principle investigator should provide details of the planned usage, as discussed above, and should also give feedback on how the work is progressing and if there is likely to be change in usage. User groups will often get a better service from the animal unit if they take the trouble to explain what they are doing and hoping to achieve. If the research group gives the animal care staff a presentation on the area of research and explains the needs of the group, this can frequently result in better utilisation of the animals.

### Contingency plans

Having agreed to production of animals in-house, in an appropriate housing system and to a predetermined health status, the next stage is to develop, in discussion with users, a contingency plan to address arrangements if things go wrong. This might cover: What happens when things break down (as they inevitably will)? Or what will happen if a problem emerges during health screening. Dependent upon the nature of the problem and the veterinary advice, will it be necessary to cull the entire colony? Would the use of a firebreak (stopping breeding for a period of time) allow a disease 'to burn itself out'? Could the colony be treated? Would the treatment conflict with the research programme? Whatever course of action is taken in such circumstances there would be a considerable impact, not only on the breeding colony, but also in terms of delay to research programmes. This will have further serious cost implications for the user groups, in terms of lost time, inability to meet deadlines, staff time and deciding who pays for the health treatments and the colony while it is non-productive and being rebuilt? Potential knock-on consequences for other user groups and their animals held within the unit should also be considered.

### Transport

Another important consideration is transport and the effect it has upon animals (see Chapter 13). Animals are regularly transported around the world for laboratory use. Generally these will be normal healthy animals, but there are times when it may be necessary to transport surgically prepared or GA animals. Special care and coping strategies must be put in place to ensure that such animals do not suffer during transport. In the case of surgically prepared animals, veterinary advice should be sought before the animals undergo

transportation. With GA animals, referral to the passport for the genotype should show if the animals need specialist care during transportation. Animals that have been transported for more than a short distance should be allowed at least a week to acclimatise, and some species can take much longer. When transporting laboratory animals, due consideration must be given to the legislation and codes of practice on animal transportation within each area or country the animals will be travelling through (eg, Council of Europe 1986, 2006; European Council (1986)); National Institutes of Health 2004; Laboratory Animal Science Association 2005; HMSO 2006). Given the potential stressors of transport and re-housing, it may be possible to make an ethical argument for in-house breeding, especially if the animals are required in a compromised state or at some stages of development/life cycle.

### Financial costs

Historically, users in academia have not paid the full costs of their animal colonies, often paying only for consumables, such as food, bedding and possibly caging. Recently, within the UK, there has been a move to full economic costing (FEC) with the result that that research animals are now very expensive for users to maintain. FEC means that the user pays for food and bedding as well as a footprint charge for the space taken up by the colony. This will cover fuel, maintenance, replacement build costs, all labour charges for the animal unit including ancillary staff and administrative staff, and consumables including clothing, laundry, environmental enrichment, equipment depreciation, quarantine, health screening etc. The result is that buying animals in has become a more attractive option; a researcher who uses six male mice bought in from a commercial supplier each week, finds that he or she is will only be paying for 12 animals per week (six housed for a week acclimatisation, plus the six they are about to use) instead of meeting the costs of maintaining a breeding colony of 60–80 animals. FEC results in the more efficient use of animals and space and, through this, the more ethical use of animals. Purchase from commercial companies may often offer ethical advantages. Commercial companies, through economies of scale, are able to minimise wastage, and are well placed to use, for other scientific purposes, those animals that have to be killed or to supply them as food for zoo animals.

### Partial in-house production

There may be good reasons for partial in-house production. Although timed-mated animals can be bought in, the stress of transportation and the legal constraints are considerable and the failure rates can be quite high. In-house production might also be necessary if there is a need for lactating females or specific age pups pre-weaning. Obtaining aged animals presents different sets of problems as these are not generally available from commercial suppliers (most of their rats and mice are used or killed by 12 weeks of age) although some companies will keep animals to specific

ages at a cost. If the animals required are not commercially available then there is no choice but to produce in-house. On the other hand, if the animals are commercially available, then it might be possible, in the case of timed pregnant or lactating animals, to buy in animals of breeding age and to time mate the animals in-house. If the dams are not used (ie, where it is the pups that are used for the research) they could be remated if necessary. In the case of aged animals, these should be bought in as old as possible and kept until the appropriate age. When maintaining groups of aged animals there is always the risk of animals being lost to natural causes. Good communication is essential to ensure that users are aware of the health status of aged animals.

### Calculating colony size

Once the principle investigator has provided information on animals, and stage of development required it is possible to calculate the required colony size. For this, it is important to know whether the animals will breed throughout the year or if they are seasonal breeders. If the latter, can the animal be induced to produce outside the normal season by manipulation of the environment, especially photoperiod and possibly temperature? Where seasonal manipulation is practised, care must be taken to ensure that the animals, especially birds, where necessary, get appropriate rest periods enabling them to complete physiological changes, such as moulting. In intensive breeding programmes, the duration of the breeding life of both male and females should be taken into account, especially if the females are producing and rearing very large litters; the calculations must reflect this and allow for adequate replacements.

### Information required to calculate the size of breeding colonies

In order to calculate breeding colony size, the following information is needed:

- Number of animals required to supply scientific needs (if a single sex is required, colony size will need to be doubled) and for replacement breeding stock.
- Reproduction data for the species, or more specifically the strain, including: type of oestrous cycle, length of cycle, breeding season, age at first breeding, gestation period, average litter size, litter interval, weaning age, age at first breeding, if seasonal breeders, then number of young per season, and economic breeding life. Obtain a growth curve for the strain so that all concerned are aware of the age/weight relationship.
- Shelf life. How long will the animal remain usable? Check the growth curve to see how long an animal remains within the required weight range.
- Breeding system: inbred, outbred, permanent pairs, temporary pairs, harems, hand mated (for timed pregnancy etc).
- Variance allowance. When calculating the size of the colony required to produce a given number of animals,

it is not possible to state exact litter sizes, so a small number of extra animals (a variance allowance) has to be included to ensure that adequate animals are produced. *The Manual of Animal Technology* (Barnett 2006) recommends adding variance allowances of 5% for colonies of 1000 pairs, 10% between 1000 and 100 pairs and 15% for less than 100 pairs.

Having ascertained the above and calculated the size of the breeding colony, it is then necessary to calculate the number of animals needed to get the stock to the stage required. This will be the numbers of animals required each week from the time of weaning to the age at which they will be issued, plus the number of animals required to be kept on as replacement breeders.

### Preservation of colonies

As mentioned earlier, it may be possible to maintain a smaller pedigree colony under higher health status housing with restricted personnel access (such colonies not only provide greater accuracy and control of production but also act as a safeguard should the expansion colony become infected), to supply an expansion colony for providing animals for the user. In the case of an outbred colony there must be a breeding system in place to maintain the gene pool as large as possible. Whatever system is used, there is always a possibility of genetic drift, incorrect matings or the risk of genetic loss if the colony becomes infected by disease. This can be safeguarded against by cryopreservation of gametes or embryos at the earliest possible stage in the development of a colony. Colonies should also be genetically monitored from time to time to ensure that the strains are still the authentic strain.

# 13 Transportation of laboratory animals

William J. White, Sonja T. Chou, Carl B. Kole and Roy Sutcliffe

## Introduction

Laboratory animals represent only a small fraction of animals moved in commerce and they differ from many in usually having a more defined health status. A wide range of purpose-bred or wild-caught animals could be used in research, but, in practice, only a small number of species are used. Animals used, and transported for research purposes, include rats, mice, guinea pigs, gerbils, hamsters, rabbits, cats, dogs, swine, non-human primates (only a few species), fish (principally zebra fish), and rarely frogs, sheep, goats, cattle and poultry (mostly chickens). The greatest numbers of shipped containers holding laboratory animals, as well as the greatest number of shipments, are of rats and mice. This chapter focuses on the transport of common laboratory animals although the principles can be applied across many species destined for research use. Species-specific information for less commonly used species can be found in other more comprehensive sources (International Air Transport Association (IATA) 2008a).

## General principles

When transporting laboratory animals, the objective is to move them in a manner that does not jeopardise their well-being or health status, minimises controllable sources of stress and ensures their safe arrival at their destination. Part of the stewardship of animal care and use is to understand, and provide for, needs and eventualities arising during transport.

There are various reasons for transporting laboratory animals. Animals are commonly produced in commercial facilities, using specialised housing and handling systems that can reliably exclude disease-causing and unwanted micro-organisms. These animals must be transported to the institutions that use them in research, testing or other activities. In the past, this traffic between commercial breeders and users comprised most of the transportation of laboratory animals. However, over the last few decades, the development of genetic manipulation techniques has led to increasing numbers of animals, with unique genotypes and phenotypes, being bred in small research colonies. These colonies have increasingly become a source of supply for other institutions, either as a small commercial enterprise, or for use on a collaborative basis. Collaborative studies between two or more institutions may require that animals

are transported more than once in larger multi-institutional studies. The number of institutionally produced animals that must be transported may be relatively small for any given institution, when compared to commercial producers, but across institutions the aggregate may represent a substantial number of journeys.

Research institutions often have a limited number of options regarding methods for transporting animals between institutions. In the UK and continental Europe, ground transportation by contracted carriers is more common than air transport because of the relatively short distances within and between countries. The majority of ground shipments involve journey times of less than 24h. Carriage by air still remains the most rapid means of transport over long distances and represents the only practical option for transporting animals between continents.

The type of journey, its duration, the physical environment during carriage, the design of the container, along with other factors influences the animals' safety and well-being during the journey. Transportation involves removal of animals from a controlled home environment and their placement in a varying and less controlled environment in which they may be transported with other animals from other locations or with non-animal freight. Even if proper arrangements and procedures are followed, it is, unfortunately, often likely that some animals will experience some discomfort or stress; adverse events may occur, albeit very rarely. In order to minimise adverse events and stress, it is essential to: understand the biological and behavioural requirements of the species; properly plan the journey; and provide adequate contingency provisions prior to commencing the journey. In practice, this means that the consignor should clearly understand all aspects of the procedures involved in transporting their animals as well as the variables that may be encountered during the journey. Since transporting animals between research institutions is not a daily or even a weekly event for most institutions, a detailed written set of procedures and a check list can be very useful in assuring that all steps in the journey have been carefully considered and that appropriate actions have been taken.

## General requirements

Animal transportation includes the entire period from packing, through dispatch, carriage and receipt by the

consignee to the unpacking of the animals at their final destination. It is important during the transportation process:

- that appropriate containers be used, constructed of strong, durable materials which meet or exceed all national and international guidelines;
- that the animals and their shipping containers be protected from adverse weather conditions such as precipitation, direct sunlight and high winds which can affect the ambient conditions within the container or the security of the container;
- that the animals be provided with an adequate supply of fresh or conditioned air that provides for their thermoregulatory, respiratory and metabolic needs;
- that the animals be protected from exposure to extremes in environmental conditions, especially high temperatures;
- that the animals be prevented from escaping, or from falling out of the container, or extending appendages outside the container, or from experiencing other conditions that result in physical harm, including illness, injury or death;
- that factors that may cause animal discomfort or stress during the journey are recognised and, where possible, minimised.

### The health and welfare of animals

Animals to be shipped should be in good clinical health. Prior to packing, each animal should be examined by an appropriately trained animal care provider, experienced in recognising signs associated with illness in that species. Animals should be excluded from shipment if there is behavioural or other clinical evidence of abnormalities that would make them unsuitable for transportation. In some cases, transport may involve animals with inherited abnormalities due either to spontaneous mutations or genetic manipulation. If animals have adapted to these abnormalities so that there are no apparent functional deficits or if the phenotypic expression of these abnormalities, in the judgment of the health care provider, does not present a risk to their well-being in transit, then these animals may be considered for transport. This is subject, however, to appropriate documentation of their abnormalities and the granting of any necessary regulatory permission for their transport. Similarly, diseased or injured animals may be considered for transport only when the purpose of such transport is for the diagnosis or treatment of the condition.

Shipment of pregnant animals should be avoided when possible. Shipment during the last 20% of gestation is risky, as it may be associated with stress-induced abortion. If the pregnancy is not the result of a carefully timed mating, shipment during this period could result in the animal delivering during shipment with risk to both the foetus and the mother. The risk of adverse events occurring during transport increases with the increasing body size of the mother and the size of the foetal mass being carried and also varies with the species. Time-mated rodents can be successfully shipped during the first two thirds of pregnancy and with caution during the first portion of the last third.

There is some variation in guidance on shipment of pregnant animals. Article 9 of The European Convention for the Protection of Animals during International Transport (Council of Europe 2003) states that pregnant female mammals shall not be transported either during the last tenth of the gestation period or for at least 1 week after they have given birth. However, the Laboratory Animal Science Association (LASA) recommends that pregnant animals should not normally be transported during the last fifth of gestation to minimise the risk of abortion or parturition in transit (LASA 2005). Larger species, such as dogs and non-human primates, can be transported nearer the time of parturition provided that the journey is direct, of relatively short duration and can be undertaken under appropriate veterinary direction and supervision. Guidance on this varies with different codes of practice, regulatory bodies and by species. However, as a general rule, shipment during the last 5–10% of gestation is considered more risky particularly for larger species. Nursing animals with their young may be transported when the young are a minimum of 7 days of age and with additional bedding and nesting material (LASA 2005).

Transport of unweaned animals presents a considerable risk to their safety and well-being. Unweaned animals may, depending upon their age, have difficulty in regulating body temperature, be incapable of eating solid food and may be unfamiliar with, or unable to access, water sources within the container. Some species such as guinea pigs can be weaned at a very early age since they are precocious at birth and capable of regulating body temperature and consuming solid food within a few days of birth. While there is no universal minimum age for shipment, animals must be capable of functioning independently from their mothers, consuming solid food and water as well as maintaining normal physiological and metabolic functions. Shipping a lactating female with her young, especially over long distances, may result in her failing to care for her young and their death. The risk of this varies somewhat between species and with the age of the young but, as a general rule, shipping lactating females and young constitutes an unacceptable risk to their health and well-being and is not recommended.

Immunologically deficient, or immunocompromised animals, are commonly transported for research purposes. Some genetically modified animals can possess unrecognised immune defects that may alter their susceptibility to disease. These animals may, as a result of acquiring human or environmental commensal organisms, develop illness that would not be experienced by animals that did not have immune dysfunction. Whenever immunologically deficient or immunologically compromised animals are transported, great care must be taken with all packing and handling and disinfection processes, to ensure that the animals will not be exposed to infectious agents. Other than these considerations, the requirements for successful transport of these animals are the same as for immunocompetent animals of the same species.

A number of anatomical conditions, such as genetic hairlessness or obesity, may impact upon the metabolism and physiology of laboratory animals during transportation and provisions should be made to account for these anatomical differences.

The greater insulation provided by body fat in obese animals compromises their ability to dissipate heat and to adapt to elevated environmental temperatures. Reducing the number of animals placed in a shipping container will help lessen the risk of excess heat by decreasing the total amount of heat generated within the container. Consideration should also be given to postponing shipments of such animals during abnormally warm weather if there is a possibility that the ambient environmental conditions could exceed acceptable ranges even for brief periods of time.

Certain strains of laboratory rodents lack a protective hair coat and this compromises their ability to thermoregulate at lower environmental temperatures and also makes them more susceptible to cuts and abrasions from rough surfaces within their shipping containers. When hairless animals are transported, extra care must be taken to select a container that does not have exposed or rough edges that could injure unprotected skin. In addition, when hairless animals are shipped during periods of cold weather, the provision of extra bedding and nesting materials will help to provide insulation within the shipping container during transport. In some instances, when hairless animals are produced as a result of breeding homozygous and heterozygous animals for the desired genotype, haired cage mates of the same microbiological status are also produced. Inclusion of some of these haired colony animals can also be used to provide additional thermal protection, as they huddle with the hairless animals.

Some laboratory animals can have metabolic or physiological conditions that may predispose them to challenges during transport. Diabetic animals, for example, require greater water intake than non-diabetic animals in order to maintain homeostasis. They also produce, as a result, large volumes of urine, which can result in unacceptably wet bedding in the transport container. In order to provide an appropriate environment, more bedding material or the addition of absorbent pads may be required. Consideration should also be given to decreasing the number of animals per container to help address this problem.

## Health

As previously discussed, health is an important concern in the transport of laboratory animals. In general, we can place infections into three groups as they relate to transportation: (1) infections that pose a risk to domestic animals or humans; (2) infections that pose a risk to the transported animals themselves; and (3) infections that may produce no clinical disease but make the animals unsuitable for some types of research. The health certifications for transport of animals, required to allow them to move in commerce and between countries, usually focus on infections that have human or agricultural/domestic animal significance. A health certificate issued by a competent veterinary authority prior to a journey or by virtue of customs inspection directed at assessing health during the journey, is the principle safeguard for assuring that the clinical health of the animal(s) is appropriate for them to make or continue a journey.

Infections that may not be harmful to the carrier animals, and which may not be regulated in transport may, neverthe-

less, make the animal unsuitable for its intended research purposes. The risk that animals can carry such infections, either as a result of infection at the source colony or during transportation, is a potential reason to hold newly received animals in quarantine housing until their health status can be verified.

Institutions transporting animals often provide health screening information for the source colony. While commercial suppliers of laboratory animals often perform extensive and frequent health screening of closed colonies, the health screening of animals may vary considerably between research institutions. A thorough description of the health monitoring programme for the colony should be sought in order to determine what, if any, additional testing should be done upon the receipt of the animals by the consignee. Verifying health status on arrival is recommended as a reasonable precaution when receiving animals from unfamiliar sources.

IATA has defined two health status categories for laboratory animals. They are (1) Conventional, and (2) Specific Pathogen Free (SPF) (International Air Transport Association 2008a). IATA defines Conventional animals as *'those for which the presence or absence of specific micro-organisms and parasites is unknown due to the absence of testing, treatment or vaccination. ... Usually, no physical precautions, such as specialised housing, are undertaken prior to or during shipment to prevent introduction of infection.'* IATA defines Specific Pathogen Free animals as *'being free of one or more parasites or infectious micro-organisms'* (IATA 2008a). They further classify SPF animals into two subcategories: (1) Conditioned SPF, and (2) Barrier-raised SPF. Conditioned SPF animals are defined as *'those that have undergone testing, treatment and/or vaccination to ensure the absence of one or more parasites or microbial agents. Conditioned SPF animals are often not maintained in specialised housing to prevent introduction of infectious agents, and are usually shipped in unfiltered containers'* (IATA 2008a). IATA cites as examples, non-human primates, dogs and cats as conditioned SPF animals (IATA 2008a). Barrier-raised SPF animals are *'animals that have been raised in the absence of one or more parasites or microbial agents in specialised facilities to exclude these agents as well as agents of agricultural and human significance. Their microbial status has been established either by testing each individual animal or by sampling representative animals from the colony. Filtered SPF shipping containers are required for transport of these animals, as are special procedures and equipment for packing, unpacking and handing them'* (IATA 2008a).

During transport, animals of differing health status and of different species might be shipped together in the same cargo area of the aircraft (Figures 13.1 and 13.2). Similarly, depending upon whether dedicated ground transportation or a common carrier is used, animals from more than one source, and hence potentially of different health statuses, could be shipped in the same vehicle. Commercial suppliers of SPF animals generally produce and ship only barrier-raised SPF animals (although the pathogens from which they are free can vary considerably between suppliers). Since the cargo compartment, whether it is in a ground transport vehicle or an aircraft, is one microbiological space, it is up to the shipping institution ('consignor/shipper') to select an appropriate container to maintain the microbio-

**Figure 13.1** Example of multiple species being held together in a ramp cart in the same airport staging area prior to loading on an aircraft.

**Figure 13.2** Containers of mice and rats being loaded into the climate-controlled hold of an aeroplane that contains other perishable goods.

logical status of the animals that are being shipped. No assumption should be made regarding the microbiological status of the outside of the shipping container when received at the consignee's institution: containers may have been exposed to unwanted micro-organisms during transit. In the case of SPF animals, surface disinfection of the container before unpacking is an important precaution to take in preventing unwanted introduction of contaminants. Aqueous halogen-based disinfectants are very useful for this purpose.

Laboratory animals, which have been infected with agents that pose a threat to humans, animals of agricultural importance, or other domestic animals or wildlife, always provide a challenge for the shipper. An infectious substance is defined as any substance which is known or can be reasonably expected to contain pathogens which can cause disease in humans or animals.

Infectious substances can be divided into two categories: Category A – an infectious substance transported in a form that, if exposure to it occurs, is capable of causing permanent disability, life-threatening or fatal disease in otherwise healthy humans or animals; and Category B – an infectious substance that does not meet the criteria of Category A. The

International Civil Aviation Organization (ICAO) Technical Instructions for the Transport of Dangerous Goods (ICAO 2007–2008) and the IATA's Dangerous Goods Regulations (IATA 2008b) provide additional detail on the transportation of these substances.

Live animals that have been intentionally infected or are suspected to contain an infectious substance must not be transported unless the substance cannot be consigned by any other means. Under such circumstances, infected animals may only be transported under terms and conditions approved by the appropriate national authorities and the carrier.

Genetically modified animals are frequently submitted for transportation. Their transport is regulated under IATA's Dangerous Goods Regulations (IATA 2008b) for genetically modified organisms. IATA defines genetically modified organisms (GMOs) as organisms in which genetic material has been purposely altered through genetic engineering in a way that does not occur naturally. GMOs, including laboratory animals which do not meet the definition of infectious substances as defined previously, but are capable of genetically altering natural populations of animals as a result of

natural reproduction, are not subject to the IATA Dangerous Goods Regulations when authorised for transport or use by the appropriate national authorities of the states of origin transit and destination. Thus, such animals do not have to be packaged and labelled as dangerous goods or meet transport standards that differ from other animals of the same species. However, shipments of such animals could be required by the countries of origin, transit or destination to have authorisation (and perhaps additional labelling) to leave, transit through or enter these countries. It is the responsibility of the consignor (shipper) to ensure that the animals to be transported comply with regulations regarding genetic modification, including local regulations in the countries of origin and destination. In most countries, transport of genetically engineered laboratory animals is allowed. In some parts of the world, misunderstanding of the terms transgenic, genetically modified (GM), engineered or manipulated can cause delays in transportation. Shippers should ensure they have secured in advance the appropriate documentation and authorisation for the movement of their shipments. Animals that are genetically modified, but which do not harbour or express pathogens or toxins are not considered to be 'dangerous goods' by the IATA, and may be shipped provided this is done in compliance with other live animal shipping requirements. However, unforeseen welfare problems associated with their phenotypic expression may arise and this risk can be avoided by transporting GM animals as cryopreserved embryos or cryopreserved gametes. Such options should be considered when planning shipment of GM stock.

### Bedding, food and water

Bedding is commonly provided for laboratory animals in shipping containers. It serves several functions, the most important of which is the absorption of moisture from urine, water released from hydration sources such as water bottles or gelled water, as well as from animal sources such as condensation from insensible water loss on internal container surfaces. Bedding also provides a means to dilute and dry out faeces produced by the animals during transport. In the case of small mammals, bedding provides a source of insulation. Due to positional changes of the container during various stages of the transportation process, as well as due to the disturbances caused by the transportation environment, nest building may not always occur. The efficacy of the bedding material, as insulation and for absorbency, varies with the nature of the bedding material itself.

Sufficient bedding materials must be provided to maintain a dry and sanitary environment during shipping. Care must be taken, however, not to place so much bedding within a shipping container that it occludes ventilation openings. In the case of SPF animals, it may be necessary to provide suitably disinfected bedding that matches their microbiological status.

Recently, concerns have been raised over wood products used for bedding, as well as in shipping container construction and in pallets used to support and secure shipping containers during transit, with respect to their potential to carry plant diseases and agricultural pests across borders.

Additional requirements for the treatment of such materials to eliminate these risks, as well as other measures imposed by countries and carriers, may eventually affect the use of untreated wood products in transportation.

Animals in transit should be provided with access to food and water during the journey. Ideally, the food provided to the animals during shipment should be of the same type and microbiological status as that they were fed at the institution of origin. Barrier-raised SPF small mammals that are shipped in filtered containers in order to preserve their microbiological status must be provided with food and water of a compatible microbiological status. In such instances, since there will be no opportunity during the course of the journey to replenish the food and water without opening the container (and thus potentially altering their microbiological status), sufficient quantities must be placed within the container at the time of packing. Larger animals, such as non-human primates and dogs, are almost always shipped in non-filtered containers, which allow for food and water to be replenished at scheduled stops during shipment. The design of these shipping containers for larger animals usually includes devices built into the container for addition of feed and water during the course of the journey. When large domestic animals undergo ground transportation, regulatory bodies require provision of feed and water, observation of the animals and specified rest periods at prescribed intervals. In the case of air transport of larger laboratory animals, there is usually no access to the cargo hold by personnel for the purposes of feeding and watering during flight and this has to be done following landing.

In their home environments, common laboratory animals are usually fed a dry pelleted or extruded diet. For non-human primates this is often supplemented by fruits and vegetables. Such foods, with high water content, can serve as an additional source of water during shipment. Unfortunately, these can spoil easily and may require some level of preparation prior to being introduced into the container. Opening the shipping container during the journey for purposes of introducing or removing materials carries with it the risk of escape. Food and water containers that are built into the shipping container but accessible from the outside may provide a route for escape or entrapment and great care must be taken when re-feeding or replenishing water supplies during the journey. It is a good practice to provide sufficient food and water not only to allow for the anticipated length of the journey but also for at least an additional 24h of transportation in case of any unforeseen delays.

Presentation of food and water should be done using a method that is appropriate to the past experience of the animals and to the behaviour patterns of the species. Purpose-bred dogs, for example, are accustomed to eating and drinking out of bowls in a lighted environment. Many common laboratory rodents, by contrast, feed principally at night; and despite the use of feeders in a laboratory environment, some rodents such as hamsters and gerbils will remove all feed from the feeder and hoard them in piles. Feeders or feed bowls are unnecessary for rodent transport since these animals forage for feed in the wild and do so quite readily when it is placed in with the bedding material.

Food consumption while in transit will often be less than when the animals are in their home environment. Commonly, this is reflected in weight loss, which will be rapidly regained during the first few days in their new home environment. The use of novel food items during transit may also contribute to reduced intake and weight loss.

Access to drinking water during transit is important to help animals maintain hydration and thermoregulate. Water in liquid form can be provided in refillable water bowls in the case of certain large animals (eg, non-human primates) or through the use of water kits in the case of small animals (eg, rodents). A water kit (Figure 13.3) consists of a sealed flexible pouch of water of the appropriate microbiological quality that is placed in a holder affixed to the wall of the container. Animals access water through a disposable drinking valve that is inserted into the pouch by puncturing the wall of the pouch. When water bowls are used, substantial amounts of water can be spilled out of the bowl either through the course of drinking or by movements of the container or movements of the animal. Similarly, with a water kit much of the water can be spilled if there is leakage around the insertion point of the drinking valve or by animals brushing against the valve thereby releasing water. This can result in the bedding within the container becoming wet. If a water kit is to be used, the animals should be conditioned to the use of a drinking valve as compared to the use of water bottles or other means of providing water in their home environment.

Alternatively, a gelled water source can be provided. Gelled water is a hydrocolloid-stabilised material containing between 70 and 98% water by weight. Various sources of calories in the form of carbohydrates can also be added to the gelled water as well as flavouring and stabilising ingredients to prevent spoilage. Animals have taste preferences and hence the presence or absence of certain nutrients may affect the consumption of gelled water during transit. A number of commercially available sources of this material

**Figure 13.3** A drinking water kit consisting of a plastic holder, a sealable plastic bag for holding the water and a drinking valve for dispensing water (the inset is a close-up view of the disposable drinking valve).

have been shown to be accepted by various species. When a large amount of gelled water is placed in a container in order to provide for extended journeys, it is important to assure that it is suitably affixed within the container as movement of this material within the container during transit could result in injury to small animals.

### Stress during transportation

Transient periods of stress will occur during transportation. This may be reflected in changes in heart rate, respiratory rate, behaviour, food and water consumption, and in changes in the cellular and chemical composition of blood. Changes in one of these parameters are not necessarily diagnostic of stress nor is it practical to routinely assess these parameters during the transportation process. Moreover, there are species differences in what constitutes an environmental stress and the magnitude of its effects as well as the manifestation of those effects. Given these limitations coupled with the limited number of species-specific studies on transportation stress, it is difficult to provide specific and widely applicable recommendations aimed at minimising stress in transport. Obviously, one should prepare carefully so as to avoid extreme situations wherein environmental control is lost.

The length of the journey is an important variable affecting stress in shipment. Avoidance of delays in shipment and transfers by good journey planning is important to minimise the overall level of stress associated with the journey. From an animal welfare point of view, transport distance and time should be kept to a minimum, and an uninterrupted journey is preferable.

Research on domestic farm animals suggests that the process of loading and unloading animals from shipping containers is more stressful than are other components of the journey (Knowles *et al.* 1995; Warriss *et al.* 1995). For this reason, acclimatisation of larger laboratory animals, such as domestic farm animals, to the container as well as to the loading and the unloading process may mitigate some of the stress encountered during the journey. For larger species, their efforts in counteracting the movements of the transport vehicle whilst in motion (Warriss *et al.* 1995) may cause additional stress. This may be less of a concern for smaller species that do not have to balance a large body mass at a substantial height above the floor. It is possible that species with more advanced cognitive abilities, such as non-human primates, may be more aware of their change in circumstances and be more predisposed to fear during transport, resulting in additional stress. Changes in presumptive measures of stress should be interpreted in context. For example, simply moving mice from one room or floor of a building to another can alter plasma cortisol levels (Tuli *et al.* 1995). Sheep undergoing a 24h journey showed increases in heart rate, plasma cortisol and glucose during loading and the initial stages of the journey but after 9h of travel, these had returned to normal levels (Knowles *et al.* 1995).

Experience has shown that there is considerable risk in sedating laboratory animals prior to transport in order to counteract stress and destructive behaviours. Tranquillisers and other psychoactive drugs can reduce the ability of

animals to respond to stresses during transport, affect their ability to thermoregulate and have unpredictable cardiovascular effects. In addition, the reaction of various species to these drugs cannot always be foreseen. For these reasons, the routine use of psychoactive medication is not recommended.

In order to enable animals to recover adequately from stress experienced during transport, it is very important that they are given a recovery period at their final destination prior to use in a research programme. This period of acclimatisation allows for recovery from the effects of stress during shipment and also allows the animals to adapt to changes in housing and husbandry. In the case of group-housed animals whose groups have changed prior to shipment or which have a disrupted social structure, this period of acclimatisation permits the re-establishment of social order and resumption of natural behaviours. During this period, some presumptive measures of stress such as changes in electrolyte concentrations, haematological parameters, blood corticosteroid levels and a variety of physiological parameters can return to normal levels. Transportation-induced changes in the immune system may take longer to recover than fluid balance, electrolytes, plasma cortisol or glucose (Wallace 1976). The longer and more stressful the journey, the longer it may take for this stabilisation to occur.

During transport, animals can lose varying amounts of body weight, often of the order of 10% or sometimes even a little more. Most of this loss occurs early in the transport process, much of which is attributable to the voiding of faeces and urine as well as decreased food and water intake. Most, if not all, of this weight is recovered within a few days upon return to a more stable environment in the acclimatisation period post shipping. Grooming and exploratory behaviour in rats and mice are restored early in the acclimatisation period as are plasma cortisol concentrations, which may have been elevated upon receipt (Landi 1982); full acclimatisation may require up to 4 days (Tuli *et al.* 1995). There are species as well as strain and stock variations in the time required to fully acclimate. Various components of immune function may take longer to recover to pre-transport capability, as may certain other metabolic functions (Damon *et al.* 1986; Bean-Kundsen & Wagner 1987; Olubadeno *et al.* 1994).

## Laws, regulations and standards

The current European regulations on animal welfare in transport (European Council 2004) came into force on 5 January 2007. While EU regulation is directly applicable, some national legislation is needed to provide for enforcement and penalty provisions, derogations from the rules and to levy the charges for authorisations. In the UK, this is done through separate enforcement legislation in England, Scotland, Wales and Northern Ireland. For example, the legislation which implemented the previous Directives in Northern Ireland (the Welfare of Animals (Transport) Order (Northern Ireland) 1997 (WATO)) has been replaced by The Welfare of Animals (Transport) Regulations (Northern Ireland) 2006, as amended by the Welfare of Animals (Transport) (Amendment) Regulations (Northern Ireland)

2007. Some useful guidance on the EU regulation has been published on the web. For example, see the DARDNI (Department of Agriculture and Rural Development Northern Ireland) website<sup>1</sup>.

The current EU regulation aims to improve animal welfare through raising transportation standards. In particular, it provides significant improvements in enforcement capability for all species transported. The EU regulation covers the transport within the EU Community, in connection with an economic activity, of all live vertebrate animals (excluding man). The regulation does not apply to the transport of non-vertebrates such as insects, worms, crustaceans (eg, crab, lobster), cephalopods (eg, octopus, squid) and molluscs (eg, shellfish, snails). However, general welfare in transport provisions protecting non-vertebrates from injury or unnecessary suffering are contained in regulations for devolved administrations in the UK.

The Convention on International Trade in Endangered Species of wild flora and fauna (CITES) and the World Health Organization through OIE (World Organization for Animal Health) have agreed that the IATA Live Animals Regulations (LAR) be employed as guidelines for the air transportation of animals. The LAR set standards concerning the transport of animals by air which include advice on general care and loading, the design and construction of containers together with appropriate packing, feeding and watering arrangements (IATA 2008a). The LAR have been adopted by the European Union as minimum standards for transporting animals, and, globally, most airlines and countries will only accept animals packed and transported according to the LAR standards. The Animal Air Transportation Association *Manual for the Transportation of Live Animals*<sup>2</sup> also contains useful information, especially concerning European legal requirements for transport of large animals (Animal Transportation Association 2000). Other useful guidance is available; see for example the publications by Elmore (2008) and Institute for Laboratory Animal Research (2006).

## Transport containers

The specifications of animal transport containers (also termed shipping containers) can vary substantially depending upon the source (ie, commercial or locally constructed) and the local, national, or international guidance upon which their design is based. The most detailed specifications for shipping containers are found in the LAR published annually by IATA. This guidance is organised by species and container type. Given its international acceptance, this guidance forms the basis for the minimum standards for container design. These may need to be modified to meet the requirements of some countries of origin and, if applicable, the countries of transit and destination. For some species such as non-human primates, dogs and cats, and farm animals (as mentioned above), it may be necessary to acclimatise them to the shipping containers prior to loading.

<sup>2</sup><http://www.aata-animaltransport.org>

## Container design and construction

The most common design of animal transport container is in the form of a rectangular box, the dimensions and shape of which are largely dictated by the species for which it is intended. Various types of containers have been developed commercially for transporting laboratory animals, some of which are illustrated in this text.

Adequate ventilation is essential and the shipping container should be designed so that it can incorporate filtered or non-filtered ventilation apertures according to the microbiological status of the animals. The container and air vents should be designed so that vents cannot be occluded, even when stacked (Figure 13.4). Many containers have additional built-in features such as spacers or stand-offs to aid in ventilation (Figure 13.5). Air vents should be sited on at least two opposite sides of the container. The combined area of the ventilation apertures should be determined according to the species, dimensions of the container, intended stocking density, whether filter material covers the ventilation apertures and the range of ambient conditions expected to prevail during transport. Ventilation apertures should be covered with wire mesh of such a gauge that no part of the animal can protrude, and be designed such that the animal cannot damage the mesh with its teeth or feet.

While non-filtered transport containers are available for rodents and rabbits (Figure 13.6), animals with restricted microbial status destined for research use should be transported under SPF conditions using microbiologically secure containers (Figures 13.5, 13.7 and 13.8) to protect them from infectious agents. SPF transport containers have ventilation apertures that are covered with some form of filter material of a pore size and filtration efficiency selected according to the degree of filtration and airflow required. Since most infectious agents are carried on particulates of larger diameter than the mean pore diameter of standard filters and since air velocity across the filters is low, small pore-size filters are not usually required. It is important to remember that filter material can decrease the ventilation rate within a container by 70% or more depending on thickness and pore size. Other factors such as stocking density within the container should be adjusted accordingly to compensate for decreased ventilation imposed by the addition of filters.

Filtered containers require a viewing port (viewing window) to allow assessment of animals whilst in transit (Figure 13.9). This is particularly important for journeys that cross national borders where some form of official inspection may be required.

A variety of materials is available for container construction. For rodents and rabbits, the most commonly used

**Figure 13.4** The back of a partially loaded, climate-controlled truck containing rodent shipping containers with integral ventilation stand-offs. The air channels between the containers allow circulation of air across the filtered openings.

**Figure 13.5** Diagram of a cardboard shipping container used for transport of mice and rats. The principle features of this design of container are noted on the illustration.

**Figure 13.6** Unfiltered rodent shipping containers.

**Plastic Shipping Container**

**Figure 13.7** A drawing of a plastic shipping container used for transporting rodents. Ventilation openings (four) are visible along the side with similar ventilation openings located on the lid of the container. Plastic stand-offs are located on the top and a continuous stand-off runs around the top of the base of the container providing a channel for ventilation along the sides of the container.

materials are plastic or varying strengths of corrugated cardboard or corrugated polypropylene. Each container may be partitioned into separate compartments, or two or more separate, primary containers may be placed into an overshipper for transport (Figure 13.8). Corrugated cardboard and corrugated polypropylene are relatively cheap and easy to dispose of, or recycle, and therefore are commonly used in non-reusable containers. For transporting larger species, materials used to construct containers include wood, plastic, metal or fibreglass. Such containers when made of plastic can be injection or vacuum moulded or, in the case of wood or metal, constructed with a strong framework and joints sheathed with solid panels with reinforced ventilation openings (Figure 13.10). Care must be taken to avoid using materials which adversely affect the health or welfare of the animal(s) to be transported, such as wood that has been treated with preservatives.

The container should be durable, non-toxic and able to withstand stacking without causing damage or crushing. Wooden containers should be constructed so that the animal cannot bore, claw or bite them open at the seams or joints. Nails, bolts, staples, sharp edges or other protrusions, on which animals could injure themselves, should be avoided; all slats and uprights should have rounded edges and be installed so that the animals cannot entrap their extremities.

The interior surface of the container must be of solid construction and can be protected to some extent from the effects of damp seepage due to urine by coating the inner surface with plastic or wax. For rodents that chew and gnaw, a wire mesh lining may be applied over all internal surfaces, including the floor and filtered ventilation openings, of disposable cardboard shipping containers to prevent escape. The wire should be applied so that the animals do not have access to loose or sharp edges. Some animals such as hamsters that aggressively dig and chew at surfaces must be shipped in containers with a double layer of wire lining covering all internal surfaces to prevent escape. Moulded plastic containers that provide a rugged smooth surface constructed such that corners and ventilation openings are not within the animals bite radius, do not require a wire lining

**Figure 13.8** Two plastic filtered shipping containers are placed within a cardboard overshipper with filtered openings. The overshipper contains two viewing windows as well as rigid foam stand-offs to allow for unobstructed ventilation.

**Figure 13.9** A disposable cardboard shipping container with a viewing window that can be accessed by peeling back an instruction label and lifting up a cut-out in the cardboard. The viewing window is constructed of Mylar™.

**Figure 13.10** Wooden non-human primate shipping containers being loaded into a climate-controlled truck. The containers are designed to hold up to three non-human primates each with separate ventilation openings.

when used with certain species. These are designed for specific species and may not work for others. Similarly, the lids of some shipping containers can be lined with a thick sheet of Mylar that, by its smooth surface design, does not fall within the animal's bite radius.

(a)

(b)

**Figure 13.11** Top is a 10× magnification of a spun-bound polyester filter typically used to cover ventilation openings in shipping containers used for certain SPF laboratory animals. Note the varying pore size openings. Bottom is the same filter material after being used to ship animals and subsequently autoclaved. Note that the remaining pores are very small in diameter. The use of moist heat has caramelised food particles and adhering dust has occluded most of the pores in the material. Effective ventilation is substantially reduced.

The lid or door of the container must fit the container securely to prevent accidental opening. Containers should have adequate hand holds or other lifting devices to enable them to be lifted without undue tilting or bringing the handlers in close contact with the animals.

If containers are to be used on more than one journey, it must be possible to adequately clean and sterilise them. Although some shipping containers for laboratory rodents may be sanitisable, the integrity of cardboard and plastic containers may change after autoclaving, irradiation or chemical disinfection. The protective board is destroyed by heat sterilisation within an autoclave. After transport, the pores of the air filters covering the vents may be obstructed by debris such as food dust, bedding, animal fur and dander, or be compromised due to autoclaving, thereby reducing airflow into the container (Figure 13.11). Therefore, whenever possible, use new shipping crates which are commonly available through commercial sources to ensure safe animal transport and biosecurity.

### Transport container stocking density

Animals should have adequate space to provide for normal postures and postural adjustments within a transport con-

tainer, including the ability to stand quadrupedally, stretch, turn around and lie down. Recommendations for transport container height and stocking density are based on species and body weight, as well as ambient temperature control and overall heat output of animals within in a given area with ventilation apertures. The calculation of animal heat output is based in part on the work by Kleiber (1975) and Besch and Woods (1977), which is outlined by Swallow (1999). The results of these and other engineering studies, modified by experience using various stocking densities, have formed the basis for the current recommendations. Stocking density guidelines for shipping laboratory animals in filtered containers to maintain their SPF status as well shipment using non-filtered containers are found in the LAR.

Compatible animals are best transported in a socially harmonious group within the same shipping container or container compartment. Species should never be mixed within the same transport container. Rodents shipped within a container should come from the same colony, be of similar age, of the same sex as appropriate, and when possible be from the same weaning or social group. Similarly, when it is necessary to transport breeding adults and their offspring, they should travel in the same container, if possible. The maximum number of animals per compartment should be reduced when the ambient temperature at ground level exceeds 24°C. Rabbits are usually transported singly or in divided boxes with or without filtered air vents.

In the UK and continental Europe, dogs may travel in a loose housing system in small single-sex groups using the cargo area of a suitably equipped ground vehicle. However, this arrangement is forbidden in certain other countries when transporting dogs by air and by ground. In these cases, each dog must have its own container, except when specifically permitted by the competent authority. These containers can be used to transport two compatible animals of comparable size (up to 14kg each) or up to three animals not exceeding 6 months of age, from the same litter. To ensure compliance with current regulations, it is important

to verify exceptions with the local competent authority (European Council 2004).

Same-sex adult macaques that have been maintained in an established compatible cohort should travel as pairs. Juveniles should be transported in pre-established single-sex pairs. Animals under 3kg can be shipped using three-compartment containers (Figure 13.10), while those over 3kg should be shipped in two-compartment containers. If co-housing is not feasible, then the animals should be shipped either in the company of compatible conspecifics in partitioned containers, or in separate containers loaded adjacent to each other. Pregnant females and females with suckling young are generally not accepted for air transport.

### Labelling and marking

Each shipping container should be marked durably and legibly on the outside with the following information:

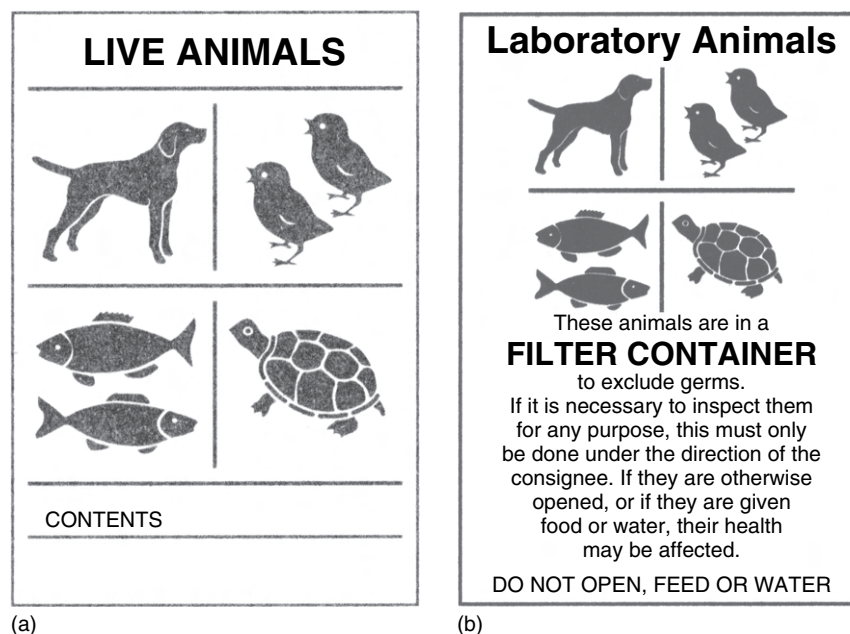

- Marked 'LIVE ANIMALS' or 'LABORATORY ANIMALS' for filtered containers containing SPF animals (Figures 13.12 and 13.13).
- Marked 'THIS WAY UP', including orientation arrows.
- Specifications of the animals within the container and ID, if applicable (usually found on the shipping label).
- The full name, address and 24h contact information for consigner and consignee.
- Any special feeding and watering instructions.

### Journey planning

#### Mode of transport

Laboratory animals can be transported either by ground or by air. In some instances, short water-borne voyages are also required (usually in a vessel designed to carry vehicles), for example when transporting animals from the UK to conti-

**Figure 13.12** Illustrations of IATA-approved shipping labels. The 'LIVE ANIMALS' label is used when shipping any live animal or the 'LABORATORY ANIMALS' label can be used instead when shipping SPF laboratory animals.

**Figure 13.13** Wooden non-human primate shipping containers with directional arrow labelling, live animals labelling and transportation documents attached to the outside of the container. Other labelling imprinted on the container is used to advise personnel that only authorised individuals should handle these containers.

mental Europe. The majority of laboratory animals required for research travel relatively short distances by road. Many laboratories make use of the services of specialised laboratory transport companies. Such transporters (including some commercial laboratory breeders) operate their own fleets of environmentally controlled vehicles in accordance with national and European laws. These animal transporters can also be a helpful source of information on the ground transportation process and on the required documentation and other shipping requirements.

### Ground transport

Purpose-bred laboratory animals such as rodents and rabbits must be transported in an environmentally controlled vehicle that can be easily sanitised and which provides ventilation rates and can maintain temperature parameters as set forth in EU regulations (eg, 1/2005/EC which requires that temperature within the cargo area be monitored and recorded throughout the journey). Among the new safeguards for ground transportation of animals that were introduced in the EU by regulation 1/2005/EC were higher standards for vehicles and equipment, and stricter requirements for those dealing with animals 'in transit' including training and certification. This regulation also provides measures to ensure better enforcement of EU rules for transport. Article 3 and Article 27 of this regulation detail general conditions for the transport of animals, as well as require-

ments for inspections and for annual reports by the competent national authority. Authorisation is generally required for journeys but transporters undertaking journeys of less than 65km from place of departure to place of destination do not require authorisation nor are they required to use drivers/attendants who have been trained and who hold a certificate of competency (Article 6.7). A journey log or appropriate satellite navigation record must be kept for each journey.

Regulation 1/2005/EU requires that all transported animals must be fit for travel. This applies to the transport of all laboratory animals including those undergoing regulated procedures under the authority of the Animals (Scientific Procedures) Act (A(SP)A 1986). Exceptions may be authorised under A(SP)A where there might be a compelling scientific need to move ill or injured animals. However, in such cases an appropriately certified veterinarian is required to confirm that such animals are fit for the intended journey. There are additional specific requirements regarding feeding and watering intervals and certain general loading requirements for cats, dogs, poultry, domestic birds and rabbits.

The journey log required by European regulation is the official record of the ground transportation journey. It includes sections on planning, place of departure, place of destination, a declaration by the transporter and an anomaly report. As envisioned, it would serve as a mechanism for approval by the competent authority of the journey prior to the journey beginning and would contain specifics of the actual journey as it occurred. This record would remain within the EU and be available for inspection for a period of 3 years.

### Air transport

The air transport process also has a ground transportation component which must meet applicable ground transport regulations. Air transport begins when the animal shipment arrives at the air cargo facility and is accepted by the carrier. Where international shipments are made outside the European Union, a customs broker or freight forwarder will need to be engaged to assist in the export process. The air waybill is the official acceptance document used by the carrier for air transport wherein liability is accepted by the carrier. This liability is limited by international convention and should be supplemented by additional coverage if the animals are very valuable. The waybill is also the document that the shipper uses to describe the contents of the shipment. Since the carrier and its personnel are not experts in animal biology and care or in taxonomy, they depend upon the shipper to provide the necessary information on the waybill to indicate the required conditions for carriage. It is the duty of the shipper to provide adequate amounts of food, bedding and water to sustain the animals during travel. The shipper must also supply the appropriate documents for export, carriage and import to satisfy existing laws and regulations in the countries of export and import.

Animals are classified as perishable cargo and are provided a climate-controlled environment in the aircraft. The consignor should provide the carrier with any specific envi-

ronmental requirements for the animals being shipped. If there are no specific requirements given, general guidance for the species as found in the IATA's Live Animals Regulations will be used. If very tight temperature or other environmental restrictions are required the shipment may not be able to be accommodated. Air cargo personnel are provided training in handling animal containers as well as basic information on animals in transport. Typically, carrier personnel use a checklist to ensure that all the appropriate steps and paperwork have been completed. They are not responsible, however, for making judgments on whether documentation has been completed correctly.

Once the appropriate paperwork is completed, the shipment will be moved to a section of the cargo facility where it can be held in a well ventilated and quiet area. Not all airports, however, have dedicated areas for this purpose. Hence, animals may share space with other perishable cargo, live animals or personnel.

After holding in the cargo facility (typically 4–6h in advance of flight departure), the shipment will be transported to the flight line for loading on to the aircraft. Typically, animals are loaded on to the aircraft last, for a first-off unloading at the final destination. Once on the aircraft, the animals are kept in a darkened environment. Even though space has been reserved for animal shipments, circumstances can arise resulting in their being kept off a particular flight for a variety of reasons including incompatibility with other priority cargo (eg, mail, human remains) and temperature embargos.

Upon arrival, the unloading process is a mirror image of the loading process. Arrangements should be made by the consignee (person receiving the shipment at the final destination), either directly or preferably through the use of a broker or customs agent, for pick up once the animals have cleared customs. The vehicle used for this should be capable of providing a conditioned environment.

Due to the complexity of air transportation and the potential for intermediate stops and delays in flight schedules, it is important that contingency plans be made during the journey planning process. The carrier should be made aware of special requirements of the animals and should be given contact information for both the shipper and the consignee, in case of unforeseen delays or adverse events.

## Documentation

Depending on the animals to be transported, their health status, the mode of transportation and the final destination of the animals, a number of documents need to be prepared and authorised and should accompany the shipment. Some certifications are time sensitive and must be submitted as originals, not copies. It is a good idea to keep copies of all documents required for shipment in case of loss during shipment – an event that could strand animals at boarder crossings or airports. A list of documents for transport of animals within Europe is provided by the EU<sup>3</sup>.

One of the documents necessary for the shipment of laboratory animals is the Export Health Certificate (EHC). This is needed for the shipment of animals between countries. Guidance in relation to this requirement is generally given by the competent authority (eg, in the UK, this is The Department for Environment, Food and Rural Affairs (DEFRA)). An EHC is an official veterinary document used to confirm that a consignment of animals or animal products meets certain health criteria. Shippers wanting to export live animals, animal products or germ plasm to an EU member state will need the health certificate signed by a government-approved 'official veterinarian'. Further information on EHCs can be obtained by contacting DEFRA in the UK or similar competent authorities in exporting or receiving countries.

Other documents that may be required include: import licences issued by the state veterinary service; CITES permits where necessary; invoices for custom purposes; fitness to travel documents, including records of certain laboratory tests, vaccinations or treatments; quarantine labels, if applicable; transfer authorisations from specific bodies that regulate the use of laboratory animals; an animal transport certificate or group plan; and, in the case of ground transportation, vehicle registration details and insurance.

Information specific to the animals being transported, including species, strain, scientific name, number, sex, age, weight, individual identification and any special care requirements related to phenotype should accompany each shipment. Some of this information is required on other documents, but placing it in one location can prove helpful. In addition, the name, address, and 24h telephone contact numbers for the consignor (person with ultimate responsibility for the shipment), intermediaries, consignee and the shipper's attending veterinarian can also be helpful in case of difficulties during shipment.

All the required documents should be collated and attached to the first container of each consignment. It is advisable to make sure that the necessary documents have been aligned with the United Nations (UN) layout key for trade documents. These are internationally agreed standards that are easily translated because common information appears in standard positions on all forms. Many countries have trade facilitation organisations, for example, SITPRO<sup>4</sup> in the UK, that can provide advice on UN aligned documents.

Correct and complete documentation is essential to avoid delays in transit. Animal shipments are often delayed in customs due to failure to provide correct documents containing the appropriate wording, signatures and authorisations. Accompanying documents can be lost in transit, highlighting the need to keep copies of all necessary documents. There is currently an air freight industry initiative to make many documents electronic so that they can be sent in advance of shipment to the competent authorities at the point of entry (POE). Basic documentation requirements for international shipment for various countries can be found in The Air Cargo Tariff (TACT) Manuals (IATA 2008c) and the LAR (IATA 2008a), both published by IATA. If a customs

<sup>3</sup><http://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=OJ:L:2005:003:0001:0044:EN:PDF>

<sup>4</sup><http://www.sitpro.org.uk>

broker is employed to facilitate the shipment, they can also provide guidance on the required documents. Individual country embassies are also a source of information. It is also helpful to have the consignee at the destination assist in determining what documentation is required and for an electronic copy of all shipment documents to be sent in advance of the shipment to the consignee.

### Points of entry

Most countries have a limited number of designated locations (border inspection posts (BIPs)) where animals can enter the country. For example, the EU and the US, operate a system of BIPs or points of entry (POE) which are approved for the importation of different species such as farm live-stock, equidae, rabies-susceptible animals, birds, fish, or any combination of the above, including laboratory animals. Animal consignments may be inspected by officials upon arrival. Authorities often require advance notification of the import or export of live animals (especially in the case of larger animals) so that the appropriate inspection personnel can be available. Recipients of animals should note that such inspections take time and journey plans should allow for delays at BIPs.

Both consignor and consignee should agree in advance of any shipment the conditions of transportation, including the departure and arrival times so that, at their destination, the animals can be placed in previously prepared cages, fed, watered and rested as quickly as possible. On arrival, animals should be removed from their transport container and examined by a responsible person with the least possible delay.

### Journey time

Most laboratory animals travel within containers with food, water and bedding sufficient in quantity for the journey. Under these conditions, there is not usually a maximum permitted journey time. However for some animals, particularly larger species, there can be specific restrictions regarding journey time and rest stops (European Council 2004). Given the broad definition of animal in this regulation, guidance might be included in future revisions to cover more traditional laboratory species.

# 14 Nutrition, feeding and animal welfare

Bart Savenije, Jan Strubbe and Merel Ritskes-Hoitinga

## Introduction

It is essential for the welfare of animals that adequate food, containing essential nutrients, is provided and ingested (National Research Council (NRC) 1995; Beynen & Coates 2001; Ritskes-Hoitinga 2004). Physical and mental processes are dependent on and influenced both by what is ingested, and when and how food is eaten (Ritskes-Hoitinga & Chwalibog 2003). Food ingestion is essential for homeostasis, a regulated state of internal balance (Strubbe 2003; Ritskes-Hoitinga & Strubbe 2004), although it always leads to some homeostatic disturbance, for example through the thermogenic effect. As many bodily functions naturally show biological rhythms, fluctuations due to food intake may result in good animal welfare, as long as the animal is able to return to the homeostatic state. Introducing species-specific fluctuations into the laboratory feeding process may, therefore, contribute positively to the welfare of laboratory animals.

This chapter provides some key concepts in nutrition, with the aim of helping animal care staff to prevent the occurrence of nutrition-based pathological and behavioural disorders in animals in their care. Using and implementing this basic knowledge will not only support good animal health and welfare, but will also contribute to standardisation and replicability of experiments. In the second part of the chapter, aspects related to feeding, rhythmicity and environmental factors and procedures are discussed. A range of examples is provided to illustrate how nutrition and feeding can influence animal welfare and experimental results. The authors suggest that better animal welfare can be achieved when nutrition is better adapted to the species-specific adaptive capabilities for returning to homeostasis (Ritskes-Hoitinga & Strubbe 2004). Thus, refining the feeding process by providing correct nutrition, together with appropriate foraging and feeding opportunities, should contribute to the animals' welfare as well as improve the quality of the science by reducing variation resulting from stress.

## Proper study design

### Minimum nutrient requirements

Animals' needs for macronutrients (lipid, carbohydrates, proteins) and the micronutrients (minerals, vitamins, trace

elements) and water differ between species. For example, vitamin C is an essential nutrient for guinea pigs and primates, whereas rats and mice do not need to ingest it. For each animal species extensive scientific documentation on (essential) nutrient requirements has been assembled in the documents of the NRC (1977–2003). Estimated nutrient requirements for each species and stage of life are presented by the NRC (1977–2003). These recommendations are usually higher than the minimum requirements, as they are often based on the intention of obtaining maximum growth. Maximum growth is, however, probably not optimal for the health of laboratory animals. For example, *ad libitum* feeding can result in kidney degeneration in rodents, whereas food restriction prevents kidney degeneration completely (Hart *et al.* 1995). As these guidelines are currently the best available and are based on scientific evidence, it is advisable to use them until new scientific evidence comes available. However, it is important to be aware that there can be strain differences in nutritional requirements, and that this may also apply to genetically modified strains (Ritskes-Hoitinga 2004). For example, in phosphatidylethanolamine N-methyltransferase (PEMT) knockout mice, the *de novo* synthesis of choline is disrupted, so the NRC's minimum dietary choline recommendation for mice is likely to be insufficient for this strain (Zhu *et al.* 2003). In such cases it is necessary to establish the nutritional requirements of the strain, in order to provide a special diet fulfilling those particular needs.

It is also essential to provide for animals' differing needs during their various life stages (ie, growth, maintenance, reproduction, lactation or work). Failure to do this can lead to incorrect interpretation of experimental results as in the report that genetically modified potatoes could compromise the immune system of young rats (Ewen & Pusztai 1999). In this study, the diet only provided 6% protein; it was later concluded that the results were invalid, as young growing rats need 15% dietary protein (Horton 1999).

### Manufacture of diet, chow versus purified diets, pellet hardness

Chow diets are the standard diets in most laboratory animal facilities, and are usually produced from natural ingredients. Manufacturers provide a whole range of diets adapted to particular animal species and their stage of life. Because

natural ingredients differ, the commercially available chow diets not only vary in composition between various companies, but can vary also between batches from the same company (Ritskes-Hoitinga & Chwalibog 2003; Ritskes-Hoitinga 2004).

Where natural-ingredient chows are used, it is advisable to obtain a batch analysis certificate with each batch used, to provide exact information on nutrient and contaminant levels. If a batch analysis certificate is not available, researchers will not be able to reject batches that may interfere with the results of their study (Nygaard Jensen & Ritskes-Hoitinga 2007). Moreover, unexpected outcomes where dietary composition may have been the cause would not be able to be explained. Some dietary chows are produced that are intended for use in several species, eg, rat, mouse and hamster. In these cases one has to be aware that individuals could ingest toxic levels of certain nutrients if they eat more than the intended amount of food where the concentration of the nutrient has been determined at the highest minimum concentration needed for one of the species, eg, iron in a diet for rat, mouse and hamster (Beynen & Coates 2001).

Purified or semi-purified diets are formulated with a combination of natural ingredients, pure nutrients and ingredients of varying degrees of refinement, resulting in far more standardised compositions than natural-ingredient diets. For rodents the American Institute of Nutrition, AIN-93 diet (Reeves *et al.* 1993) is recommended, as the composition is such that (with slight modifications) it fulfils nutrient requirements (NRC 1995; Ritskes-Hoitinga 2004). Often, with these diets the composition is such that pelleting is not possible so that alternative types of presentation become necessary (Ritskes-Hoitinga & Chwalibog 2003). Because purified diets are constituted with a better control of dietary composition, more reliable and reproducible results are obtained (compare Ritskes-Hoitinga *et al.* 1989 and 1991). From the point of view of good science, purified diets ought to be used much more frequently than is currently the case. However, depending on composition, there can be problems with palatability and variation in intake: the choice of diets has to be made on a case-by-case basis. Pilot studies are advisable where the effect of the dietary composition is unknown and uncertain.

The hardness of pellets and blocks is measured as the amount of pressure that is required for crushing a pellet. If pellets are too hard (over 20 kp/cm<sup>3</sup>), the growth of pre-weaned mice is reduced significantly (Koopman *et al.* 1989). This is partly because the young mice have to work hard to eat the pellets, and partly because the lactating females are not able to eat enough to satisfy the needs of both themselves and their young (Koopman *et al.* 1989).

About 30% of genetically modified mice have been reported to show signs of weakness and to have reproduction difficulties (FELASA Working Group *et al.* 2007), and this has led to the marketing of special high-fat diets for breeding transgenic mice. The eating problems may be the result of a 'general weakness' of genetically modified strains, but dental problems, muscular weakness, neurodegenerative disorders etc, could all contribute to a reduced food intake. The higher-fat diets marketed for these animals are not as hard, so mice do not need to work as much and can ingest food more easily. The disadvantage of a higher fat

content is an increased risk that the mice will develop atherosclerosis. In addition to the various kinds of pelleted diets, manufacturers also produce so-called extruded diets, which have a softer composition and which provide greater availability of nutrients. The reader should consult the manufacturers for detailed information.

## Contaminants and trace elements

Contaminants are defined as undesirable substances (usually foreign) which, when present at sufficiently high concentration in the food, can affect the animal and therefore the outcome of experiments (British Association of Research Quality Assurance (BARQA) 1992). Maximum permitted levels of dietary contaminants have been published by the United States' EPA (Environmental Protection Agency 1979); BARQA (1992); GV-Solas (2002). For certain contaminants like selenium, an essential trace element with a narrow safety margin, information on maximum safe levels is provided by the NRC (1995). A table comparing the maximum contaminant levels specified in the three guidelines listed above can be found in Ritskes-Hoitinga (2004). Which guidelines are followed will depend on the goal of the scientific procedure and on the necessity to protect welfare (Ritskes-Hoitinga 2004; Ritskes-Hoitinga & Strubbe 2004). The researcher should decide and choose maximum contaminant levels permissible in order to avoid compromising the results. When working under Good Laboratory Practice (GLP) guidelines the maximum levels must always be defined before the start of the study.

## Avoiding toxic nutrient levels: quality assurance, diet and experimental outcomes

### Quality control

Manufacturers design diets to contain (much) more than the required minimum nutrient densities. This helps to prevent nutrient deficiencies, even taking into account periods of storage during which some nutrients (eg, some vitamins) may be lost. Moreover, variation in nutrient concentrations in so-called standard chows can be quite considerable, due to the use of natural ingredients that vary in composition (Beynen & Coates 2001; Nygaard Jensen & Ritskes-Hoitinga 2007). This variation can affect results (Wainwright 2001; Ritskes-Hoitinga 2004) and sometimes nutrient concentrations may get close to toxic levels. It is therefore important to have an analysis certificate for each batch of diet used, so that experiments can be planned correctly and unwanted effects prevented. Diet can also be used in environmental enrichment strategies where the animals are provided with choice of diet or allowed to work for food. However, this approach complicates matters with respect to standardisation and quality control and can have adverse consequences. This topic is dealt with more extensively in a later section.

The NRC reports (NRC 1977–2003) provide information on the minimum nutrient requirements for each species, and on known toxic levels of these nutrients. Unless the goal of the experiment is to examine toxicity, nutrient levels that might cause toxic effects should obviously not be used, as this

would both compromise animal well-being and experimental results. Even when the goal is to examine nutrient toxicity, very high concentrations are not advisable as they may result in reduced growth and early death. From an animal welfare point of view, testing the dose–response relationship of several subtoxic concentrations is preferable to testing one or two high toxic concentrations (Ritskes-Hoitinga *et al.* 1998). Moreover, such a strategy will provide more detailed information on the metabolic effects of the nutrient, and this approach is therefore an important refinement.

### Safety margins

Methionine is an example of a nutrient with a narrow safety margin. The minimum recommended level for mice during growth is 0.3% (NRC 1995). When studying the influence of higher dietary methionine levels on atherosclerosis in ApoE deficient mice, dietary methionine levels of 2.2% and 4.4% (W/W) proved to be toxic, resulting in reduced growth and premature death (Zhou *et al.* 2001; Ritskes-Hoitinga 2004). In a follow-up study, a dietary methionine level of 1.4% (W/W) did not give any obvious signs of toxicity, thereby resulting in better mouse health and welfare and a more reliable interpretation of study results (Zhou *et al.* 2003).

### Toxic effects

The recommended nutrient levels for good health and those that cause toxicity vary between species. For sheep, the copper density of the diet is critical, as the difference between that for good health and that causing toxicity is very narrow. Errors in feed mixing can easily lead to mortality in this species (NRC 1995–Sheep 1985). Sheep are able to store sufficient reserves of copper to tide them over periods of up to 4–6 months when grazing copper-deficient forage (NRC 1985). When used in research, sheep are often fed pelleted chow as well as hay and grass on a daily basis, in order to avoid mineral and vitamin deficiencies. In these cases total copper intake must be kept below toxic levels. Moreover, because sheep are usually group-housed, a chow diet can lead to copper intoxication in some individuals, if the food intake is not distributed evenly among the individuals in the group. Characteristic symptoms copper intoxication are haemolysis, icterus (easily detected directly around the eyes) and haemoglobinuria (NRC 1985).

Dietary phosphorus (P) levels are critical in mice, rats and rabbits, as excessive concentrations lead to soft tissue calcification (NRC 1995; van der Broek 1998; Ritskes-Hoitinga *et al.* 2004a). This typically affects the kidneys in rabbits and (female) rats, whereas in mice more widespread calcification involving kidney, tongue and heart is seen. Kidney calcification can negatively affect kidney function (Ritskes-Hoitinga *et al.* 2004a, 2004b). Not all dietary P is available to mice and rats as they cannot access that bound to phytates, whereas rabbits can access all dietary P because of the role of their intestinal microflora (NRC 1995–Rabbits 1977). The recommended dietary P level (at a calcium level of 0.5%) for growing mice and rats is 0.3% (NRC 1995), and for rabbits 0.2% (NRC 1977). This minimum recommended dietary (available) P level for rabbits is also the maximum recommended level (Ritskes-Hoitinga *et al.* 2004a).

### Deficiencies

Usually manufacturers ensure that the nutrient densities of diets exceed the minimum requirements, which helps to prevent nutrient deficiencies following storage. Providing animals with the opportunity to forage and/or select what they want to eat in addition to a complete chow diet, means that intake needs to be carefully monitored. For example, it is well known that providing sunflower seeds to parrots *ad libitum*, in addition to a complete diet, can lead to vitamin A deficiency, as the parrots prefer to eat sunflower seeds. Similarly, scattering corn and wheat in the substrate provides rodents with foraging opportunities, and is thought to be enrichment. However, the amount that is provided needs to be calculated and monitored. Rodents eat according to energy need, so it is important to ensure that most of the energy intake is not from the corn and wheat, as this will suppress intake of the complete diet, potentially leading to mineral and vitamin deficiencies. In summary, it is important to calculate the amount of treats that can be provided without disturbing the balance of nutrients required for health.

Foraging is an important activity of primates in the wild, and can be profoundly affected by captivity (Wolfensohn & Honess 2005). Collecting and eating food is necessary to satisfy physiological, behavioural and social needs, and it is therefore important to consider both forage and eating time when feeding primates. Small portions should be provided unpredictably rather than providing large portions in a predictable schedule (Wolfensohn & Honess 2005). Tables listing the nutrient densities of foods commonly used for primates are presented in the *Nutrient Requirements of Non-Human Primates* (NRC 1995–Nonhuman primates 2003). The size of the food pieces should be such that the primates can hold them, as primates like to manipulate their food. It is important to keep track of the nutrient balance of the total ration presented, as commercial diets are formulated to have a balanced composition according to the animals' needs and this balance may be disturbed if inappropriately large amounts of additional items that do not have a balanced composition are consumed. It is often recommended that a varied diet should be provided (eg, fruit supplements with the chow diet), and care is needed to ensure that the balanced composition of the total diet is maintained (Wolfensohn & Honess 2005). As dietary supplements are also given for environmental enrichment or as part of positive reinforcement training, the selection of these treats and the amounts given are crucial. Treats that are nutritionally complete or high in moisture and low in calories, such as fresh fruit and vegetables, are better choices than nuts and raisins, as these are energy dense and nutritionally incomplete. Data on the nutrient composition of commonly used food supplements are provided by Wolfensohn and Honess (2005) and the Foods Standards Agency and Institute of Food Research (2002). Age-related disorders in primates are often related to nutrition. Dietary restriction that does not lead to essential nutrient deficiencies may tend to increase longevity and to decrease the incidence and age of onset of age-related degenerative conditions. Dominant animals may become obese (Kemnitz 1984) as they may dominate access to food. This can be modified by changing spatial distribution and mix of food types.

## Isocaloric exchange

When a standard complete food is offered *ad libitum*, animals ingest according to their energy need. Energy need depends on the life stage, and is generally defined in MJ metabolisable energy per metabolic weight ( $\text{kg}^{0.75}$ ): for growth the need is typically recommended as  $1.2\text{MJ}/\text{kg}^{0.75}/\text{day}$  (but this depends upon rate of growth in relation to adult body mass and species that grow very rapidly, eg altricial birds, have greater daily requirements per metabolic weight than more slowly growing ones such as primates), for maintenance the need is typically about  $0.45\text{MJ}/\text{kg}^{0.75}/\text{day}$ , for gestation, about  $0.60\text{MJ}/\text{kg}^{0.75}/\text{day}$  (depending on species and litter size) and for lactation, about  $1.3\text{MJ}/\text{kg}^{0.75}/\text{day}$  (depending on species and other factors). Metabolic weight is used to make proper comparisons between species, correcting for size-related variation in metabolic rates. Because fat in the diet has an energy density 2.25 times higher than that of carbohydrate and protein, changing the fat concentration will result in a change in energy concentration of the diet and thus on amount of food ingested. If the fat content of the diet is changed, compensation is necessary by changing carbohydrates (or proteins) on the basis of calories (isocaloric exchange) not weight. This is the only way to ensure that the intake of all nutrients, except for fat and carbohydrate (or protein), remains similar in test and control group. Only isocaloric exchange isolates the effect of a change in fat (and carbohydrate) content in the diet and makes it possible to reliably interpret study results. Examples of how this is done can be found in Beynen and Coates (2001), Ritskes-Hoitinga and Chwalibog (2003) and Ritskes-Hoitinga (2004).

## Aspects of feeding

### Rhythms of feeding in nature versus the laboratory situation

Living organisms in nature are continuously influenced by external stimuli, many of them having regular or rhythmic patterns. These include lunar/tidal, solar/daily and seasonal/yearly patterns of light, temperature, food availability, and so on. Because these environmental rhythms are usually quite predictable, animals can usually adapt their physiology to cope with them. The ability to anticipate critical environmental events has clear advantages and survival value in nature, and may be related to the fact that predictability and controllability often have a stress-reducing effect on animals. Species have evolved adaptive anticipatory strategies through the process of natural selection with the result that many species have innate behaviours that are environmentally and temporally appropriate, such as hibernation, migration and seasonal reproduction. Other behaviours that maximise reproductive success include eating patterns that minimise exposure to predators or harsh environments while maximising food consumption. Learning can modify the timing of innate feeding behaviours based upon whether past behaviours were successful in providing adequate nutrients or not. Hence, animals are able to adjust their patterns of ingestive behaviour to adapt to a wide

spectrum of environmental conditions, as long as these conditions are predictable (Strubbe 1994b).

These evolved characteristics and strategies are still present in animals in the laboratory today, although domestication has led to changes (Strubbe 1999); chickens housed in battery cages spend less time voluntarily foraging for food than wild jungle fowl (Ritskes-Hoitinga & Strubbe 2004). It is necessary to know what these genetically determined characteristics are and whether and how one must to adapt to them in the laboratory, because they can impact on the animals' well-being and the experimental results. For instance, for practical reasons most scientific tests on animals in the laboratory are performed during the light phase. However, for nocturnal animals this seriously interferes with sleeping behaviour. Regular and predictable changes found in nature are usually absent in the laboratory. The very important light-dark cycle is normally replicated artificially in the laboratory and kept constant throughout the year, in order to synchronise daily rhythms. However, it is not necessary to mimic all natural conditions to produce better welfare for the laboratory animals. Reducing or eradicating infectious diseases in the laboratory clearly improves animal welfare and experimental results.

One of the best-understood rhythmic patterns is the 24h circadian cycle that underlies many physiological processes and behaviour. The rat is the species that has been most extensively investigated with regard to rhythms and their links to feeding, because this animal exhibits most of the general characteristics of mammalian timing systems. Rats are nocturnal and this remains the case when they are maintained under experimentally controlled light-dark rhythms in the laboratory. Under undisturbed *ad libitum* feeding conditions in the laboratory, rats maintained on a 12h dark and 12h light schedule eat most of their total daily food during the dark hours, with peaks at the beginning (dusk) and end (dawn) of the dark period (Kersten *et al.* 1980).

Whereas the dusk peak is needed to compensate for the lower energy stores in the body following the resting phase, the dawn peak has a more anticipatory function to maintain adequate energy over the forthcoming resting phase (Strubbe *et al.* 1986a). Even before the dawn peak the stomach is hard packed (Armstrong *et al.* 1978) and rats do not reduce feeding when liquid food is infused into the stomach (Strubbe *et al.* 1986a). This indicates that satiety signals are neglected during this period in order to allow preparatory 'over-consumption'.

While each rat may have its own characteristic feeding pattern, such patterns usually do not deviate much from the common pattern in free-feeding animals in the laboratory and from animals in nature. This pattern represents a conserved, probably genetically determined, natural behaviour that, in the wild, would reduce the risk of predation.

### Light aversiveness

Nocturnal feeding in rats could, at least in part, be a product of light avoidance. Light is known to be aversive to some nocturnal species and in particular to albino species. When rats are provided with smaller and darker nest boxes inside their cages, they spend most of their time during the light

phase inside these nest boxes. This remains true when the food hopper and water bottle are placed at a location remote from the nest box (Strubbe *et al.* 1986b; Brinkhof *et al.* 1998). During the dark phase, rats eat in close proximity to the food hopper, whereas when they eat during the light phase, they make rapid excursions from the nest box to the food hopper, take a morsel of food and quickly return to the nest box to consume it. Consumption of food in the nest box increases with light intensity and can therefore be used as a measure of the light's aversiveness (Brinkhof *et al.* 1998; Strubbe & Woods 2004). Aversion to light should, therefore, be taken into account when assessing feeding activity in rats during the light phase. In commonly used rat and mouse cages, the layer of food pellets in the food tray offers some protection from the light. Extremely bright light is, however, never advisable since it may induce retinal damage (Schlingmann *et al.* 1993, 1995). The message here is that the presence of a burrow will certainly increase animal welfare for nocturnal animals, and for rats large burrows are recommended (Jegstrup *et al.* 2005).

### Circadian rhythms

When an animal lives in an environment in which it is exposed to predictable light cycles every 24h, its behavioural patterns entrain on (or synchronise with) the light cycle of the environment. Important patterns can be revealed when the normal light–dark cycle is absent. Thus, when light is kept constant (either with continuous light or continuous dark), animals are no longer able to synchronise with the environment. The result is that many behavioural patterns, including feeding patterns, are governed by a, now unentrained, endogenous oscillator. This operates at a 'free running' rhythm with a daily period that is near, but not identical, to that of one rotation of the earth. From this term, circadian has been derived (circa = approximately, dies = day). The free running period ( $\tau$ ) is dependent on the individual and is genetically determined, so that in the absence of a light–dark change, or other effective cue, animals' rhythms will be at different phases, which could increase experimental variance. For this reason, a constant light–dark cycle is usually maintained in the laboratory. It is therefore important always to control and check the lighting conditions in the experiment rooms and when experiments are performed in the laboratory, it is extremely important to do this under entrained conditions, unless specific chronobiological experiments require a 'free run' design.

The anatomical site of the light-entrainable oscillator or clock that controls circadian rhythms has been the subject of considerable investigation. The hypothalamic suprachiasmatic nucleus (SCN), which lies just dorsal to the optic chiasm, has been identified as the site of the clock that generates circadian rhythms in mammals. When the SCN is lesioned in mammals, there is immediate and permanent disruption of the circadian rhythm of food intake and the animal's feeding pattern becomes arrhythmic (Strubbe *et al.* 1987).

Importantly, a SCN lesion does not induce blindness, and during the dark phase rats will still eat in the vicinity of the

food hopper and in the light they will still take each food pellet back to the nest box. SCN lesions also disrupt many other behavioural and physiological circadian rhythms. For example, in restriction experiments where rats are forced to eat and drink during the light phase, there are strong interacting influences between food intake and sleep (Spiteri *et al.* 1982; Strubbe *et al.* 1986b; Brinkhof *et al.* 1998; Ritskes-Hoitinga & Strubbe 2004). As soon as the *ad libitum* food intake is reinstated, rats revert to their original pattern of food intake (Spiteri 1982). Rats forced to eat during the light phase suffer gastrointestinal problems, comparable to the problems associated with jetlag and shift work in humans (Ritskes-Hoitinga & Strubbe 2004). Interacting effects between circadian clock influences and behaviour and physiology are abolished in rats with SCN lesions (Strubbe *et al.* 1987; Strubbe & van Dijk 2002). This suggests that circadian pacemaker activity in the SCN normally dominates the temporal patterning of food intake, water intake and sleeping behaviour and is not shifted permanently by long-term shifts in food or water availability. As humans work mostly during the light phase, researchers must carefully consider the implications of their choices as to how and when they feed and treat nocturnal animals in the laboratory.

### Memory for feeding time and feeding schedules

In the laboratory, feeding schedules can be part of the experimental design. Rats are quick learners and will readily adapt to these feeding schedules, however, in other rodent species, such as the mouse and hamster, this can be much more difficult, if not impossible. Hamsters on a schedule of one meal of 2h/day experienced a very rapid drop in body weight (20% in 1 week), making it necessary to stop this experiment (Ritskes-Hoitinga, unpublished observations). It is essential to know and adapt to the characteristics of the species in feeding studies, and where there is uncertainty, pilot studies are recommended. If food restriction is a scientific necessity, feeding meals at certain times can be used to achieve the restriction. Sometimes exact coupling of food intake between test and control groups is necessary in order to promote standardisation, so-called 'pair feeding' (see below).

### Meal feeding

Although feeding schedules are used to increase standardisation of experiments, they are, mostly, quite unnatural and artificial. Such schedules interfere with the natural rhythms of drinking, eating and sleeping as dictated by the circadian oscillators. Interference will also occur with the rhythms of many (food-related) physiological processes. When food is consumed, especially large meals, the food itself perturbs many ongoing physiological processes that are closely regulated by the body. As obvious examples, blood glucose concentration and metabolic rate both increase during and after meals, and the effects are greater when larger meals are eaten. In order to minimise the impact of these challenges, the well prepared individual can make meal-anticipatory responses that lessen the magnitude of the meal-induced

perturbations. This has obvious advantages for an individual who, due to environmental constraints, is forced to consume all of its daily food in one or two very large meals. Rats can easily be trained to ingest the required amount of food in a limited amount of time. Within a week's time, rats can be trained to ingest their daily food intake in two meals of 0.5 h each during the light phase (Ritskes-Hoitinga *et al.* 1995). One meal of 2 h/day can be sufficient for an (adult) rat to obtain the necessary energy and nutrients but this does depend on the physiological state of the animal. Although rats can be trained to adapt to eating one or two meals per day, the internal rhythm of the circadian clock is maintained. Therefore, in these scheduled feeding designs, there is a strong interference with the circadian feeding behaviour and concomitant gastrointestinal physiology. The time of day when the food is offered is critical to physiology and welfare. Meal-feeding during the dark phase as compared to during the light phase, resulted in bile flow and physical activity being comparable to *ad libitum* feeding (Ritskes-Hoitinga & Strubbe 2004) and resulted in more normal physiological responses.

Animals can eventually adapt to feeding schedules in which fewer, larger meals are eaten, and this is usually associated with more efficient handling of the diet, including a slower gastrointestinal passage time and hypertrophy of the gastrointestinal wall. These changes help the animal to cope with the situation, despite the fact that the feeding schedule can be unsuited to its physiology and uncomfortable.

Virtually every digestive or metabolic variable that has been investigated changes in anticipation of meals. These meal-related changes are often called cephalic responses, because many of them are initiated by signals from the brain. When six equal meals are spread over the daily cycle with equal inter-meal intervals, these anticipatory responses are not seen (Strubbe 1992; Kalsbeek & Strubbe 1998). However, where rodents are used and the study requires a schedule of one to two meals per day, these anticipatory responses do occur. Generally it is preferable to feed more often as rats normally eat eight to ten meals per day. Welfare is certainly affected when forced artificial schedules are used.

### Restricted feeding

Severe obesity and diabetes mellitus are becoming increasingly prevalent in Western societies, and reducing body weight by adequate control of food intake is one of the best therapies. However, it is also one of the most difficult treatments in humans, since it usually induces a feeling of a permanent state of hunger and as a consequence stress and mood problems, such as depression, occur. This is also the case in several husbandry systems, for instance in broiler breeders, where severe long-term food restriction is applied during rearing to prevent health and reproduction problems at a later age (De Jong *et al.* 2003).

In food restriction studies, instead of food being provided *ad libitum*, the energy supply is restricted, while still ensuring nutritional adequacy, ie, that all essential nutrients are supplied in the required amounts (Hart *et al.* 1995). For dogs,

pigs, cats, monkeys and many other animals it is considered bad veterinary practice to feed *ad libitum*, as the animals will become obese (Hart *et al.* 1995).

### Long-term food restriction

Rodents are fed *ad libitum* in the majority of experimental studies. Feeding rodents *ad libitum* may be attractive from a practical point of view because no special feeding system or special care is required. However, on the basis of results from long-term toxicological studies, it is questionable whether this is a sound scientific or welfare approach.

*Ad libitum* feeding leads to long-term negative health effects compared with restricted feeding (75% of *ad libitum* intake). These include shorter survival time, increased rates of obesity, degenerative kidney and heart disease, and cancer at an earlier age (Hart *et al.* 1995). Food restriction can have other positive effects on health. For instance, the relative body weight reduction 48 h after surgery (jugular cannulation) is smaller in food-restricted animals as compared to *ad libitum* fed rats (both at 3–4 and 17–18 months of age) (Hart *et al.* 1995). It is claimed that animals become more 'robust' when food intake is restricted, that is, that they can cope better with experimental stressors and related procedures (Keenan *et al.* 1999). Diluting the diet, for example, by including a higher fibre content under *ad libitum* conditions, does not give the same positive health effects as compared to food restriction (Hart *et al.* 1995).

In most instances, health problems due to being overweight are not considered a problem, because laboratory animals do not live to an age at which problems occur. However, for research into aging and kidney physiology, there are clear reasons to use food restriction instead of *ad libitum* feeding. Long-term food restriction is also very useful when long-term reductions of body weight are required, such as in obesity and type 2 diabetes research.

Keenan *et al.* (1999) have demonstrated that *ad libitum* feeding is the least controlled experimental factor in the laboratory. Considerable variation in experimental results from rodents on *ad libitum* feeding schedules was seen during the 1980s to 1990s in toxicology (Keenan *et al.* 1999). One possible explanation could be the continuous selection of faster growing individuals in outbred strains (Keenan *et al.* 1999). As rapid growth has often been considered an indicator of good health, robustness and leading to better reproduction, heavier individuals may have been selected for the breeding process. However, faster growth tends also to be associated with a shorter lifespan. By selecting within outbred colonies on the basis of fast growth, sub-populations may arise, leading to more variation within outbred populations. Feeding rodents at approximately 75% of the *ad libitum* food intake is recommended for long-term toxicity studies in order to make certain that a sufficient number of animals survive the required 2-year period (Hart *et al.* 1995). Under *ad libitum* feeding conditions, body fat content can be more than 25% (Toates & Rowland 1987). By restricting food intake to 85% of *ad libitum* intake, body fat content will be less than 10%, which is similar to that found in wild-caught animals (Toates & Rowland 1987). In order to make sure that all individuals eat the same amount of

food, it is advised to house them individually (Keenan *et al.* 1999). However, this may have a negative welfare impact because of social isolation, as rodents are social animals. In order to solve this, one possibility is to feed group-housed animals individually. In line with current agricultural practice, microchips, computer technology and automated feeding devices have been used for feeding individual rats restrictedly under permanent group housing conditions. This strategy needs to be further developed.

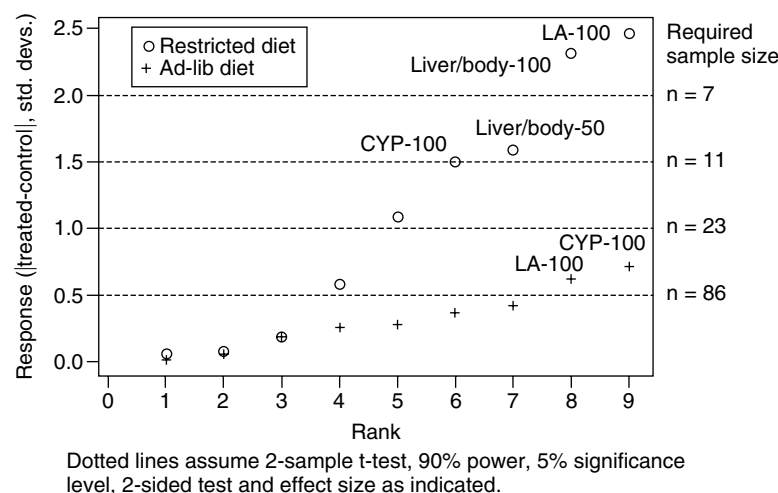

An aspect of food restriction that deserves much more attention is the issue of standardisation and reduction. Under *ad libitum* feeding conditions, animals can freely choose the amount of food eaten. By definition, animals are fed a standardised amount of food under restricted feeding conditions, which automatically improves standardisation of experiments. Upon testing chloral hydrate in rats under *ad libitum* versus food-restricted conditions, it was found that a significant difference in the liver enzyme activity of LA (lauric acid) between control and test group occurred at a dose of 100mg/kg (Leaky *et al.* 2003; Ritskes-Hoitinga 2006; Ritskes-Hoitinga *et al.* 2006). Under *ad libitum* conditions 86 animals per group were necessary, whereas only 7 animals were needed under food-restricted conditions to prove that this difference was statistically significant (Figure 14.1). This indicates that a reduction of 92% in the number of animals used was possible under these conditions because the magnitude of the effect was much greater under restricted feeding conditions than under *ad libitum* feeding, which is a well known effect of food restriction (Hart *et al.* 1995).

However, it is not only from the point of view of the numbers of animals used, that welfare issues associated to food restriction need to be addressed. Long-term food

restriction may (temporarily) cause feelings of hunger. This can be a strong stressor leading to abnormal behaviour such as stereotypies and will affect animal's welfare by causing mood problems (Dixon *et al.* 2003). One study with rabbits showed that a lower frequency of stereotypical behaviour occurred when rabbits were offered a restricted amount of food at their natural time of the day compared with restricted feeding at an unnatural time of day and as compared to *ad libitum* feeding (Krohn *et al.* 1999). This indicates that feeding a restricted amount of food at the 'proper' time is beneficial for welfare, even when compared to *ad libitum* feeding. When a restricted feeding schedule is used, it should be remembered that as soon as food becomes available again, the animal will ingest a large meal in order to compensate for energy deficits from the fasting period.

### Short-term food deprivation

Short-term food deprivation, such as overnight fasting or other food deprivation schedules, is often used in research. For example, fasting may be necessary when blood samples need to be lipid-free for certain analyses. These short-term food restriction periods (ie, hours) are needed for certain experiments and can also improve standardisation and reproducibility of experiments. However, food deprivation for a period of 24h results in a different metabolic state than under *ad libitum* feeding conditions (Strubbe & Alingh Prins 1986). After rats have been deprived of food for a period of 24h or more, all glycogen deposits have been used. Food deprivation in rats for a period of 12h leads to a shift from carbohydrate to fat metabolism (Strubbe & Alingh Prins 1986). An excellent overview of how food restriction influ-

**Figure 14.1** Chloral hydrate caused a significant increase in the liver enzyme activity LA-100 (LA is lauric acid, 100 refers to a dose of 100mg/kg). Under *ad libitum* conditions, 86 animals were needed in order to show a statistically significant difference, whereas under food restriction conditions, only seven animals were necessary to find a significant difference between the treatment and control group (ie, a 92% reduction). Food restriction also leads to an increase in effect size as compared to *ad libitum* conditions (Leaky *et al.* 2003; Ritskes-Hoitinga 2006). 'Effect size' is the magnitude of the difference between the treated and control group, calculated by taking the absolute differences between the treated and control means and dividing this difference by the standard deviation for each group; 'rank' indicates the numerical position of a certain parameter in the magnitude of the effect size; crosses refer to *ad libitum* fed groups, circles refer to restrictedly fed groups; CYP-100 refers to liver enzyme activity measurement of the enzyme CYP at a dose of 100mg/kg; liver/body is the liver/body weight ratio at the dose of 50 and 100mg/kg. (Dr. Michael Festing is greatly acknowledged for these calculations.)

ences the physiology and well-being of various species has been published by Rowland (2007).

### Pair feeding

If a test group's voluntary food intake differs from that of the controls, it is advisable to take steps to equalise the intake between the groups. Such differences can occur when the palatability of the test diet is negatively influenced, or where the substance has a negative effect on appetite or health, resulting in reduced food intake. For standardisation, test and control animals must ingest a similar amount of food at a similar time of day, otherwise it will be impossible to judge the effects of the test substance and/or procedure independently of its effects on food intake. Because NRC requirements are based on obtaining maximum growth rate, a level of 75% of the NRC recommendations is still considered sufficient to fulfil all needs.

There are four possible methods for achieving pair feeding and these are: (1) weighing; (2) coupling of food dispensers; (3) gavage/permanent stomach cannula; and (4) feeding machine. In the first method the amount of food eaten by the test group is weighed, and the control group is fed the same amount of food the next day. A disadvantage of this method can be that the total daily food supply is provided at once to the control animals, perhaps at an unnatural time point of the day (eg, perhaps during the resting phase in rodents). This may induce quite a different eating pattern and overloading of gastrointestinal processes in the controls as compared to the test animals, thereby preventing proper comparison between test and control animals. In the second method, using food dispensers, rats can be trained to obtain a pellet by pressing a lever. By coupling food dispensers for test and control animals, the dispenser of the control rat provides a pellet at exactly the same time as the test animal 'asks for' and eats a pellet. This system standardises amounts eaten and ingesting patterns. In the third method, permanent stomach cannulation and gavage make it possible to provide all animals with exactly the same amount of food at the same time points (Balkan *et al.* 1991). However, inserting a permanent stomach cannula requires a surgical procedure and both the stomach cannula and gavage method omit the oral digestive process. In the fourth method, feeding machines with regulated opening of valves make it possible to open and close food hoppers at the same times during the day for test and control animals. Meal training is another possible solution for a pair-feeding schedule.

### Gavage feeding

In research on pharmaceutical agents or nutrients, it can be important to avoid any negative influence of taste on food intake. In such cases, gavage is used to introduce substances directly into the stomach. Gavage may also be required for radioactive isotopes or immunosuppressants, where exact dosing is required and health-damaging substances must not be spilled into the environment. However, the application of a meal directly in the stomach as compared to vol-

untary eating of a similar meal, can affect experimental results (Vachon *et al.* 1988). In this study by Vachon *et al.* (1988), voluntary consumption yielded results more comparable to those from human studies. A disadvantage of stomach tubing is that it bypasses all the oropharyngeal processes, including the physical effects of chewing and the addition of salivary enzymes that initiate the digestive process. Gavage can also cause stress to the animals, resulting in suppression of gastrointestinal activity. By training the animals to become accustomed to the procedure and giving them positive rewards, the use of the stomach tubes becomes gradually less stressful.

Another possibility is to insert permanent cannulas in the stomach (or small intestine), which makes it possible to apply substances directly into the stomach or small intestine without stress (Strubbe *et al.* 1986a) and without risk of contamination of the environment and the person executing it. These permanent cannulas are used, for example, to measure the satiety effects of filling the gastrointestinal system with purified nutrients at different anatomical locations. After the initial surgical procedure, rats can walk freely in their home cage. Due to the presence of the cannula attachment to the skull, individual housing is often used, however, this will impact on the animals' welfare. Social housing is possible if the cannula attachments are protected from bites by a metal cap.

### Working for food

When food is always available, but not 'free', animals readily change their feeding patterns based upon other kinds of constraints. When an energy cost is placed on gaining access to food, rats change their strategy to minimise total daily work while maintaining a constant body weight (Collier *et al.* 2007). Specifically, as the cost of gaining access to food increases (eg, the number of responses an animal must make to gain access to food; or some other aspect of physical effort), two changes occur: the rats eat larger meals, and they eat fewer meals (Figure 14.2).

It is difficult to determine how much time/energy ought to be spent on working for food. The choice the animals make does not necessarily optimise long-term welfare. Sometimes, the animals are inclined to eat a large amount of easily available food fast, in order to make energy deposits. This in turn, may have a negative impact on the animals' health and welfare in the long term. As a result of domestication and selection, animals may change in ways that impact on their needs for optimal welfare. Comparing the behaviour of the white leghorn chicken and its ancestor, the wild jungle fowl, a remarkable difference has occurred in food searching behaviour. When given the choice between freely available food from a plate and food that was hidden in the bedding in a semi-natural environment, the white leghorn chose to search for food in the bedding and consumed 30% of their feed from this source, whereas wild jungle fowl consumed 70% of the total diet from the hidden food (Ritskes-Hoitinga & Strubbe 2004). This indicates that there may be a behavioural adaptation as a result of domestication and selecting strains for increased production.

**Figure 14.2** Daily pattern of food intake of a rat on consecutive days. The black lines represent bouts of feeding activity. On day 5, the distance between the food hopper bars was reduced, requiring increased effort to obtain food through the bars. Notice the large meals of extremely long duration in the beginning. After a few days, the animals could work their way through the narrowed food hopper bars just as fast as before. Reproduced from Ritskes-Hoitinga, M. and Strubbe, J.H. (2004) Nutrition and animal welfare. In: *The Welfare of Laboratory Animals*. Ed. Kaliste, E., pp. 51–80. With kind permission of Springer Science and Business Media.

## Diets

A change is likely in the animal's feeding strategy if diet and palatability are changed. However, after a few days the free-feeding pattern will return to the original state with the same meal frequency (Strubbe & van Dijk 2002; Ruffin *et al.* 2004).

A regular chow diet can be used for animal maintenance and during numerous types of scientific procedures but, in nature, a greater variety of ingredients is often available and consumed. So, is greater variety and the opportunity to choose and select better for the welfare of the animals? When rats were given the choice between various diets providing energy from different sources, the rats chose carbohydrate-rich diets in the evening hours, and fat-rich diets just before the start of the resting period (Strubbe 1994a, 1994b). The same time-dependent pattern of macronutrient selection was also seen in humans (van het Hof *et al.* 1997). The evolutionary explanation may be that carbohydrate-rich diets will quickly provide the animal with a source of readily available energy, necessary to supply the energy deficits that have arisen during the resting phase. The selection of macronutrients is governed by several neurotransmitters in the central nervous system such as galanin, neuropeptide Y (NPY) and serotonin (Strubbe 1994a; Kyrkouli *et al.* 2006). At present, in the authors' laboratory, the animals are often only offered one standard diet throughout the day but varying the diets offered can improve their welfare. It has been reported that monkeys that had access to a herb garden in the Zoo 'Apenheul' at Apeldoorn in the Netherlands, made a selection of specific herbs according to their health state<sup>1</sup>. Food selection is individually determined, and it may be better for welfare to permit individual selection of foods. At first glance, this may appear to conflict with attempts to standardise experiments, however, if individual needs are properly met, standardisation of experiments can be improved by adopting this approach. It will be a challenge to define how this should be achieved in practice.

Normal feeding patterns in rats also vary with their physiological and metabolic state. When energy demands are increased, such as during lactation or during forced daily exercise, rats first increase the size of meals up to their normal maximal meal size and later increase the number of

such meals as energy demands increase further (Strubbe & Gorissen 1980).

## Group housing

Although restricted feeding schemes and solitary housing have advantages for the standardisation and execution of experiments, restricted feeding schedules and solitary housing may have welfare consequences. Animals of social species ought to be housed socially, unless there are clear reasons for doing otherwise. When harmonious social housing is not possible, then all possible efforts should be made to improve animal welfare in other ways.

Housing and husbandry conditions can influence both the amount of food animals ingest, and the animals' feeding patterns. Whether an animal is group or individually housed has implications for food intake and results of scientific procedures. Individually housed mice of both sexes were found to have higher food intake than mice housed in groups of two, four or eight per cage (Chvedoff *et al.* 1980; Beynen & Coates 2001). Mice housed individually or at two per cage had a higher body weight and body weight variability than the other groups. When the mice were housed at eight per cage, gastritis occurred more frequently compared with individually housed mice (Chvedoff *et al.* 1980). These results indicated that four mice per cage was the optimum group size in this particular study. Peters and Festing (1990) showed that maximum body weight gain at different cage densities depended on the cage size and the mouse strain chosen: the inbred Balb/c thrived best in a high-density housing, whereas the outbred MF1 had a higher body weight gain in low-density housing. If mice are housed in a group, they usually lie together, reducing their total surface area. Reduced heat loss per animal in the group is the result and, due to this 'behavioural thermoregulation', food intake is reduced (De Vries *et al.* 1993; Woods & Strubbe 1994). If test compounds are incorporated in the food, the investigator should be aware of the phenomenon that group size influences intake and, therefore, the intake of the compound.

Behavioural and ingestion patterns can also be influenced by the social structure in the group. A dominant animal may prevent others from eating at certain times. Food intake patterns of socially compatible groups of S3 rats showed the normal feeding pattern with a clear dawn peak for all individuals. In contrast in a group that was socially incompatible, the dominant animal prevented the rats lower in

<sup>1</sup><http://www.kennislink.nl/publicaties/wat-kunnen-wolapen-ons-leren-over-gezondheidsbevorderend-gedrag>

hierarchy from having a dawn peak at the natural time. Some had to shift to an earlier time during the dark phase, and some even shifted to the beginning of the light phase (Ritskes-Hoitinga & Strubbe 2004). It is unclear whether the phase of circadian rhythm had shifted permanently.

Thus, group housing can influence experimental outcome, either by influencing food intake and feeding patterns or by other factors. In one case, incompatibility between individuals in a group of dogs led to stress and vomiting of food until 8 h after the meal. Ingestion of this vomited food caused a disturbance of the experimental results. Upon changing the treatment and handling of the group of dogs in many ways, a social compatible group of individuals led to more reliable and reproducible results (Ritskes-Hoitinga *et al.* 2006).

### Concluding remarks

When carrying out research using animals, it is a challenge to feed them in such a way that their health and welfare is maintained and results are reliable and reproducible. To do this requires knowledge of nutritional and behavioural requirements. This chapter provides an overview of factors that must be taken into account when feeding animals in the laboratory. Much more research is needed into how different feeding methods can be used as enrichment in order to improve laboratory animal welfare.

# 15 Attaining competence in the care of animals used in research

Bryan Howard and Timo Nevalainen

## Introduction

During the last two decades, there has been very considerable improvement in our understanding of the needs of animals, although there is much still to learn, and many of the measures implemented to improve husbandry have been empirically formulated. There is an urgent need for more investigative work into the most appropriate husbandry conditions of many laboratory species and those who are routinely engaged in animal care may often be well placed to carry out or assist in such research.

In addition to animal welfare-based changes to the way animals are housed and cared for, there have been other developments that have brought science into the animal facility and technology into the day-to-day routines of staff working there. New ways of keeping animals include: the group housing of rabbits, primates and dogs; ventilated racks and other biocontainment facilities; high-intensity aquatic environments; computerised systems for monitoring the environment and maintaining animal records; and high-performance room ventilation systems, which minimise carbon costs whilst maintaining rigorously defined air quality within rooms with a low burden of aeroallergens. Changes such as these have coincided with the emergence of new experimental methods and models, including transgenics, high health status, chronic studies on animals with instrumentation, radiotelemetry and indwelling catheters.

The importance of ensuring competence of those who care for and use animals has never been higher. Training programmes should be designed and delivered with a view to developing the knowledge and skills appropriate to the duties of individuals, whilst promoting the diversity and flexibility necessary for career development. All staff must commit to their own development, so it is important that at the outset they explicitly agree what constitutes satisfactory performance in relation to the outcomes required and that the reasons for training and the ways in which both staff and the organisation will benefit are made clear (Silverman 2002). Training helps staff to develop basic competencies and, in the case of ongoing training, to use new equipment and procedures. Training is important for maintaining and updating knowledge about legislative and regulatory developments, and for the renewal of competencies, particularly in areas not frequently addressed (Pritt & Duffee 2007). The

amount and nature of training required by individuals is likely to differ, which, with variation in preferred learning styles, resource allocation and conflicting work demands puts considerable pressure on those responsible for delivering training in the workplace. Training without follow-up is ineffective and a clear, transparent means of measuring progress should be set in place that allows both staff and their supervisors to monitor and recognise success as the learning objectives are achieved.

## Legal and ethical considerations

All those working with animals need to be made aware of their obligations under national and regional legislation, and this is an essential part of the training process (see also Chapter 8). In most instances, legislation adopts the ethical framework of the Three Rs of Russell and Burch (Russell & Burch 1959). In general terms, this states that animals should only be used when no non-sentient alternatives exist, that then as few as possible should be used, and that the experiments should be conducted so as to minimise the adverse impact on each animal concerned (see Chapter 2).

Everyone involved in the care and use of laboratory animals is partially responsible for an activity which requires legislation to make it legal, and consequently must make ethical decisions and accept the consequences of those on an ongoing basis. The people who have most influence on the well-being of laboratory animals are those who care for them on a regular basis. Although the conduct of scientific procedures almost invariably impacts on their well-being, that impact is usually transient or of relatively short duration. On the other hand, animals must be bred, transported and cared for before the study starts and during its progress; and at the end of the investigation they must usually be humanely killed. Animal care staff and their supervisors are in the frontline of this process and it is important that they should clearly understand the ethical principles involved and the concerns which society expresses. Appreciation of this can be particularly difficult when some individuals, albeit only a tiny minority, threaten violence or intimidation against those involved. While it may not always be appropriate to focus on the theoretical background of ethical decision making, all persons involved in animal experimentation should be able to apply ethical principles to clarify and feel

confident about their role and the activities of the institution and regulatory systems within which they work. Moreover, a common ethical appreciation of those caring for and conducting experiments on animals within a particular establishment results in the development of shared values, which underpin a pervasive culture of care. Such an institutional culture is intolerant of acts which unnecessarily impair animal welfare, thereby supporting legal compliance, establishing ethical sustainability and ultimately enhancing the robustness of scientific studies.

Because of the underlying importance of these ethical principles in relation to the day-to-day activities of animal care staff and others, it is important that staff are made aware of the ethical framework and the law as soon as they commence work. These are important topics in formal training courses, but should also be promoted by ethical review processes within establishments and by supervisors and colleagues. This is one of several topics in which formal teaching, by lectures, seminars or study of online materials, is less effective than interactive teaching, in which learners are encouraged to ask questions and to solve problems that address ethical issues. Good communication is central to developing shared ethical values, and both care staff and scientists should be able to talk freely with each other using a common understanding focused on high-quality care routines, welfare issues and science and based on acceptance of individual responsibility and accountability.

### Other purposes of education and training

Consideration of the needs for education and training should not be restricted to regulatory requirements, but should use them as a starting point. Regulatory requirements tend to be broadly drafted and include general statements such as the need for 'appropriate education'. Details of curriculum content, the minimum length of initial training and maintenance of up-to-date knowledge and skills are not addressed in detail (see for example European Directive 86/609, European Council 1986). A similar situation applies in the United States (see Duffee *et al.* 2003). Although the objectives of national laws and regulations on education and training are similar, the means by which they are achieved and implemented can differ considerably.

Training is also necessary to achieve high-quality science and good animal welfare (Nevalainen 2004). University science curricula do not usually specifically address issues relating to animal welfare, good scientific practice or associated ethical subjects. A strong case can be made for referring to these topics within the curriculum. Many undergraduates who are taking biology-based courses will not progress to carry out research involving animals, and therefore do not need to gain competences in these areas, but it is important that all of those who acquire or use information in a scientific or technical way should appreciate how that information has been obtained. The value of including such information in undergraduate degree courses has been explored by assessing student opinions (Carlsson *et al.* 2001) but more needs to be done to determine the most appropriate level and time of presentation.

### Sources of information

Various courses and training opportunities are available, such as those organised by major laboratory animal breeders, which deal with general laboratory animal care, as well as the research techniques used by particular establishments or research groups. In addition, national/regional laboratory animal science associations frequently hold symposia or conferences, at which specific aspects of animal use are discussed and placed within context. Ideally, completion of such courses should be recognised formally, so that credit can be given to individuals who take the time and effort to keep their skills up to date.

Efforts have been made in some areas to harmonise training, but this may be easier for general courses than for specific research techniques, because of the greater number of organised training opportunities, the much greater size of the target group and the development of national and international guidelines. Specialist knowledge, for example in the husbandry and care of genetically altered animals, can be gained at an individual level by reading texts and visiting specialist websites, for example that of the International Society for Transgenic Technologies<sup>1</sup> etc.

Harmonisation of general courses within countries has been achieved in some cases, but to achieve the same within a continent or globally is much more of a challenge. None the less, efforts in that direction have been initiated by the International Council for Laboratory Animal Science (ICLAS)<sup>2</sup>. In contrast, the quality and volume of specific training offered by research groups is highly variable, and it is difficult to conceive a mechanism for ensuring sufficient training for the variety of specific procedures conducted.

### What is competency?

Competency has been incorporated into European legislation for over two decades (European Council 1986), and remains central to current proposals to revise the European Directive 86/609<sup>3</sup>, although this identifies a competent person only as someone '*who is considered by a member state to be competent to perform the relevant function described in the Directive*'. Beyond this the proposed Directive provides no guidance as to what might be expected from a competent person, although it recognises that quality and professional competence is required for assuring the welfare of animals, both for overseeing the care of animals on a daily basis and during the conduct of procedures. Reference is made to some duties which must be carried out only by competent persons, including performance of euthanasia and confirming the well-being and health of animals at least once daily. Those conducting scientific procedures must have appropriate veterinary or scientific education and training and have evidence of the requisite competence (Article 20, paragraph 2, sub-paragraph 1). Authorisation to carry out such investigations is valid only for a strictly limited period (5 years)

<sup>1</sup><http://www.transtechsociety.org/>.

<sup>2</sup>[www.iclas.org/harmonization.htm](http://www.iclas.org/harmonization.htm).

<sup>3</sup><http://www.europarl.europa.eu/sides/getDoc.do?pubRef=-//EP//TEXT+TA+P6-TA-2009-0343+0+DOC+XML+V0//EN&language=EN>

and at the end of that time extensions shall be granted only on the basis of evidence of continuing competency.

There is very little agreement about the meaning of the word 'competence', although most people agree that it refers to the ability to perform a task or perhaps the skill with which it is performed. However, the word is more frequently used in a broader way, to refer to a person's overall ability to carry out a role satisfactorily, rather than just certain elements of it. It is also sometimes used to describe the detailed aspects of an individual's job performance, for example; *'this technician had demonstrated competency in sexing day-old mice'*. The EU Knowledge System for Lifelong Learning defines competence as *'an ability that extends beyond the possession of knowledge and skills. It includes cognitive competence, functional competence, personal competence and ethical competence'*<sup>4</sup>.

For the purpose of this chapter, competence will be regarded as the ability of an individual to properly perform specific tasks that fall within their job remit. The term encompasses a combination of knowledge, skills and attitudes, which are applied to tasks being undertaken and which ensure that these are carried out efficiently and effectively. In the case of laboratory animal science, the relevant attitudes encompass recognition and application of the Three Rs at every opportunity, a high level of skill and empathy with animals for which the individual is responsible, openness and willingness to seek assistance and guidance whenever appropriate, and the ability to effectively communicate concerns if issues relating to animal welfare arise.

In the case of animal care staff, the range of skills that a competent person should possess would include the following:

- appreciation of the ethical issues associated with the scientific use of animals and the application of the Three Rs;
- working knowledge of national and local legislation and regulations; insofar as these relate to the sourcing, care and use of the species concerned, including any requirements of local ethical or care and use committees;
- ability to recognise departures from good health and knowledge of actions to take where this is detected;
- knowledge and skill in the handling and caring of animals including breeding stock and animals undergoing experiments;
- awareness of normal behaviour, and ability to recognise the causes and signs of pain, discomfort or distress and awareness of how to minimise these;
- skill in the administration of medicines (where prescribed by a veterinarian), basic husbandry procedures such as identification methods, breeding and checking for physical signs of good health;
- dexterity in animal handling, skill in selecting a suitable method and carrying out euthanasia if necessary and awareness of how to dispose of carcasses;
- ability to communicate effectively with other care staff, including supervisors, and with scientists who may be carrying out experiments on animals being cared for;

- appreciation of the importance of good hygiene and biosecurity, and awareness of the procedures necessary to maintain these;
- appreciation of health and safety issues which may arise in the animal facility and awareness of how these should be addressed;
- understanding the importance of maintaining accurate records and aptitude in record maintenance.

Additionally, specific competencies may be developed relating to the ability to administer compounds, withdraw biological samples, carry out specific observations or make measurements using validated equipment, as directed by a scientist or other person, appropriately authorised and subject to compliance with local and legal requirements. Those with aptitude may develop competencies such as managing staff, overseeing facilities or the provision of specialist services.

A distinction can be made between basic competences relating to the ability to perform relatively routine tasks efficiently and effectively, following detailed instructions, where relevant, and more advanced competences in which individuals vary their behaviour when necessary, but always in an appropriate way. Highly competent people react almost intuitively by assessing the situation in its context, drawing from a repertoire of possible actions, determining which of these is most appropriate, monitoring the consequences of that action and adjusting their actions as appropriate. Highly competent people require experience and the ability to monitor outcomes and adapt actions according to the consequences. Such behaviour involves a continuous process of acting and reflecting. Basic and advanced competence can be developed by training. Both require an understanding of regulatory and other constraints on actions, and the ability to ensure that appropriate authority is obtained where necessary.

Development of competency involves a complex mix of education and teaching. Education is the process by which knowledge is accumulated, whereas teaching can be defined as the promotion and facilitation of learning. Of itself, teaching imparts neither knowledge nor skill – it simply helps the learner to acquire, understand and interpret information efficiently and effectively. The term training has been used to describe the facilitation of skills development. From the perspective of competence, teaching involves instruction and practice, which develop and enhance performance so as to help learners to carry out their responsibilities. The development of appropriate attitudes is a much more complicated issue, and depends partly upon the previous experience of the learner, organisational attitudes within the workplace and the professionalism and enthusiasm of those responsible for delivering training and education. The extent to which inherent attitudes can be modified by training is the subject of considerable debate, but there is no doubt that both the attitude of teachers and relationships with peers have an important influence.

### Oversight of training

As noted earlier competence is *'the ability of an individual to properly perform specific tasks'*. This ability requires possession

<sup>4</sup>[http://www.gramlinger.net/f\\_arbeit/LLL/glossary.pdf](http://www.gramlinger.net/f_arbeit/LLL/glossary.pdf).

of appropriate manual skills, but without an appreciation of the principles that underlie the task, performance becomes automatic and unresponsive to any variation in demands, such as might arise from an unexpected event or a significant observation, this should not be regarded as competence.

A distinction also needs to be made between knowledge and understanding (Foshay & Tinkey 2007). The former refers to information which can be recalled to mind, but the latter requires that the facts can be assembled and used to enable concepts and principles to be developed and assessed and so contributes to flexibility of actions. Whilst knowledge of facts may be necessary to underpin understanding, additional processing is necessary to use them in a meaningful way.

Basic technical procedures can be learnt by following a series of steps without understanding why they are taken or the consequences of performing them; this is knowledge without understanding and an example might be close adherence to a standard operating procedure (SOP). However, when something is meaningfully understood, it is remembered much longer, provides the basis for developing further understanding and can be adapted to deal with emergencies or novel and perhaps more complex situations. For factual knowledge to become meaningful knowledge, it needs to be linked to a broader, previously learned, closely related context; a process known as assimilation. The weaker the association with that context, the less coherent is the resultant understanding and it may become necessary to substantially revise that context in order to enable conflicts to be resolved. The education, training and development of persons working with laboratory animals requires the learning of skills, the presentation and assimilation of knowledge and the incorporation of all these into a framework of understanding and responsiveness.

Although all individuals are ultimately responsible for developing their own knowledge and competence, legislation usually places additional responsibilities on those overseeing animal facilities. This responsibility often resides in a committee, such as an institutional animal care and use committee (IACUC) or ethical review committee, or an individual who has been granted a licence authorising specific animal experimentation at the establishment. Whatever the details of the arrangement, it is important that management should provide opportunities for individuals to acquire knowledge and skills, and establish mechanisms to ensure satisfactory standards of performance. Each establishment should establish a flexible framework to identify training needs and provide a mechanism for the promotion of learning, for example by delivering formal or informal training. The remit should include both primary training and lifelong learning, also known as continuing professional development (CPD). There are three key stages in such a framework:

1. planning and developing strategies to meet shortfalls and improve performance of the research programme;
2. taking action to maximise the performance of staff in the workplace;
3. evaluating the impact of training and development on the performance of individuals and the research output of establishment.

Many practical benefits result from a logically structured training programme including:

- Increased productivity in terms of scientific output and the quality of publications generated by skilled and motivated people who work more effectively.
- Improved motivation and greater understanding of the role of staff within the workplace. Improved personal development and recognition of achievements. This enhances morale, reduces staff turnover and absenteeism, and creates a climate in which change is more readily embraced. Motivation also encourages teamwork in the conduct of scientific investigations, with closer liaison between animal care staff scientists and those overseeing projects.
- Reduced costs and wastage, because skilled and motivated people work more effectively and consistently, delivering higher-quality scientific outputs.
- Recognition that the facility is comprised of effective and well trained individuals. This together with improved quality of programmes makes it easier to attract grants or commissions, or to identify promising research leads and lines. At academic establishments in many European countries, there is increased emphasis on the consistency and quality of scientific work.

The development of a training programme provides an opportunity to review current policies and practices and to identify areas where improvement is possible. It also provides a framework for planning future strategy and developing actions, and enables the creation of a structured system to enhance the effectiveness of training and development activities. Critical to this stage is the identification of priorities for education and training (Conarello & Shepherd 2007). The programme should take account of the size and type of establishment, the current knowledge and skills of staff, the complexity of the work, the rate of staff turnover and the level of support and advice available within the workplace. The framework provided by the four Federation of European Laboratory Animal Science Associations (FELASA) categories is often a convenient starting point. One strategy is to benchmark the provision of education and training against that of similar establishments undertaking similar work, and to adopt similar performance standards. Alternatively, views may be sought of key individuals such as line managers, veterinarians, senior scientists or their representatives, a member of the ethical review process and perhaps other key individuals such as client representatives or officials concerned with regulatory compliance. Often such a body already exists in the form of an animal care and use committee or similar, and in such cases this is likely to be the most effective tool. The training plan must identify clear targets based on the Three Rs, quality of science and the business or academic objectives of the organisation. The process should take account of perceived future skills requirements resulting from the introduction of new equipment or new technologies. While the training programme is being developed, there must be wide consultation with staff, particularly in large organisations or where staff work in distinct teams in different parts of a single organisation, for example where biosecurity arrangements preclude frequent mixing.

Mention has been made earlier of the importance of developing a culture of care within the establishment. Staff

involved in animal experimentation should be trained to understand and appreciate what is required of them and to know how to perform effectively (Romick *et al.* 2006). Staff should be equipped with the necessary training, information tools and materials to perform effectively alongside others, and should be well acquainted with actions to be taken when problems arise. This information can be communicated by a variety of means, including: team briefings, focused seminars dealing with the technical and scientific progress of specific projects, circulation of newsletters, staff meetings and performance reviews. Whichever method is used, regular flow of information is important to ensure that all staff are acquainted with the activities of the organisation.

### Job categories

Within Europe, appropriate education and training of all those engaged in the use of live vertebrate animals for scientific purposes are required by both the Council of Europe (Convention ETS 123, Article 26, Council of Europe 1986) and the European Union (Council Directive 86/609/EEC, Article 14, European Council 1986). In 1993, the parties of the European Convention ETS 123, issued a resolution to promote the development and uptake of training and educational programmes to meet the competency requirements set out in the Convention. The resolution acknowledged FELASA proposals, which identified four different categories of persons working with experimental animals:

- Category A: persons taking care of animals;
- Category B: persons carrying out experimental procedures;
- Category C: persons responsible for directing or designing experiments;
- Category D: laboratory animal science specialists.

FELASA subsequently published further clarification of these requirements basing its recommendations on functions common to the different categories, rather than on nomenclature, which may vary from country to country (FELASA 1995, FELASA 1999, FELASA 2000). Recommendations for practical, theoretical and ethical aspects were applicable for all categories and included implementation of the Three Rs, and the teaching syllabus for Category C persons is coming to be accepted more widely as providing a basis for training staff working in a range of different areas.

#### FELASA Category A Persons

These are sometimes known as animal care staff or, when their duties are principally related to routine animal husbandry and care, as animal caretakers. Four levels of complexity of job function are identified within this category.

Level 1 relates to persons who provide basic laboratory animal care, working in accordance with verbal or written instructions and under close supervision by an experienced member of staff. Such staff should appreciate the needs of the animals they work with and understand the legal and ethical principles associated with their care and use. Amongst other things, Level 1 staff may carry out routine cleaning, feeding

and watering, check animals for their well-being, operate and maintain cleaning and sterilisation equipment and monitor and record animal environmental conditions.

Level 2 persons have more experience and are able to work more independently. They are expected to have greater knowledge and practical skills than Level 1 staff and may work within specialised animal facilities involving special biocontainment measures or complex care routines and may assist in training Level 1 animal care staff. They are likely to be responsible for daily routines, breeding programmes and specialist husbandry procedures such as post-surgical care and monitoring.

Level 3 persons may hold supervisory or managerial posts and be regularly involved in training and developing animal care staff and overseeing their activities. They are also responsible for more complex activities such as allocation of resources, oversight of breeding programmes, monitoring health and safety issues, preparing reports and liaising with researchers.

Level 4 persons are familiar with theoretical and practical aspects of laboratory animal science and may occupy senior managerial positions within complex animal facilities or possess other specialised skills relevant to their organisation. Some personnel at this level may have responsibilities resembling those of FELASA Category D laboratory animal specialists. Category A Level 4 staff may not be present in small-scale animal facilities.

At the time of writing, FELASA is revising its Category A training guidelines and is likely to recommend fewer levels.

#### FELASA Category B persons

These are scientists who carry out experiments on animals (FELASA 2000). Article 26 of the Council of Europe Convention (Council of Europe 1986) requires that such persons shall be appropriately educated and trained. The competencies identified by FELASA for those working at Category B level include awareness of the ethical framework within which animal experiments are conducted and national and European legislation and regulations which have arisen from these. They should be skilled in performing the techniques they will use, be able to handle animals of the relevant species without stressing them, be able to recognise departures from good welfare and to take appropriate action to avoid or at least minimise these when they occur. Within Europe, there remain considerable differences between national requirements for training and development, although there is a proposal in the draft new Directive, to urge member states to work towards common standards. Similarly, the European Science Foundation has called on member organisations to develop and organise accredited courses on laboratory animal science, including information on animal alternatives, welfare and ethics with a view to establishing more uniform standards<sup>5</sup>.

<sup>5</sup>European Science Foundation Policy Briefing 15 (August 2001 – second edition). Use of animals in research <http://www.esf.org/publications/policy-briefings.html>

### FELASA Category C persons

These persons design and oversee experiments on living animals (FELASA 1995). They should possess a university degree or equivalent in a biomedical discipline at the level of Bachelor or Master, and have completed a basic training programme equivalent to 80h. In addition, where it is intended to use specialised techniques, such as surgery, or to work with different species, such as non-human primates, dogs or cats, additional expertise should be obtained by collaborating with experienced investigators and animal care staff, or by attending specialised courses. Category C persons must: appreciate the basic needs and care of animals and the importance of maintaining them in good health; have familiarity with methods of alleviating pain, including correct use of anaesthetic and analgesic regimes; and understand the need for safe working practices. Because they may be involved in designing experiments, they must also be aware of the importance of implementing the Three Rs.

### FELASA Category D Persons

These are specialists in laboratory animal science (FELASA 1999). The category may include veterinarians, some Category A staff at Level 4, nutritionists, geneticists, architects designing and supervising construction of facilities, pathologists working in diagnostic laboratories etc. Most specialists are university graduates who have acquired particular expertise and experience relevant to laboratory animal science. In addition, they should be aware of all key aspects of the care and uses of laboratory animals. Category D persons should be capable of managing animal, human and physical resources in a laboratory animal facility, securing the health and welfare of animals, providing support to investigators, ensuring compliance with all relevant laws, regulations and guidelines, ensuring the availability of education and training in the humane care and use of laboratory animals and making personal contributions to the humane care and use of laboratory animals by carrying out research in laboratory animal science.

### FELASA recommendations for the syllabus for Category A persons

FELASA proposed that Category A persons preparing for a career in animal care, should initially study for Level 1 examinations (FELASA 1995). These involve learning to handle the commoner species of laboratory animals – the rat, mouse, guinea pig, hamster and rabbit. They should also learn the different techniques and demonstrate competence in handling them and carrying out euthanasia. Trainees are also expected to understand relevant legislation and ethics, and to know how to meet the basic needs of animals including their care and husbandry, as well as learning about routines in animal houses, including health checks, etc.

After a period of approximately 2 years gaining relevant experience by working in animal facilities, FELASA envisaged Category A persons commencing studies towards Level 2. They are expected to develop a deeper appreciation

of legislation relating to the care and uses of laboratory animals and an awareness of safety issues in the animal facility, including safe working practices. During this period, care staff should acquire an understanding of the biology and husbandry requirements of a range of different species, including their nutritional requirements and relevant feeding practices, and the principles and practices underlying management of breeding colonies. They should understand the impact of ill-health on animal colonies and be competent to assess, record and report the health status of species for which they are responsible. Care staff are expected to develop competence in handling a range of less common species of animals, to understand the different methods of euthanasia and know how to choose between them. The syllabus also requires an understanding of the commoner scientific and technical procedures that might be carried out on laboratory animals.

Level 3 builds on the experience gained at Level 2 and at least 3 years of relevant work experience at Level 2 is recommended. Level 3 training prepares personnel for management responsibilities, and includes study of theoretical and practical aspects of managing an animal facility, including budgetary controls, resources allocation and oversight of staffing. Staff at this level are expected to have a good working knowledge of legislation. They should understand the principles of designing animal facilities and the practicalities of environmental monitoring (including the need for and the use of measuring equipment). The syllabus includes more detailed study of the care requirements of a range of different species, a working knowledge of how to recognise and alleviate pain, suffering and distress. It also requires an understanding of the management of conventional and specialised breeding and non-breeding colonies, including a more detailed understanding of their nutritional requirements and the way these should be met. It is also expected that personnel at this level should understand the principles of study design and the conduct of experimental procedures, including anaesthesia, surgery, post-operative care, etc.

### Implementation of training schemes for animal care staff training schemes

Several national training schemes have been established for animal care staff and some of these are recognised worldwide. Three of these will be considered in outline here: those organised by the American Association for Laboratory Animal Science (AALAS), the Institute of Animal Technology (IAT) and the Canadian Association for Laboratory Animal Science (CALAS). In general, the syllabus does not differ greatly from that recommended by FELASA.

Each scheme recognises three levels of competence, summarised in Table 15.1. The lowest level in each case is appropriate for trainee technicians who have relatively recently entered the field and the experience required is relatively basic. AALAS requires those seeking this qualification to have at least 6 months' experience of laboratory animal science, depending upon their academic qualifications at the time the work commences. IAT does not lay down specific requirements; CALAS expects applicants to have a high

**Table 15.1** Levels of competence recognised by three major care-staff associations.

Organisation	Qualification		
	Basic	Intermediate	Advanced
<b>AALAS</b>	Assistant laboratory animal technician	Laboratory animal technician	Laboratory animal technologist
<b>IAT</b>	First Certificate in Animal Husbandry	First Diploma in Animal Technology	National Certificate in Animal Technology
<b>CALAS</b>	Associate registered laboratory animal technician	Registered laboratory animal technician	Registered master laboratory animal technician

school diploma or have worked in animal facility full-time for at least 3 years and to have already successfully completed three basic study modules. In each case, assessment is based on written examinations. IAT and CALAS also stipulate an oral examination and, in the case of the latter, a formal practical examination.

For all three organisations the intermediate level qualification is the basic qualification for experienced laboratory animal technicians. Entry requirements are rather more diverse. The stipulation by AALAS is similar to that for the entry level – at least 6 months work-experience, possibly extending up to 3 years, depending on previous formal educational experience. In the case of the IAT, a candidate would normally hold the First Certificate in Animal Husbandry, although this is not mandatory and some exemptions are available for previous educational experience. CALAS is more prescriptive and requires 5 years of experience after successful completion of the basic qualification.

The most advanced level of qualification is intended for individuals entering senior management positions within animal care facilities. Entry requirements are generally more rigorous, and in the case of CALAS include completion of the intermediate qualification and 5 years of additional continued employment in the field of laboratory animal science.

All organisations encourage involvement with continuing educational programmes, and contribute to the provision of these, but CALAS is the only one requiring all persons holding registered qualifications to meet annual requirements in order to maintain their status.

By contrast, in Australia a national scheme for training animal care staff has been established by the National Training Information Service, and is delivered by a number of local providers at Certificate and Diploma levels over a period of 2 years. The process is competency-based and recognises three levels, corresponding to those who perform care tasks, those who manage them and persons who evaluate and revise practices<sup>6</sup>.

### Orientating the new employee

Recruitment of new employees is often regarded as a means of addressing a particular task within the department, but it should also be seen in the context of developing future talent and contributing to the overall culture of care within

the establishment (Pritt & Duffee 2007). The first few days are important in setting ground rules for the new position, but also in shaping the attitude of a new colleague and integrating him or her into the workforce. Orientation is best done by the immediate line manager, who understands the role of the new employee but is not so senior as to appear remote from the work to be done; although it is helpful to briefly introduce the recruit to senior management at an early stage (Silverman 2002). Make sure that sufficient time is made available for the person to fully understand the key aspects of their role. If it is not the immediate supervisor who is providing the orientation, new employees should be introduced to that person as soon as possible.

Right at the beginning of employment, the line manager should ensure that immediate work details such as the employment contract, pay roll, medical tests etc are dealt with; it may also be necessary for recruits to attend courses or be briefed about responses to emergencies, such as fire procedures and what to do in case of accidents. On a new employee's first day it makes good managerial sense also to sit down and discuss the function of the organisation and the facility within which the employee will be working, the staffing structure and the organisational culture, including responsibilities, humane treatment of animals, sources of advice, whistle-blowing policies, etc. A clear, alternative channel of communication should be established wherever possible, although not for regular use. Where the organisation has a clear mission statement this should be presented and placed in context. Inform the new person about the management style of the organisation and the department, how the role of each individual relates to the organisation and what is expected of them. This personal touch demonstrates the manager's awareness of the activities of the department and informs the recruit about the context of the role so that it is easier for them to come back with questions subsequently should that be necessary. The training expectations and opportunities and the routes for promotion should also be explained. Where it is anticipated that close supervision will be needed for some time this should be indicated clearly.

It is a good idea to accompany new employees to the first rest break of the day, and at this to introduce him or her or to other staff. This provides a relatively stress-free way of introducing the employee to colleagues and vice versa.

If possible, a check list should be developed for orientating new employees. This should identify what information needs to be given up front, and what new arrivals should work out for themselves. Examples of the former may

<sup>6</sup><http://www.ntis.gov.au>

include matters bearing on health and safety, current working routines (such as working hours, lunch and rest breaks), holiday entitlements etc and key contacts both for gaining advice and seeking assistance when necessary; it is a good idea to have this laid out in a staff handbook or similar so that misunderstandings can be avoided. The nature of material which new employees should work out for themselves depends upon the level of employment, and may be relatively basic, or may relate to much more complex issues, for example staffing roles, workloads and procedures and practices. It is also helpful to have available written briefing materials appropriate to the role of the employee. Such materials may include information about staffing numbers, grades and competences, animal health records, SOPs, minutes of committee meetings etc; again, a check list is helpful.

### Developing practical skills

The most effective method of delivering training depends upon the topic to be addressed, the learner's background and preferred way of learning, the trainer's skills and preferences and the facilities available. Wherever possible, a mix of teachers and teaching styles is preferable to a continuous series of lectures, practical classes or seminars. Formal lectures should be restricted to between 45 minutes and an hour, followed by a short break (or a question and answer session) during which students can assimilate what they have been told. Whatever method of training is adopted, students should be encouraged to actively use the information by encouraging participative learning, which is a powerful way of reinforcing learning and relating it to real-life issues.

Competence in the care of animals depends crucially on practical skills, the development of which is an essential part of training in laboratory animal science and requires careful consideration. Hands-on exercises provide a means of relating theoretical understanding (taught alongside or previously) to hands-on skills. Despite this, the teaching of practical skills often receives less attention than that given to knowledge and understanding, probably because it involves a more demanding learning environment and it is more difficult to assess and record levels of performance. These obstacles are easier to overcome than is often assumed.

No course can teach all of the practical skills required by someone working in laboratory animal science, so the objective is to equip students with sufficient theoretical understanding and practical skill to enable them to address practical issues in a safe, ethical and systematic way and to know when to seek help and from whom. Practical skills may be developed as part of formal training courses, subsequently under supervision or, ideally, both. Whichever route is chosen, learning should be supported by enthusiastic, experienced staff. This helps to develop a commitment to achieving and sustaining practical competence in preparation for working independently. In order to ensure the quality of the process, it is important that learning takes place within a structured framework, is overtly linked to underlying theoretical principles, is formally documented

and is properly assessed. However, it must also be made clear that this basic training is only the first stage of a life-long process of learning and development, during which time practices and procedures are likely to change.

Animal care staff can generally devote considerable time to developing expertise and competence, but throughout this process they should be supported and mentored by experienced colleagues. It is particularly important that new employees are made to feel part of a team and that the contribution of their work to the team and the animals for which they care is acknowledged. It is during this early period of training that a good working relationship with more experienced care staff is developed.

If it is proposed to use live animals, the instructor should judge whether this is essential for development of the relevant skills, students must be made aware of their ethical and legal responsibilities and it may be necessary to consult with the ethical review process before commencing. Animals should never be subjected to unnecessary pain, suffering or harm, although the use of animals to teach techniques such as handling, restraint, sexing and basic technical procedures, can cause distress to naïve animals. One way of dealing with this difficulty is to maintain a small stock of animals that have been accustomed to being handled, and are used principally for training purposes. Such animals become compliant, their behaviour is more predictable and they are less likely to be perceived as threatening. Animals used for teaching practical skills should be in good health.

If possible, lessons should be organised to be species- or technique-specific, and learner groups kept as small as possible; one-to-one training is best. In addition, only the smallest number of animals necessary to develop appropriate skills should be used and there must be adequate technical oversight so that each student can be closely supervised during the learning period, and given assistance if necessary. Learners should be allowed to progress at their own pace, to ask questions, receive accurate and supportive feedback and helped promptly to rectify faults. If a formal lesson is involved, it must allow sufficient time for a concluding question and answer session. This allows learners and teacher to critically assess progress and performance. In addition tutors should subsequently assess how well the session went.

Before initiating lessons involving the handling of animals, it is a good idea to explain the techniques with the help of video presentations, practise with surrogate models and then to progress to non-sentient models, which are made as realistic as possible. Sometimes it may be appropriate to carry out a technique on a recently killed animal or possibly one that has been anaesthetised or sedated. These techniques allow tasks to be paused during their performance thereby allowing discussion of key aspects, which would not be possible using conscious animals. When this stage has been completed, or where sentient animals are not involved, teaching usually proceeds with the demonstrator carrying out the practical task, with a commentary explaining its purpose and importance, indicating possible health and safety issues and emphasising possible refinement and reduction methods, safe working practices etc. Skilled performance of a task is characterised by speed and dexterity. Indeed some tasks are difficult to conduct at slow speed;

examples include: capturing an animal in a large cage, opening the mouth of a rabbit or rat to examine its teeth or performing euthanasia.

After demonstrating the task, each student should be asked to repeat it several times, and whilst doing so to provide a commentary. Putting the process into words helps learners to remember the different stages or steps involved. In addition, requiring students to demonstrate a technique immediately after it has been shown to them is a useful way of identifying deficiencies or problems that exist in the completion of that skill and enabling these to be corrected before they become assimilated.

As with teaching theoretical knowledge, a list of practical skills, which a student is required to learn, should be shown to students at the beginning of their training. Also, each class should be logically structured, and one way of achieving this is to prepare a worksheet, which lists the stages and competencies expected. An assessment schedule should be prepared, based on those key points and the assessment process itself should be clearly separated from the process of learning. It is good practice to ask whether the trainee is ready for the assessment to begin or whether he or she would prefer to defer it to later. The proficiency with which the task is performed should be judged using a formal check sheet which lists the key elements which make it up; for example such a list might include having minimal impact on the animal's well-being, successfully achieving the required effect, speed, precision, safe working practices, understanding the underlying rationale etc. Wherever possible a means should also be found of allowing the trainee to comment on the learning process and difficulties which he or she may have experienced, so that future learning sessions can take account of these perceptions.

When training personnel who are already working with laboratory animals at a different establishment, learning may be enhanced by adopting a bidirectional process, in which the instructor asks how the procedure is done at the learner's home institution followed by a discussion about the strengths and weaknesses of various aspects of the method.

## Evaluating competence

It is important that supervisors should be able to assess the competence of those for whom they are responsible. This presupposes that competency can be demonstrated by measurable actions and that the effectiveness with which these are performed can be assessed. Competence cannot easily be measured by setting written examinations or formally structured practical examinations. In particular, it is difficult to assess the attitudes of individuals or their ability to respond promptly and effectively to the unexpected, and in such matters the quality of supervision and workplace support is paramount. Fortunately, in the case of animal care staff, basic competence can usually be judged by observing the performance of individuals in the workplace, the way they handle and respond to the needs of animals, their ability to identify signs of distress or disturbance and their appreciation of the biological requirements of an animal.

## Records of competence

In order for an establishment to provide evidence that measures have been taken to ensure that staff working with laboratory animals are competent, it is important that appropriate records are maintained (Pritt *et al.* 2004). Records should include all staff, including researchers, animal care staff, long-term visitors and students, maintenance, quality assurance and other technical staff whose work may have a direct or indirect effect on the well-being of laboratory animals. At regular intervals line managers should review progress with each employee to ensure that appropriate competences are either proven, or being addressed; this can take place at periodic staff appraisals or performance reviews.

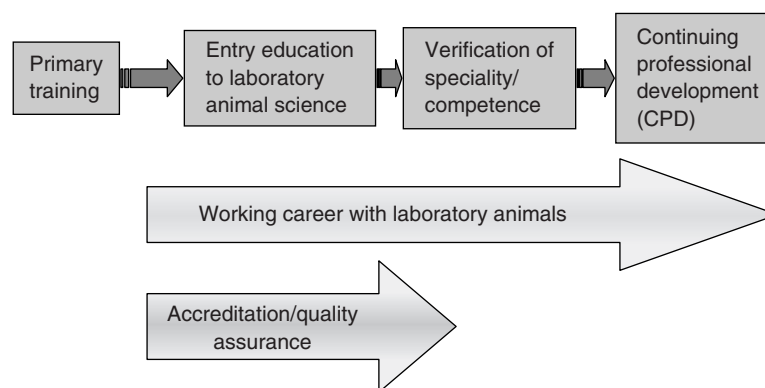

An induction checklist similar to that recommended for the orientation of new employees, can be used for those whose work involves only a very limited range of issues.

Records of training and competence have a number of functions:

- They enable each staff member to be able to demonstrate that they have taken measures to develop appropriate competences.
- They provide staff members with an overall training structure, which over time they will expect to complete. They also demonstrate progress.
- They enable supervisors and managers to gain an overview of the training and development currently undertaken, the resources required to meet this and future demands.
- They demonstrate compliance with the requirements of the Directive and national legislation.
- They save time by ensuring that staff and their supervisors can find relevant information easily.
- They provide a means of analysing areas where a particular focus on training is appropriate, in order to ensure that all staff are brought up to a satisfactory level of competence.
- They may be useful in allocating scientific and technical staff to particular projects, for which they have demonstrated competence.

A distinction should be made between records of competence and records of training, which are less immediate measures of performance. The record should establish when employees started to learn about each task which they are expected to perform, when and by whom competence was deemed to have been achieved, evidence of periodic updating and, where appropriate, the level of that competence. For example, an employee may be deemed competent to perform a task under supervision, unsupervised or to train others to do it. As competences progress, the trainer or line manager should sign off each task for each student. Personnel who attend external training sessions should maintain certificates of attendance with the remainder of the file, in a scanned electronic format when this is necessary.

Records may be kept as a hard copy files such as a loose-leaf folder. This is a relatively simple process, is easily understood, robust, in so far as only one copy exists and it therefore contains all relevant documents and can be made the responsibility of each employee. The disadvantage is that they are available only to the person who holds them,

**Figure 15.1** Schematic representation of life-long education in laboratory animal science.

they could be misplaced, it is time consuming to compare training and competencies of a number of employees and they are geographically restricted to one area of the organisation and therefore unavailable to others who may wish to make use of them.

There are several benefits to maintaining records of competence on relational databases. They can be set up to actively notify staff, supervisors and managers of the current status of training and additional requirements; they may also facilitate evaluation of courses attended by summarising assessment outcomes, course or course provider evaluations and assessments and comments. Electronic records are easily backed up and retrieved and may be distributed by e-mail or printed out when necessary. However, it is important to ensure that electronic records are filed securely, that they are accurate and kept up to date and can only be accessed by authorised personnel.

### Life-long learning or continuing professional development

The necessity of life-long learning, also called continuing professional development (CPD), cannot be overemphasised. Training and education in laboratory animal science must be seen as a continuum starting immediately after completion of entry or formal training and proceeding throughout an individual's career; this is illustrated in Figure 15.1. During this process, there are various quality assurance elements (eg, accreditation of entry education programmes, certification of individuals, speciality examinations and assessment of competence).

It is anticipated that in Europe revision of the Directive (86/609/EEC) will extend the requirement for education and training to include maintenance of competence in all categories. In Europe, the speciality board for veterinarians – ECLAM (European College of Laboratory Animal Veterinarians) – and in the US, ACLAM (American College of Laboratory Animal Medicine), have both introduced systems of life-long learning<sup>7,8</sup>. In the US, AALAS also has a Registry Program for all levels of animal care technicians where documented CPD is required. There is an urgent and compelling need to establish additional systematic frameworks for life-long learning for all the categories of individu-

als working with laboratory animals, and at the time of writing FELASA has engaged with this task by setting up a working group to consider a number of proposals.

The existing and future systems of life-long learning rely on: supplementary courses, such as those described for experimental design (Howard *et al.* 2009); seminars which are organised by several commercial companies; scientific meetings; workshops; and electronic course offerings. It is also likely that more training and education opportunities suitable for life-long learning will appear in the near future. The importance of supervision and CPD training in achieving and maintaining competence and in contributing to good science and welfare needs to be more widely recognised within the research community, both locally within research establishments and by those funding research<sup>9</sup>.

In all training and education there are some items which one is required to master, some with which one should be familiar and finally those which may be nice to know. Allocation of learning should be weighted accordingly with required items filling a majority (about 80%) of the allocated time, while the 'nice to know' pieces may only need a 5% timeslot.

### Quality schemes

The delivery of training is a long-term process usually involving inputs from a number of different individuals. In view of this, it is most important that there is a mechanism in place to ensure high-quality delivery at an appropriate level and time, and that it is effective and within budget. Wherever possible, the assurance of quality should involve a mechanism quite independent of the training process, so as to avoid any conflict of interest. At its simplest, this may involve scrutiny of the results of assessment but a more thorough approach is to also consider the experience of those who have been trained, the quality of their work before and after training and their productivity.

People need to be competent in all aspects of animal care and use with which they will be involved. There are various ways of assessing competence and various problems that need to be overcome in order to do so. Practical skills cannot usually be taught in a short course so there need to be ways of assessing people over the requisite period. Most guide-

<sup>7</sup><http://www.eclam.org/index.php?id=3>

<sup>8</sup><http://www.aclam.org/education/training/index.html>

<sup>9</sup><http://www.apc.gov.uk/reference/2006%2012%2013%20Home%20Office%20response%20on%20Mod%20training.pdf>

lines and recommendations in laboratory animal science require an examination at the end, and sometimes also during the training period. The aim of the examination should be to assess how the student would deal with real-life situations. It is good practice for instructors to combine various taught elements in order to check comprehension. A good examination tests students' understanding by requiring them to retrieve, evaluate, weigh and apply their knowledge and to demonstrate learnt skills.

Irrespective of the training method, feedback from the trainees is a crucial part of the process. This may be done at the end of the educational experience as well as at intermediate time points. Common approaches are by use of an anonymous form or by verbal communication. Questionnaires are increasingly being used on the internet, and quite often a standard format is adopted within an institution, which allows comparisons with other courses.

In addition to training period evaluation, participants can be asked to carry out a self-evaluation (ie, do they feel that they truly learned and did the final outcome genuinely match expectations they had prior to the course). This can be anonymous if in a written form.

The way in which feedback is used for planning future training depends on several factors. Sometimes teachers have difficulties in finding proper ways to make improvements because the feedback may be conflicting. Usually feedback which has active elements proves the most useful and rewarding.

As indicated above, some countries have established schemes to certify the education and training of both animal technicians and veterinary specialists in laboratory animal science or medicine. For example, in UK the Home Office requires that Named Veterinary Surgeons have received appropriate post-graduate specialist training. At present, there are few schemes with similar aims for research technicians and scientists, and attendance at a course of verified quality is often considered to be sufficient. Unfortunately, there are limited opportunities for research technicians to achieve specialist competence certification. There is an example of such a system in a related professional area. The Federation of European Toxicologists & European Societies of Toxicology (EUROTOX) administers a programme based on theoretical training in toxicology and associated practical working, completion of which allows use of the title 'European registered toxicologist'<sup>10</sup>.

Within Europe, the most widely based accreditation scheme is that established by FELASA in 2002. This offers assurance about course quality and is intended to promote wider harmonisation of education and training provision in laboratory animal science (FELASA 2002). The scheme is operated by an accreditation board and is open to courses which develop full competence in any of the FELASA categories. It also provides for the recognition of other well established, non-European courses in laboratory animal science, provided they lead to the development of comparable competences. Currently, the scheme does not extend to

CPD, although this may be added in the future. Course organisers wishing to apply for accreditation submit details of the curriculum, describe the methodology and materials used in teaching and course frequency and size. The board also requests sight of assessment results, evaluations of the course by students and information about the background of teaching staff; clarification or further information may be requested if necessary. Members of the board visit each course and prepare a report which is considered by the full board and also sent to the course organiser. Courses organisers submit an annual, or for courses lasting more than 1 year, biennial report. The accreditation process is conducted and maintained in strict confidence.

# 16 Positive reinforcement training for laboratory animals

Gail Laule

## Introduction

Every animal kept in captivity deserves high standards of animal care. Laboratory animals are no exception; nonetheless, animals housed and managed in a laboratory setting do provide unique challenges. Issues of particular welfare importance, and of relevance to this chapter, are that they may be handled more frequently and subjected to a wider range of more invasive husbandry and medical procedures than most other captive animals.

To maximise the welfare of laboratory animals, it is most desirable to perform these procedures with as little stress for the animals as possible. Less stressed animals make better research models and produce the most reliable research results (Bloomsmith 1992; Reinhardt 1997a, 1997b; Lambeth *et al.* 2006). There are, therefore, dual incentives to protect and enhance the well-being of the animals and mitigate the special conditions of the laboratory setting.

In day-to-day management activities, animals are being trained all the time, whether the staff realise it or not. Every time anyone interacts with an animal, there is some training/communication occurring. The more frequent the interaction, the more established the resultant behaviours become. Animal care staff such as veterinarians, researchers and technicians can produce changes in the animals' behaviour even though they may be unaware that they are effectively training the animal. When a member of animal care staff places a desirable food item in a cage, opens the door and the animal moves into that cage, training has occurred because behaviour has been impacted which can be explained in operant conditioning terms. Nonetheless, much better results can be attained by consciously and deliberately implementing the training process.

The specific terms and techniques of operant conditioning have changed little since B.F. Skinner conducted his original research and presented his results in his book, *The Behavior of Organisms*, in 1938. What has evolved, however, has been the increasing use of these techniques in the care and management of captive animals. There has also been a corresponding development of interest in measuring the effects of training through objective and scientific studies. Therefore, this chapter provides a review of basic training methods, practical suggestions for integrating a positive reinforcement training approach into the management of animals in the laboratory setting, as well as examples of new applications and assessments of training.

Most of the applications of training for management, husbandry and medical purposes in the biomedical field have focused on non-human primates and dogs. As a domestic species and common household pet, laboratory dogs are usually managed differently to other animals, with direct contact in the form of petting, playing, walking on a leash and manual restraint for simple procedures. Training is used to augment an inherently positive human-animal relationship where simple verbal praise has significant value to many individual animals. There are many good resources on the training of dogs within the laboratory setting (Joint Working Group on Refinement (JWGR) 2004; Lindsay 2005; Meunier 2006) and many others on general dog training that present positive training techniques that can be applied to the laboratory setting (Donaldson 1996; Pryor 1999; McConnell 2002; Colflesh 2004) so this area will not be covered in depth in this chapter.

On the other hand, non-human primates are wild animals and do not have an inherent affiliation to humans, in fact, often quite the opposite. The variety of species and numbers of individual animals in laboratories make them prime subjects for a detailed discussion on methods to most effectively and humanely manage and maintain primates in the laboratory setting. The use of training techniques with primates is focused on developing a positive human-animal relationship, gaining safe access to individuals whether singly housed or in a group setting, and gaining an animal's voluntary co-operation in husbandry and medical procedures so that more negative forms of restraint and coercion can be reduced or eliminated.

Farm animals used in research are also prime candidates for training, especially swine. As another group of domesticated animals, the emphasis is on developing a positive human-animal relationship and using positive handling techniques to minimise stress during restraint and to gain voluntary co-operation to the extent of their cognitive abilities, with swine being more amenable to more complex training objectives.

Finally, rodents, rabbits and birds, which make up the vast majority of animals used in research, raise different issues, as they are small enough to be easily handled and restrained for most procedures. Although rodents are capable of learning a wide range of tasks as evidenced by numerous experiments by Skinner and others (Skinner 1938; Ferster 1953; Skinner & Ferster 1970; Herrnstein 1997), in most cases training will be fairly basic, with a focus

primarily on developing a positive human–animal context based on patience and empathy, and a calm, gentle handling style. A culture of training animals to cooperate also encourages a proactive approach to finding the most positive, least invasive method of achieving research objectives.

Despite the differences in training objectives between species, the techniques discussed in this chapter are universal and applicable to all species and individuals to varying degrees. An array of benefits is possible for all laboratory animals, and therefore these techniques should be considered and applied whenever it is reasonable and feasible to do so.

### Positive reinforcement training

Operant conditioning offers two basic options for managing behaviour: positive reinforcement and negative reinforcement or escape/avoidance. The training discussed and recommended in this chapter is based on the use of positive reinforcement. In a positive reinforcement-based system, animals are rewarded with something they like for responding appropriately to the animal care staff's cues or commands (Pryor 1999). Animals gain the opportunity to voluntarily co-operate in procedures, rather than being forced to do so. Positive reinforcement training does not require food or water deprivation. Animals are always provided their daily allotment of food and water and training rewards are often the more preferred diet items, or special treats reserved for training alone.

This differs from negative reinforcement training, where the animal performs the correct behaviour in order to escape or avoid something it does not like. This 'something' can be as simple as being physically handled or lightly restrained. Operationally, it may not be feasible to use positive reinforcement exclusively; however, the positive alternatives should be exhausted before any kind of negative reinforcement is employed. If an escape/avoidance technique is necessary, its use should be kept to a minimum and balanced by positive reinforcement. For example, restraining an animal in a squeeze cage can be immediately followed by offering the animal a preferred food treat.

### Negative reinforcement

The use of negative reinforcement to modify and control behaviour is achieved by pairing pain, discomfort or an unpleasant experience with a particular object or behaviour (Pryor 1999). Fear of the discomfort triggers an escape/avoidance response, which leads to performance of the desired behaviour. Unfortunately, captive animal management practices have traditionally included a large measure of negative reinforcement. The most commonly used negative reinforcers in the laboratory include equipment like nets, gloves or crowding boards used to coerce animals into squeeze cages and other restraint devices. In most facilities, devices like squeeze backs are used as a routine means of encouraging and/or forcing animals to the front of the cage for access and manipulation. Unfortunately, the use of tactics like these is sometimes accompanied by other

unpleasant stimuli like authoritative or loud voices and physical threats, up to and including chasing of animals (ie, primates in large corral situations, livestock in pens) by animal care staff.

Although negative reinforcement works, it could be argued that there is an inherent cost to the animal's overall welfare by being forced to co-operate through the threat of a negative event or experience that elicits fear or anxiety (Reinhardt 1992; Laule & Desmond 1997; Pryor 1999). Studies with farm animals have shown a high degree of fear response associated with negative handling methods, which is surprising since these are domesticated species. In one study on the handling of heifers, using negative methods that included hits and slaps, remote blood sampling through indwelling jugular catheters showed both acute and chronic stress responses in fearful animals (Breuer *et al.* 1998). Negative handling methods with chickens often lead to escape reactions with associated injury, decreased breeding behaviour and greater inter-flock aggression (Jones 1997).

A study on dog training methods found that dogs trained exclusively using reward-based methods were reported to be significantly more obedient and to exhibit fewer problem behaviours, such as food stealing and over-excitement, than dogs trained using negative methods (including punishment), or even a combination of positive and negative methods (Hiby *et al.* 2004).

Smith and Swindle (2006, p. 62) note that swine are highly intelligent and have excellent memories. Therefore, much more effort is necessary to overcome the effects of negative handling experiences compared with the effort expended in using positive reinforcement for training (Smith & Swindle 2006).

### Benefits of positive reinforcement training

In contrast to the costs to animal welfare associated with the use of negative reinforcement, positive reinforcement can achieve similar results with minimal costs and significant benefits. Positive reinforcement training (PRT) can be used to enhance the care, management and welfare of laboratory animals in a number of ways (Kirkwood *et al.* 1989; Reinhardt 1997b; Laule *et al.* 2003). From an animal welfare perspective, PRT may provide animals with greater choice and control and a chance to work for their food (Neuringer 1969; Anderson & Chamove 1984; Sackett 1991; Laule & Desmond 1997), both factors that have been associated with enhanced psychological well-being (Hanson *et al.* 1976; Markowitz 1982; Mineka *et al.* 1986).

For example, consider the animal receiving an injection for a research protocol. Without training, the animal has no choice as to how that event occurs. If escape/avoidance training is used, the threat of a negative stimulus is necessary to achieve the desired behaviour in which the animal presents a leg for the injection, thus exposing the animal to stress from both the injection and the threat. Using a positive reinforcement approach, the animal is trained through shaping and rewards to voluntarily present a leg for an injection, and concurrently desensitised to the procedure to reduce the associated fear or anxiety. (The processes of shaping and desensitisation are described in detail later in

this chapter.) It would seem logical to argue that having a clearer choice as to how events such as injections happen, and being less fearful of them, will contribute to an animal's psychological well-being.

PRT provides the tools to improve husbandry and veterinary care (Reichard & Shellabarger 1992; Laule & Desmond 1994; Bassett *et al.* 2003; Schapiro *et al.* 2005; Coleman *et al.* 2008), enhance co-operation in collection of urine, semen and blood samples (Phillipi-Falkenstein & Clarke 1992; VandeVoort *et al.* 1993; Stone *et al.* 1994; Laule *et al.* 1996; Reinhardt 1997b; McKinley *et al.* 2003; Smith *et al.* 2004), reduce abnormal and/or stereotypic behaviour (Laule 1993; Bloomsmith *et al.* 2007; Bourgeois *et al.* 2007), reduce aggression (Bloomsmith *et al.* 1994), improve socialisation (Desmond *et al.* 1987; Desmond and Laule 1994; Bloomsmith *et al.* 1997; Baker 2004), enhance enrichment programmes (Bloomsmith *et al.* 1997; Laule & Desmond 1997) and increase the safety of the attending personnel (Bloomsmith 1994). A summary of literature on training primates is provided by Prescott *et al.* (2005), together with a clear step-by-step guide for a transport box training protocol.

PRT provides the opportunity for subjects to be desensitised to frightening or painful events, so the events become less frightening and less stressful (Reinhardt *et al.* 1990; Turkkan *et al.* 1990; Perlman *et al.* 2004; Videan *et al.* 2005; Lambeth *et al.* 2006). Many husbandry and veterinary procedures can be implemented with less disruption to all animals, by reducing the need to separate animals from their social groups for many procedures (Schapiro *et al.* 2003; Laule & Whittaker 2007). With greater accessibility to more co-operative animals comes a reduction in the use of restraint and anaesthesia (Bloomsmith 1992; Reinhardt *et al.* 1995; McKinley *et al.* 2003).

Experience has shown that trained animals maintain a high degree of reliability in participating in these procedures and are less stressed while doing so (Reinhardt *et al.* 1990; Turkkan *et al.* 1990; Lambeth *et al.* 2006). Evidence for this includes reports from a number of investigators of reductions in cortisol levels, stress-related abortions, physical resistance to handling and fear responses such as fear-grinning, screaming and acute diarrhoea in a variety of primate species (Moseley & Davis 1989; Verstein & Reinhardt 1989; Reinhardt *et al.* 1990).

One area of great interest and concern is the reduction of self-injurious behaviours (SIBs) in captive primates. Bloomsmith *et al.* (2007, p. 211) reviewed a number of recent studies that, '*... although preliminarily in nature, indicate that stereotyped behaviour and SIB in nonhuman primates can be modified through the use of operant conditioning.*' No studies achieved complete elimination of the problematic behaviour, but significant reductions were documented.

## Training objectives

The following are examples of training objectives relevant to the laboratory setting:

- achieve voluntary co-operation by animals in husbandry, medical and research procedures (ie, blood

draw, injections, urine collection, enter restraint cage, blood pressure measurement, topical treatment, oral dosing, etc);

- reduce fear and discomfort;
- decrease abnormal or stereotypic behaviour;
- reduce or eliminate aggressive behaviour toward conspecifics and/or animal care staff;
- facilitate introductions and socialisation with conspecifics.

## Training methods

To achieve all the benefits that PRT offers requires skilful and effective implementation. It is beyond the scope of this manual to provide a step-by-step guide to the training of laboratory animals. However, throughout this chapter some sample training protocols for specific behaviours have been provided. The following is a brief discussion of the basic tools and techniques of PRT, and suggested steps to be taken in the training process. Although these are used most often with primates, the basics of PRT, i.e. giving an animal something they like for responding correctly, applies to the management of any animal.

### Positive reinforcer

A positive reinforcer is anything that the animal likes. Food, tactile contact, verbal praise, a favoured enrichment item, access to conspecifics and play are all potential reinforcers. Food, which is the most often used reinforcer, can be part of the normal diet, enrichment allotment or an extra treat. It is always desirable to have a variety of reinforcers to choose from.

### Conditioned reinforcer (bridge)

A conditioned reinforcer is an initially meaningless signal that, when repeatedly associated with primary reinforcers such as food, becomes a reinforcer, in and of itself. The animal learns that every time it hears the signal, a reward will follow. The most commonly used conditioned reinforcers in animal training are a spoken word, such as 'good', a hand-held clicker or a dog whistle. The use of a conditioned reinforcer, particularly a clicker, is highly recommended for training laboratory animals. It is a way of saying, 'Good, that is what I want!' It provides precise information that tells the animal exactly what you're looking for. Immediately following the response, the actual reward or positive reinforcement is delivered. The whistle or clicker is called a 'bridge' because it bridges the gap between the behaviour occurring and the food reward being delivered.

### Stationing

In order to train any behaviour, you must have the animal's attention. This requires reinforcing the animal for remaining

in one place and looking at you. Stationing requires periodic reinforcement on an ongoing basis.

## Target

A target is an object the animal is trained to move towards and to touch. Commonly used targets include a ball on the end of a stick, a plastic bottle, a wooden dowel or any object that can be easily held by the trainer or attached to the enclosure. Primates are normally trained to touch their hand to the target. With other species, such as dogs, cats, rodents, cattle and pigs, the animal is taught to touch the target with the nose. This usually occurs spontaneously as most animals are curious to touch or sniff something new. However, if necessary, the behaviour can be taught by moving the object towards the animal's hand or nose a little bit at a time and reinforcing each time it gets closer. At the same time, the trainer should reinforce any forward movement the animal makes towards the target, until contact is made.

A target is useful in several ways. First, the trainer can control gross movement, by rewarding the animal for coming to the target when presented or for going to a target pre-placed elsewhere in the cage. Second, the animal can be trained to stay at the target to achieve or extend stationing. Once this behaviour is established, socially housed animals can be trained to each remain at their own individual target, allowing the trainer to access individual animals within the group. Finally, the target can be used to more safely access body parts, by training the animal to move a foot, paw, arm, leg, chest, back, side, etc to the target.

## Shaping or successive approximation

The primary method for training behaviour is shaping, which is the process of breaking a behaviour into small, individual steps that build upon each other, eventually leading to the completed behaviour. Teaching an animal to touch a target by moving it incrementally closer and closer and reinforcing any movement the animal makes towards it, no matter how small or tentative, is a simple example of shaping. In most cases, shaping starts with reinforcing a naturally occurring behaviour. For example, to train a dog to open its mouth, the first step may be to hold a food treat up for it to see. When the mouth opens in anticipation, a quick 'Good' followed by the delivery of the treat is the first step in the shaping process. The following training protocol illustrates the potential approximations in training a pig to enter a squeeze cage which might be necessary for certain procedures.

- Choose a verbal and/or hand cue for the behaviour, such as 'inside'; use a hand-held clicker as a bridge.
- Place the squeeze cage in the enclosure, or attach to the door of the home cage, and bridge and reinforce when pig looks at the squeeze cage.
- Bridge and reinforce any movement towards the squeeze cage.
- A target can be used to direct the animal to the squeeze cage.

- Bridge and reinforce any exploratory behaviour such as sniffing the squeeze cage, looking inside, touching it with nose or foot.
- Bridge and reinforce any forward movement into the squeeze cage; a target can be attached to the inside back of the squeeze cage and the animal reinforced for moving towards it.
- Use verbal cue 'inside' whenever the animal initiates movement towards the squeeze cage or trainer encourages movement towards or into the squeeze cage.
- Once the animal is entering the squeeze cage, send the animal in and out of the squeeze cage (reinforcing movement in both directions) to firmly establish the cue and strengthen the desired behaviour.
- Reinforce the animal for remaining in the squeeze cage for progressively longer periods of time.
- Begin to move the door, a small amount at a time for short periods of time, bridging and reinforcing each approximation, and slowly increase both until the pig will remain inside while the door closes.
- Slowly increase the amount of time the door is closed.
- When the pig is comfortable in the squeeze cage with the door closed, begin to repeat the last two steps with the squeeze back until the pig will stand calmly when completely restrained by the squeeze back.

The key to successful shaping is the ability to identify appropriate-sized steps. Steps that are too big can create confusion and frustration in the animal. Too small steps can lead to loss of motivation and boredom. Generally speaking, the most common mistake made by new trainers is to expect too much from the animal and attempt steps that are too big. The aim should always be to end each training session on a positive note, no matter how small the step achieved.

## Time out

Punishment, by definition, is designed to eliminate behaviour and occurs after the behavioural response. (Note: The term 'punishment' is often confused with 'negative reinforcement' which has the opposite effect and significantly different timing. Negative reinforcement is designed to increase the likelihood of a behaviour occurring and is used at the same time the behaviour occurs.) In positive reinforcement training, the only acceptable punisher is a time out. Physical punishment is not appropriate except in a life-threatening situation for person or animal. A time out is a very mild form of punishment in which reinforcement is withheld for a brief period of time immediately following an inappropriate response. A time out can vary in quality and length, from the trainer breaking eye contact for several seconds, to walking away for a couple of moments at the most. A time out is a very simple, powerful response to misbehaviour, with two basic rules:

- Do not use a time out too often, or it will lose its effectiveness.
- Always follow a time out by giving the animal another chance. Even if you leave the area altogether, come back and start fresh with no grudges.

## Extinction

Extinction is a very useful method of reducing or eliminating a problem behaviour by no longer reinforcing it. The trainer must determine what exactly the reinforcement is (food, attention, etc) and then ensure that it is consistently withheld whenever the behaviour occurs. Extinction is most effective when paired with reinforcement of a more desirable alternative behaviour. For example, a macaque has been inadvertently reinforced with attention for reaching out to grab people with her hand. The remedy is to ensure that all staff stop giving her attention whenever she reaches out and, simultaneously, that the animal is given attention every time she keeps her hand inside the cage.

## Regression

Training and learning are complex processes and progress is not linear. In fact, it occurs in steps forwards and backwards. Progress the animal makes one day, seems to be forgotten by the next. Then suddenly learning accelerates, and the animal moves two steps forwards. Each of those steps backwards is called regression, and it is a normal part of training.

## Addressing fear

Animals in laboratory environments are faced with a wide array of fearful stimuli and experiences. Hediger (1950) warned of the potential of an enemy-prey relationship developing between humans and captive animals. Animal care staff are in the position of power – controlling food, water, access to physical spaces, choice of conspecifics, movement patterns, daily routines, implementation of research protocols and so on (Caine 1992; Laule 2003). The more negative events the animal experiences in relation to humans, the stronger the link between the stimuli (humans) and the fear response (Hemsworth & Coleman 1998). Studies have shown repeatedly that routine procedures by familiar personnel may result in persistent stress responses (Malinow *et al.* 1974; Manuck *et al.* 1983; Line *et al.* 1989). Increased fighting and wounding in chimpanzees is seen at times of greater human activity (Maki *et al.* 1987; Lambeth *et al.* 1997).

The first strategy employed by animals when feeling threatened and/or fearful is normally escape or flight. However, laboratory animals often cannot escape the fearful stimuli (humans) nor, in most cases, can they even get out of visual range of humans. When an animal cannot escape from a threat, this tends to lead to either the fight response, which we label as aggression (Hediger 1950), or an avoidance behaviour (Boissy 1995). Avoidance is often seen as the rodent who runs from the human hand, the dog that cowers in the corner of the kennel, the pig who emits a loud vocalisation or squeal when approached, or the primate who is pressed against the back of the cage and refuses to approach, even for a food treat.

Laboratory animals will show fearful responses when subjected to a wide array of medical procedures, particu-

larly invasive ones such as blood draws, dosing of medications, injections and administration of topical drugs. Similarly, restraint procedures such as the use of a squeeze cage, tether, gloves, pole and collar, restraint chair, sling and restraint board trigger varying degrees of fear, discomfort and stress in most animals.

More and more studies have shown that routine procedures traditionally viewed as neutral events can be quite stressful to a laboratory animal. Studies on primates in laboratories, conducted nearly 20 years ago by Line and Markowitz and their colleagues (Line *et al.* 1987, 1989) found prolonged alterations in heart rates and cortisol levels after routine procedures such as cage cleaning. Increases in glucocorticoid concentrations, weight loss and suppressed immune system response have been reported in rodents (Obernier & Baldwin 2006), rabbits (Toth & January 1990) and dogs (Bergeron *et al.* 2002) when they are moved, even if it is just to a new cage in the same facility. Whary and colleagues (1993, p. 331) report that in rodent stress studies '... *the most important stress-inducing factor is a sudden change in housing method rather than the method itself*'. Other common procedures that can elicit fear or anxiety in laboratory dogs include change in routine, separation from a stable social group, wearing equipment such as jackets and introduction to new people or conspecifics (Beerda *et al.* 1999).

When ongoing fear is unresolved, the animal can remain in a chronic stress response or state of distress (Moberg 1985; Toates 1995). This state has significant and detrimental physiological effects including slower growth, lower reproductive success and immunosuppression (Selye 1976; Broom & Johnson 1993; Wielebnowski 2002). It can also lead to an array of abnormal behaviors (Meyer-Holzappel 1968; Erwin & Deni 1979; Anderson & Chamove 1980).

Non-human primates are particularly prone to stereotyped behaviours when housed currently (or previously) in sub-optimal or inappropriate environments. These include pacing and repetitive somersaulting, headnodding, self clasping and rocking (Bellanca & Crockett 2002; Lutz *et al.* 2003; Bourgeois & Brent 2005); abnormal appetitive behaviours such as coprophagy and regurgitation and reingestion (Bellanca & Crockett 2002; Struck *et al.* 2007); over-grooming and resultant alopecia (Honest *et al.* 2005); and self-injurious behaviours with and without wounding (Tiefenbacher *et al.* 2004; Bloomsmith *et al.* 2007; Bourgeois *et al.* 2007). Rodents display repetitive backflipping (Callard *et al.* 2000), stereotypic digging (Wiedenmayer 1997), barbering (DeLuca 1997) and bar- and wire-biting (Orok-Edem & Key 1994; Würbel *et al.* 1998). Rabbits exhibit excessive grooming and barnawing (Hansen & Berthelsen 2000). Dogs and cats engage in self-injurious biting (Laboratory Animal Refinement and Enrichment Forum (LAREF) 2007); and pigs engage in barbiting and excessive rooting and rubbing (Smith & Swindle 2006).

From a practical perspective, it will be difficult to gain the voluntary co-operation of an animal in any husbandry or research procedure if that animal is overwhelmed by fear. The animal must be able to tolerate the stimulus to the degree that a food reward is accepted and learning is possible. Therefore, it is important to:

1. recognize fear;
2. acknowledge its effects;
3. adjust behavioural criteria and expectations accordingly;
4. develop and implement strategies to reduce fear.

Positive reinforcement training provides animal care staff with the techniques to adopt a proactive approach to diminish the level of fear and thus the accompanying stress that an animal experiences. Doing so can directly enhance welfare, reduce resultant abnormal behaviour and increase the likelihood of achieving a greater degree of co-operation by the animal in behavioural objectives.

### Improving the human–animal relationship

An appreciation of the human–animal relationship is important. A patient, empathetic handler will contribute much towards the well-being of an animal, no matter what the circumstance or the species. Whether handling a rat, restraining a dog or reassuring a primate, a gentle hand, quiet voice and measured approach can create a more positive experience for the animal.

Smith and Swindle (2006) emphasise the importance of the influence of animal care staff on pig behaviour in the laboratory. With gentle handling and positive reinforcement techniques pigs can be readily trained to tolerate a simple physical examination, to walk out of their cages to another location and to accept restraint, including manual, mechanical (i.e. a sling) and chemical.

One of the most effective ways to establish a positive relationship with captive animals is to have some positive interaction with them on a daily basis. Bayne *et al.* (1993) found that 3–5 minutes of daily positive interactions and treat provisioning for singly housed rhesus macaques (*Macaca mulatta*) resulted in decreased abnormal behaviour and overall fear. Similarly, Baker *et al.* (2003) found that PRT, used as an enrichment strategy for primates, resulted in reduction of abnormal behaviour and anxiety-related behaviour. Studies have shown that petting a dog can have a calming effect and decrease heart and respiratory rates (Gantt *et al.* 1966) and may be effective in reducing cortisol responses to aversive situations, such as physical examinations, injections and blood sampling (Hennessy *et al.* 1998). Ferrets that are handled regularly become less troublesome to handle and less fearful (Ball 2006). Numerous studies demonstrate the beneficial effects of frequently handling research animals in a patient and calm manner before initiation of study protocols (Meaney *et al.* 1991; Chapillon *et al.* 2002; Conour *et al.* 2006).

Tuli *et al.* (1995, p. 132) suggest that ‘animals habituated to a handler or animals that are gentled in early life show less handling stress in later life’. Davis (2002) documented the ability of a variety of species to discriminate between handlers that were either simply familiar or those that had been associated with a positive experience. Finally, Wolfle (1985, p. 450) argues, ‘It is not an overstatement to say that the right animal technician instils qualities in the animals that make them better and more reliable research subjects.’

PRT is a powerful vehicle for creating a positive bond between human and animal. The very nature of the process

– gaining the voluntary co-operation of the animal and rewarding behavioural performance with something the animal likes – enhances both the behaviour and the motivation to perform it, and all within the context of a positive interaction. Furthermore, specific training techniques that are directed at reducing fear can serve the dual purpose of achieving a positive human–animal relationship while reducing stress on the animal.

### Desensitisation

Desensitisation is a process designed to ‘train out’, or overcome, fear. By pairing positive rewards with any action, object or event that causes fear, that fearful entity slowly becomes less negative, less frightening and less stressful. The effectiveness of desensitisation can be assessed in two ways. Is there a positive change in the animal’s willingness to voluntarily co-operate in the event? And are there changes in the animal’s behaviour in relation to the fearful entity that indicate reduced stress or fear? Through desensitisation, animals learn to tolerate and eventually accept a wide array of frightening or uncomfortable stimuli. Effective desensitisation relies on two elements: precise reinforcement and good judgement in determining where the process should start and how fast to move through the steps to the completed behaviour.

Precise reinforcement means catching the exact moment the animal experiences the stimulus. For example, when training an animal to accept an injection, or to tolerate a blood draw, the feeling of a needle piercing the skin is a potentially frightening and painful experience. Effective desensitisation requires pairing many positive rewards directly with that experience, or with a similar experience. Training may include pairing positive rewards with the experience of being touched with a progression of items, starting with the trainer’s finger or a wooden dowel, then a capped syringe, then a needle with the end cut off so it is blunted and finally the real needle. In each case, the bridge (such as verbal ‘good’ or clicking sound) must occur at the exact moment the animal feels the object touch the skin. The bridge is then immediately followed by a reward. The animal must experience this over and over again, with the touch slowly moving from very light to the final experience of actually piercing the skin. If desensitization is done well, the animal will voluntarily accept the injection, or allow the blood draw, and recognisable signs of stress and fear will be diminished or absent.

The second key to effective desensitisation is determining the starting point and how fast to progress. If fear of the syringe is so great that the animal cannot accept a food reward in its presence, then learning cannot occur. In that case, the first step may be to offer the animal a brief glimpse of the syringe, or increase the distance between the syringe and the animal, pairing these experiences with the bridge and food reward. The next step may be moving the syringe towards the animal in small increments, each one paired with the bridge and reward. How quickly progress occurs and how big each step is depend on how the animal reacts to each approximation.

Desensitisation can be used in many situations. Animals can be desensitised to husbandry and research procedures,

new enclosures, unfamiliar people, specific people like the veterinarian, novel objects, strange noises and other possible aversive stimuli.

### Habituation or acclimatisation

Habituation refers to the process of gradually getting an animal used to a situation which it normally avoids, by prolonged exposure. It differs from desensitisation in that there is no direct pairing of a positive reinforcer with the stimulus, or with the experience of fear or anxiety in relation to the stimulus. The animal simply experiences the event repeatedly until it no longer displays the behavioural signs of fear or stress. At that point it is assumed to have habituated to it. This is a widely accepted approach to managing laboratory animals and their fearful, painful or stressful experiences (Ruys *et al.* 2004). The reliance on habituation, rather than desensitisation, is one of practicality. Time constraints and limited staff place pressures on animal care staff to get the necessary behaviour in the easiest and quickest way possible.

For example, habituation is often used to accustom primates to chair restraint. It is readily acknowledged that forced restraint is stressful for an animal. Behavioural signs include physical resistance and struggling, heightened agitation, alarm vocalisations and facial expressions of fear and defensive threats (Reinhardt *et al.* 1995). Physiological changes include increased respiration and heart rate, activation of the hypothalamic–pituitary–adrenal (HPA) axis and the secretion of glucocorticoids in proportion to the intensity of the perceived threat.

With repeated exposure to the restraint, behavioural and physiological responses diminish, which is cited as evidence that the animal has become habituated to the experience. However, as one study by Ruys *et al.* (2004) showed, this may not be indicative of actual habituation to the event. Changes in behaviour may be simply an effective coping strategy as the animal learns that attempts to escape are futile and therefore submits. Study results showed that after repeated chairing of rhesus macaques (*Macaca mulatta*), although expected behavioural changes occurred, there was still an HPA response, albeit diminished, and increased cortisol levels, especially in the initial period of restraint. Their conclusion was that ‘... the pattern of results that we found suggests that rhesus macaques habituate behaviourally but not physiologically to their chair restraint’ (Ruys *et al.* 2004, p. 212).

This study is referenced because it is a good reminder that compliance on the part of the animal may not be indicative of the level of stress the individual is experiencing. The handling and training methods used should increase behavioural compliance and at the same time reduce stress and fear. Simply providing repeated exposure to an uncomfortable event may not be enough. A better approach is to reverse the process through the use of desensitisation techniques. As the animal becomes less fearful, behavioural compliance increases.

This was demonstrated in a study by Lambeth *et al.* (2006) where researchers examined records of 575 anaesthesia events for 128 chimpanzees. Animals either voluntarily pre-

sented an arm or leg for the injection, or were given the injection involuntarily, through coercion or the use of a dart gun. The training process used a combination of shaping and desensitisation. Haematological and serum chemistry values indicative of acute stress in chimpanzees (ie, total white blood cell (WBC) counts, absolute segmented neutrophils (SEG), glucose (GLU) levels and haematocrit (HCT) levels) were analysed in both conditions. Results showed that total WBC counts, blood GLU levels and SEG levels were significantly lower in animals that voluntarily presented than in animals that received an injection involuntarily. Perhaps the most noteworthy results came from within-subject conditions showing that individuals had significantly lower WBC and GLU levels when they voluntarily presented for the injection than when they did not.

Therefore, whenever possible, it is worth the time and effort to desensitise animals to uncomfortable or frightening events, rather than by simply habituating them to it. However, habituation can be quite useful as a preliminary step before formal desensitisation. For, example, in the sample training protocol for training a pig to enter a squeeze cage, the first step might be to attach the squeeze cage to the pig’s enclosure and allow free access to it for a couple days. Adding some food inside may make exploration of the cage more likely. This process of habituation, implemented before actual PRT begins, may shorten the time required for training and desensitisation. Furthermore, if habituation is the only method employed, animal care staff should at the very least provide some positive reinforcements, i.e. food rewards, in conjunction with the experience as frequently and as generously as possible.

### Socialisation training

With the growing requirement to house social primates in pairs or small groups, it is necessary to have the ability to facilitate introductions and increase the likelihood of maintaining stable groupings of animals. One PRT method has been used successfully with a wide range of species to address these objectives (Desmond & Laule 1994; Laule & Whittaker 2007).

### Co-operative feeding

Co-operative feeding is a technique used to enhance positive social behaviour and reduce agonistic behaviour (Bloomsmith 1992; Bloomsmith *et al.* 1994; Cox 1987; Desmond *et al.* 1987; Laule & Whittaker 2007). It is of particular value in managing socially housed primates in laboratories. Many staff caring for captive animals have used subterfuge and distraction when attempting to provide subordinate animals with food, enrichment or other desirable resources. However, these techniques actually exacerbate aggression, causing dominant animals to become more vigilant in order to maintain control of the desirable resources. In captivity, aggressive interactions can have serious consequences if group members or cage mates are unable to escape the aggressors.

Co-operative feeding conforms to operant conditioning theory, which states that the consequences of a behaviour

determine whether or not it will recur (Pryor 1999). During co-operative feeding, the dominant animal receives reinforcement, in the form of desirable foods, whenever the subordinate animal receives these resources. This technique reinforces the dominant animal for behaviour that is co-operative rather than aggressive, thus strengthening co-operative behaviours. When consistently and skilfully applied, co-operative feeding has two positive outcomes: (1) the dominant animal becomes less aggressive and more tolerant, and (2) the subordinate animal becomes less fearful and more willing to accept rewards in the presence of the dominant animal.

Co-operative feeding can be used to enhance introductions of animals, prior to and after they are given physical access to each other. Initial training can be done with animals separated in adjacent cages. However, they must have visual access to each other so the dominant animal can see what s/he is being reinforced for. A housing situation with multiple animals may require more than one trainer in the initial stages. If so, one trainer should control the dominant animal and the other trainer feed the rest of the animals, following the protocol so the dominant animal is being reinforced specifically for the other animals being fed. The training should progress so that eventually one person feeds the animals.

The following is a sample protocol for applying co-operative feeding to two pair-housed primates. Tools include a clicker and food, including some special food items for the dominant (target) animal.

- Cue the target animal to sit, then reinforce.
- Give the second animal a piece of food and as he takes it, bridge and reinforce the target animal with two to three pieces of food for sitting and staying without interfering (if necessary, cut the food smaller to keep volume down).
- Provide verbal and visual information to the target animal – look at him and say ‘Good!’ as you feed the other animal, say ‘No’ if he breaks position and immediately ask him to sit again.
- Ignore minor interferences (head bob, reaching for food, etc) as long as the second animal is successful in taking food.
- If the target animal is aggressive towards or intimidates the second animal so he won’t take food, bring the target animal back to sit/stay, then resume the feed.
- Use a high rate of continuous reinforcement at first (one piece for second animal, two to three pieces for the target animal) then as progress is made, the amount and frequency of reinforcement for the target animal can be slowly reduced.
- Give the target animal a special treat at the end of every successful session.

### Training programme development

The success of a positive reinforcement-based animal training programme in the laboratory environment depends on many factors. Primary among them is the ability of the personnel to understand the principles of operant conditioning

and effectively apply PRT techniques. Training is a skill that takes time and practice to develop. Poorly planned and implemented training will yield minimal benefits at best. Second, the commitment and motivation of personnel will have an enormous impact on the quality of the training experience and the results achieved. Third, consistency in handling and training techniques between all staff who work with the animals is critical. Positive reinforcement methods should be applied to the daily husbandry and cleaning routine as well as to the training of specific behaviours for research protocols. Fourth, learning occurs through repetition. Therefore, the more opportunity the animal has to practise the behaviour, the quicker results will be realised.

It is important that every institution recognises the need to invest resources in training staff in PRT techniques. By developing staff that are familiar with these techniques and have some degree of competence in using them, the quality of care of laboratory animals can be greatly improved. Although it may not be feasible to develop equal training skills in all animal care personnel, one approach that is effective is to develop multiple levels of skills in staff. For example, everyone who works with the animals should have a basic understanding of operant conditioning techniques and be capable of using and maintaining trained behaviour once it is complete. They should also be capable of implementing simple training protocols, for example, incorporating reinforcement into interactions with animals when they comply with husbandry and medical procedures. A smaller subset of staff should have training skills that allow them to design training protocols and train new behaviour. These individuals can then plan and implement PRT to improve daily handling and husbandry procedures and better prepare animals for research protocols. Finally, at least one individual on site should have sufficient training skills to resolve difficult situations as they arise, as well as coordinate and oversee PRT activities.

Despite the complexity of this process, if viewed in the long term, the apparent costs of implementing a positive reinforcement training programme can be turned into real benefits for the staff, animals and the institution. Training sessions provide a context where person and animal can have a mutually positive interaction and positive interactions ultimately strengthen the human–animal bond, enhancing the quality of life for laboratory animals. Finally, in a pragmatic sense, training success can reduce the use of restraint and anaesthesia and save time, labour and money over the long term (Bloomsmith 1992; Luttrell *et al.* 1994; McKinley *et al.* 2003).

### Practical approach to training laboratory animals

The reality of life in the laboratory may not always be ideally suited to a formal PRT programme. For example, care staff are normally responsible for large numbers of animals, limiting the amount of time they can spend with individual animals. Housing conditions vary from small caging, that severely restricts the animal’s range of physical movement, to big corrals with large numbers of animals, that are difficult to access on an individual basis. Research protocols

often dictate or restrict the amount and type of food animals can receive, the type of physical activity they can engage in and acceptable enrichment options. Finally, staff are often given only short periods of time to prepare animals for research procedures.

In many cases, PRT, in its purest form, may not be feasible in this setting. Limitations in the training skills of staff and time constraints may not allow for the step-by-step shaping process of a behaviour using totally positive reinforcement. The cognitive abilities of different animals, as well as the complexity of the behavioural requirements, will also vary. Although the techniques of PRT are universal, species and individuals within species will have their own unique temperament. A significant element of skilful training is the ability to be sensitive and responsive to these often subtle differences, and to adapt and respond appropriately. However, even with basic skills, it is feasible to integrate positive reinforcement techniques into existing management procedures for most species. In order to develop such a system, the following actions are recommended and ideally should be integrated into existing operational procedures.

1. Use the basic principles of positive reinforcement training to improve the human–animal relationship. For example, in a primate colony, moving through a room with multiple cages and stopping for even a few seconds to say some kind words and deliver a food treat to each animal can contribute greatly to a positive human–animal relationship. It may reduce the animal’s fear of humans and create the context for more co-operation on the part of the animal in future procedures. Therefore, it is most beneficial to incorporate this simple conditioning into care routines at breeding centres and import/quarantine facilities. Whenever possible, hand feeding and rewarding can evolve into training of simple cues and responses such as coming to the front of the cage and remaining there, sitting, climbing on the cage front, presenting a hand or arm and so on. This is also a great opportunity to start the training process with young animals, which are generally quite responsive to PRT. The sooner this process is begun, the greater the benefits in the long term.
2. Provide animals with the opportunity and motivation to co-operate voluntarily in activities and procedures by incorporating two basic positive reinforcement training techniques into interactions. First, provide a cue or a signal that clearly tells the animal what he is being asked to do. If the animal can perceive and understand the signal, it can then respond with the correct behaviour. Second, if the animal responds appropriately, provide a reward. Even if the animal care staff must resort to negative reinforcement (ie, moving a cage back to restrict space, or showing the animal a net) to gain compliance, when the behaviour occurs, the treat is given. Over time, the use of negative reinforcement is steadily decreased until it is no longer necessary. With a clear signal and regular reinforcement, the animal now has the information necessary to co-operate and the motivation to do so. It is surprising how often those two elements are overlooked.
3. Always give the animal a reasonable opportunity to co-operate in the desired behaviour. Time constraints may be an issue, and numbers of animals that require training may be high, but every animal deserves a measure of patience on the part of the human. For example, if a primate must be restrained in a squeeze cage, rather than immediately moving the cage wall all the way forward, the wall should be moved in increments, offering the animal the chance to co-operate by moving to the front of the cage after each increment. When it complies, a reward is given. Total co-operation will not be immediate, but over time the animal will learn what is expected and will probably co-operate without having to be fully restrained. In the same way, when it is necessary to handle or restrain a rodent or rabbit, a patient, gentle hand and a treat following the procedure is the most humane and positive way to carry out the task and gain greater co-operation.
4. Always look for and employ the least invasive methods to achieve objectives. Research protocols put great demands on animals and animal care staff. Results are dependent upon consistent means of collecting samples, administering oral medications, applying topical applications and so on. However, it is often possible to meet the specific study requirements in a less invasive or stressful way. For example, collecting urine samples from group-housed callitrichids through training animals to urinate quickly and reliably into a vial (McKinley *et al.* 2003) or on a clean platform inside the cage (Smith *et al.* 2004) yields the same results, ie, the individual urine sample, as separating animals for extended periods of time until they urinate. In two studies, one with rats (Huang-Brown & Guhad 2002) and another with rabbits (Marr *et al.* 1993), animals were trained to take their oral doses of medication in chocolate and a sucrose solution respectively. In both cases, drug absorption and serum levels were appropriate. This allowed the animals to avoid a very stressful experience of gastric gavage, while meeting the study needs.
5. Plan ahead: prepare for research protocols by identifying which animals will be involved, what behaviours are needed, what equipment will be used, how long the procedure will take, how often it will occur and other relevant factors. Then focus some effort on a daily basis towards preparing the animals for the protocol. There are two fundamental objectives of this work. First, to desensitise each animal to components of the process that may be new, frightening or uncomfortable such as medical equipment, the feel of a needle prick, the experience of being restrained and so on. The second is to gain the voluntary co-operation of the animal in as much of the research protocol as possible.
6. Find ways to train regularly and frequently – animals, like humans, learn through repetition. Ideally, PRT sessions should be conducted on a daily basis with each of the animals. For best results, it is advisable to limit the number of individuals conducting new training. During this phase, consistency between sessions is a critical factor in the effectiveness of the training and how quickly new behaviours are completed. Consistency

can be achieved in a couple of ways. Individual animal care staff can be assigned to individual animals, training them for all new behaviours related to the protocol. It is also possible to assign a back-up trainer to work on the behaviours during the primary trainer's days off, as long as good communication is maintained between those individuals. This allows for a 7 days a week training regimen, providing opportunities for daily practice and repetition. Another option is to divide up responsibility for training new behaviour so that several individuals work with each animal, but each person only works on his or her assigned behaviour.

7. Incorporate PRT into the daily routine. If regular training sessions are not possible, then training should be incorporated into the daily routine. For example, every time animal care staff interact with the animals during cleaning, feeding, visual inspections etc, they carry with them an instrument or apparatus that will be used in the procedure and give each of the animals a treat. If possible, when some large piece of equipment is to be used, it should be brought into the room and the animals given a treat while it is present. A simple process like this, done regularly, can dramatically reduce the fear response to the item. Similarly, training for voluntary co-operation in the research procedure can be initiated and implemented. Even a couple of behavioural responses each day can have a beneficial impact. For example, a member of animal care staff can introduce a target to teach stationing and each day ask the animal to come to the target for his enrichment. Or he or she can: carry a syringe and just show it to each animal prior to giving the enrichment; or hold the dog or cat's paw for a couple of seconds; pick up the rat or rabbit; rub the pig's belly with the sling, and then reinforce or enrich. By identifying individual components of the final behaviour and working on these relatively small units on a daily basis, the animal is slowly conditioned to accept and co-operate with the process. Even if the final behaviour is not trained in its entirety, there is a greater likelihood that the animal will be more co-operative and less fearful when the actual procedure is implemented.
8. If habituation is used to provide repeated exposure of the animal to a procedure, add reinforcement to the process. As discussed earlier, habituation may only eliminate the behavioural responses to the situation, but not actually reduce the associated stress. By adding at least a cursory element of desensitisation to the process, ie, pairing this repeated exposure with positive rewards, the animal has the opportunity to comply and feel less fearful while doing so.

### Concluding remarks

The use of positive reinforcement training as an animal care and management tool offers many benefits to biomedical facilities and to their animals, staff and researchers. Primary among these is the ability to gain the voluntary co-operation of animals in husbandry and research procedures. Through

techniques like desensitisation, the fear and stress associated with these procedures can be significantly reduced. PRT can be applied in a wide array of situations with a wide variety of species. When appropriately and skilfully applied, positive reinforcement techniques represent a viable option to the traditional approach to the management of laboratory animals. By making the shift to a more positive reinforcement-based system, the welfare of the animals is significantly enhanced while providing better research models for the biomedical community.

# 17 Euthanasia and other fates for laboratory animals

Sarah Wolfensohn

*To be or not to be: that is the question:  
Whether 'tis nobler in the mind to suffer  
The slings and arrows of outrageous fortune,  
Or to take arms against a sea of troubles,  
And by opposing end them? To die. ...*  
Shakespeare: Hamlet (1601) Act 3 Scene 1

Is it better to be dead, or better to be alive and suffering? Does being a laboratory animal count as an 'outrageous fortune'? Is that any worse or better than being a farm animal or a pet or a wild animal (Wolfensohn & Honess 2007)? These are difficult questions with no simple answers, as ethicists, philosophers and even great playwrights have found. Many hours, days or even careers have been spent debating this question down the centuries. But endless debate does not help the welfare of a laboratory animal whose fate a scientist, a vet, an animal care technician or an ethical review committee is trying to decide. Decisions on euthanasia must be reached swiftly and appropriate actions taken promptly if suffering is to be prevented. Euthanasia is defined as the bringing about of a gentle and easy death (Oxford English Dictionary); so should not, itself, cause pain or suffering.

The optimum time at which to kill an animal in the laboratory will be affected by a range of parameters, and the combination of the factors that lead to a decision as to precisely when to carry out euthanasia has evolved into the concept of the humane endpoint (Hendriksen & Morton 1998). The idea behind the humane endpoint is to define a set intervention point which allows the collection of quality scientific data but limits the amount of suffering, either contingent or direct (Russell & Burch 1959), to which the animal may be subjected. The endpoint may be purely temporal; for example, the animal will be killed x hours/days/weeks after a particular technique is carried out when the adverse effects are not expected to increase but a time limit is set nonetheless, thus reducing the potential for contingent suffering. Or there may be a defined measurable point relating to a physiological parameter; for example, when the blood glucose level reaches x mmol/l which indicates that the animal is in the required physiological state to gather the data, but not yet experiencing deteriorating clinical signs. Or, in some cases, the defined intervention point may be based on a collection of scores cumulatively measured, sometimes with weightings for more challenging clinical conditions, to ensure that any potential suffering is limited

to the minimum consistent with obtaining satisfactory data. The collection of usable data is essential since, without that, any suffering caused would be pointless and unethical, as the animal would have been used without purpose or scientific output. Well designed experiments detect early signs of distress, allowing the definition of a point at which adequate data can be obtained, but the suffering of the animals is kept to a minimum. The precise time at which to kill the animal must be based on appropriate and accurate clinical judgement, assessing the degree of suffering and the potential loss of data. Ideally, the maximum achievable information should be obtained from each animal while keeping suffering and distress to the minimum. Using this concept of the humane endpoint will refine the procedure and reduce the costs to the animals, improving the justification and the cost-benefit equation for the experiment. It is unusual for laboratory animals to reach death in a laboratory as an expected consequence of a procedure without the intervention of euthanasia. For further detail on humane endpoints see Chapter 2.

Someone in the laboratory will have to carry out the procedure of euthanasia and actively kill the animal rather than leaving it to die, and this in itself generates a particular set of problems. Euthanasia is not necessarily the most difficult part of the procedure for the animal, indeed if carried out competently it may be easier for the animal than those parts of the procedure that may have caused pain, suffering or distress. On the other hand, the carrying out of euthanasia can be the most difficult part for the researcher.

For a doctor, euthanasia is illegal in most countries. For medical practitioners, treatment is aimed at palliative care, analgesia and supportive therapy, a quality death, but one that occurs naturally and is not actively brought about. Conversely, for veterinary practitioners, euthanasia is part of everyday life in the surgery. The majority of domesticated animals end their lives at the hand of man: millions of food animals are slaughtered in the UK each year (see Table 17.1), production animals are killed once they cease to be viable economic units and pet animals are often subjected to euthanasia once a decline to inevitable death begins to be apparent. The reasons for requesting pet animal euthanasia are many, some of which reflect concern for the animal's well-being; but some are a mixture of concern for the animal and concern for the owner's feelings and their own ability to cope with death, and some are a reflection of the brutal financial facts of animal care and death. Phrases such as 'I

**Table 17.1** Number of agricultural animals slaughtered in the UK in 2006 (MLC 2007).

Species	Number of animals slaughtered
Cattle	2 643 000
Sheep	16 414 000
Pigs	9 096 000
Broilers	807 200 000
Turkeys	17 300 000

wouldn't want him to suffer', 'I don't want to see him suffer', 'I want to be able to remember him as happy', 'I don't want the children to see him die', 'I don't want to pay for treatment' are regularly heard in veterinary consulting rooms and reflect the complex interactions of factors that lead to the decision of when, or if, to carry out euthanasia.

For the veterinary surgeons themselves, carrying out euthanasia can give rise to a mixture of emotions depending on the individual circumstances. They are in a unique position of being able to offer a quiet and painless death to animals under their care (Bowlit 2007), but in some cases it may be interpreted by the pet owner or by the veterinary surgeon himself, as a failure on the part of the veterinary surgeon to effect a satisfactory cure (BVA Ethics and Welfare Group 2007). Depression is common among veterinary surgeons and as a demographic group they have one of the highest suicide rates, possibly due to stigmatisation of mental health disorders and a reluctance to seek medical help, professional and social isolation and ease of access to lethal drugs. Combined with the acceptance of killing as an act, a proven ability to carry it out efficiently and a high level of stress in the working environment, the proportional mortality ratio for veterinarians is significantly higher than for medical or dental practitioners, farmers or pharmacists (Mellanby 2005; Bartram & Boniwell 2007). Coping with death of research animals can also take its toll on the emotions of those involved (Pekow 1994; Halpern-Lewis 1996).

All of these factors play their part in the way that euthanasia is viewed in the context of a laboratory animal environment; sometimes making the researcher more and sometimes less willing to carry out euthanasia. Individual psychological state is important and must be handled carefully by all those involved, but must not be allowed to affect the welfare of the animal under study.

Experimental animals may need to be killed for a variety of reasons but virtually all will be killed long before their natural life expectancy comes to an end. It may simply be that the end of the experiment has been reached and all the necessary data have been collected. Animals may also be killed if their health gives cause for concern, if they have reached the end of their breeding life, if they are unwanted stock, or if tissues and blood are required for *in vitro* studies. Article 8 of Council Directive no. 86/609/EEC states that the animal should not be subjected to severe pain, distress or suffering and that if it is not possible to treat it with pain-relieving means it shall be immediately killed by a humane method. Killing an animal is never a pleasant task for the person carrying it out; but it does not have to be unpleasant for the animal, provided it is carried out competently, swiftly and humanely.

An animal is regarded as continuing to live until the permanent cessation of the circulation or the destruction of the brain, therefore any method of killing used must ensure that one or both of these criteria is met. As with any scientific procedure, humane killing requires a certain amount of preparation. Points that should be considered include:

- **Training.** The person carrying out the killing must be able to do so without causing distress to the animals involved. Any method of killing can cause distress if badly performed, so staff must be suitably trained and competent in the methods and with the equipment they will be using.
- **Handling.** Animals must be handled carefully and competently without causing them distress. Animals will often be calmer if held by a person with whom they are familiar. Staff must be competent to hold animals properly and securely. Some methods of killing may require two or more people to hold the animal; there must be sufficient trained people available to do the job properly.
- **Location.** If an animal is frightened but conscious it may show behavioural responses such as vocalisation, struggling, urination and defecation. Any fear or distress experienced can be communicated by sound or smell to other animals causing further distress. Some of these responses may be exhibited by unconscious animals before death occurs. When killing entire cages of animals it is advantageous to kill them in the home cage as this causes much less stress (Hackbarth *et al.* 2000) than removing them to an unfamiliar location. In the case of rodents, the reactions of conspecifics may not be apparent when an animal is killed in the same room; although for other species it is considered preferable to remove them to another area away from the group before they are killed. In any event, in an emergency, it is better to euthanase the animal immediately rather than to move it.
- **Equipment.** Some methods of killing require equipment such as anaesthetic induction chambers, carbon dioxide cylinders, bottles of anaesthetic agents, needles and syringes, or firearms. It is essential to make sure that any equipment is clean, prepared and ready for use at the start, cleaned again before subsequent use with another animal, and that the operator is fully competent to use it.

There are several different methods of euthanasia available. There is a variety of guidelines that can provide assistance with the considerations relating to the carrying out of euthanasia (Canadian Council on Animal Care (CCAC) 1980; Close *et al.* 1996, 1997; American Veterinary Medical Association (AVMA) 2001, 2007; Reilly 2001; American Association of Zoo Veterinarians (AAZV) 2006; Office International des Epizooties (OIE) 2007). The following points should be considered when choosing a method of humane killing (Wolfensohn & Lloyd 2003; Carbone *et al.* 2004):

- death must occur without producing pain;
- the time required to produce loss of consciousness must be as short as possible;

- the time required to produce death must be as short as possible;
- the method must be reliable and non-reversible;
- there must be minimal psychological stress on the animal;
- there must be minimal psychological stress to the operators and any observers;
- it must be safe for personnel carrying out the procedure;
- it must be compatible with the requirements of the experiment;
- it must be compatible with any requirement to carry out histology on the tissues;
- any drugs used should be readily available and have minimum abuse potential;
- the method should be economically acceptable;
- the method should be simple to carry out with little room for error.

The different methods are often divided into those using physical methods and those using chemicals administered by various routes.

### Chemical methods of euthanasia

#### Overdose of injectable anaesthetic agent

The aim is to cause respiratory depression, leading to hypoxia and death. With modern injectable agents used in combination to achieve balanced anaesthesia, there is generally a fairly wide safety margin, and indeed with some anaesthetics it is actually quite difficult to kill an animal using a reasonable injection volume. The drug of choice to carry out euthanasia is therefore pentobarbital, which does not have a wide safety margin and so has been superseded as an agent to provide quality anaesthesia. It is preferable to give it intravenously for the most rapid action but in the smaller species it is generally administered intraperitoneally, using a suitably sized needle. The smaller the needle, the better, as it will cause less pain on insertion. Pentobarbital causes pain on injection and combination with a local anaesthetic agent will help to reduce this (Ambrose *et al.* 2000). In larger animals, if it is not possible to locate a vein, the animal should be sedated first with an agent administered by an easier route. When the sedative has taken effect and the animal can be handled more easily, the pentobarbital can be administered intravenously to kill it quickly and humanely. Pentobarbital must not be given intramuscularly as it is very irritant to the tissue and this will cause pain. Intrathoracic injections in the conscious animal are also painful, and an intracardiac injection of pentobarbital should only be attempted after the animal has been rendered unconscious.

#### Exposure to carbon dioxide and overdose of anaesthetic by inhalation

The use of carbon dioxide for euthanasia, while very common, is controversial, leading to much debate over the most humane method of euthanasia (Conlee *et al.* 2005;

Hawkins *et al.* 2006). One of the principal advantages is that it can be carried out leaving the animal in its home cage and placing the entire cage in a carbon dioxide cabinet. The animal is not handled and the operator is able to remain detached from the process of killing. A controllable source of carbon dioxide should be used, it is not acceptable to use dry ice; preferably there should be a thermostatic mechanism to ensure that the gas reaching the animal from the cylinder is not uncomfortably cold.

Neonatal animals and cold-blooded vertebrates are resistant to hypoxia, and diving birds and mammals can hold their breath for long periods, so the use of carbon dioxide is not recommended in these animals. It is now established that rats and mice find carbon dioxide aversive (Leach *et al.* 2002a) and its use as a euthanasia agent is considered unacceptable by many (Leach *et al.* 2004). Carbon dioxide exposure causes immediate bradycardia due to nasal nociception activation and pain, although Hackbarth *et al.* (2000) found that when rats were exposed to carbon dioxide in the home cage without disturbance there were no such aversive signs. For humans, carbon dioxide inhalation is painful at 50–100% exposure concentrations (Danneman *et al.* 1997). If rodents are exposed to a high concentration (>50%) of carbon dioxide, the time to unconsciousness and therefore the time for which the pain has to be endured is at least 10–15 s (Hawkins *et al.* 2006). Many guidelines for euthanasia state that the concentration of carbon dioxide should be *rising*. However, if the chamber is filled slowly it can take around 2 minutes to reach unconsciousness at 35% carbon dioxide (Golledge *et al.* 2005). While this avoids the acute pain seen with 100% carbon dioxide, there is significant dyspnoea and tachypnoea which may be very distressing to the animal even if it is not actually painful. In Hawkins *et al.* (2006) it is stated that carbon dioxide aversion in rats starts at 10–15% concentration and that this aversion is very high, not even being overcome by motivation of 24 h of food deprivation. In humans, dyspnoea occurs at 7% carbon dioxide, is severe at 15–20% and said to be very unpleasant. Rats will show escape behaviour at 15–20% carbon dioxide. The choice with carbon dioxide would therefore appear to be between a high concentration initially, resulting in a faster more painful death; or a lower rising concentration of carbon dioxide, resulting in a slower death with less pain but more distress from dyspnoea. Neither of these is satisfactory.

The question is therefore whether there are any better methods that combine the advantages of not having to handle the animal and the aesthetic acceptability of being remote from the animal at the point of death, but which does not cause the animal respiratory distress or pain.

The use of carbon dioxide for stunning or for euthanasia in farm animals has also been shown to be aversive, whereas combination of the carbon dioxide with argon is less so (Gregory *et al.* 1987; Raj 1999 (pigs); Raj & Whittington 2003 (chicks)). The use of argon raises health and safety concerns since it is difficult to detect and when used in rats and mice they still show some aversive behaviour even though this is less than with carbon dioxide (Leach *et al.* 2002b).

Euthanasia can be carried out by administering an overdose of inhalation anaesthetic. The animal is placed in a suitable induction chamber with the vapour. It is important that the animal is physically separated from the liquid agent

since volatile anaesthetics are very irritant to mucous membranes. While inhalation anaesthetics are less aversive than carbon dioxide, they are still not particularly pleasant. Halothane has been found to be least aversive for rats and enflurane for mice (Leach *et al.* 2002b), although such agents should be used with appropriate scavenging systems to ensure compliance with health and safety regulations. It is important to ensure that the animal is left in the chamber with the inhalation anaesthetic for long enough, and to confirm that it is dead, since it may recover if it is removed too soon and allowed to breathe room air.

Rodents communicate by pheromones in urine and faeces and placing the animals on disposable paper which can be replaced each time, is a simple way of controlling this potential stress factor. Chambers of this type should always be used in an extraction cabinet or with a suitable ducting system to reduce exposure of staff to the volatile agent. Similarly, as for injectable agents, modern inhalational anaesthetic agents are developed to have a wide safety margin so it can be quite difficult to kill an animal with such agents. It may therefore be preferable to use them to induce unconsciousness and then kill the animal using carbon dioxide at 100%. This way the detection of pain from nociception will be avoided and death from hypoxia is rapid. It has therefore been suggested to use halothane (but this agent is shortly to be withdrawn from some markets) to induce loss of consciousness, then to infuse carbon dioxide to cause death. However the change from use of a single agent is not currently acceptable in some jurisdictions (Home Office 1997) and it is not so simple or convenient for the user. It also may give rise to a training issue, but these considerations should not be used as an excuse not to change if multiple agents would be more humane. No doubt the use of carbon dioxide versus other methods will be subject to further debate in the future. Inhalation methods may be less suitable for large animals since they are more difficult to restrain.

### Overdose of anaesthetic by immersion

For fishes and small amphibia, euthanasia can be achieved by percutaneous administration of tricaine methane sulphate (MS 222), administered by immersion. As for inhalation euthanasia in the rodent, care must be taken to ensure that the animal is left in the solution for an adequate length of time and that death has occurred when it is removed.

### Physical methods of euthanasia

Physical methods of euthanasia can be distasteful to have to carry out, and this can lead to a tendency to be hesitant. However, if carried out properly these methods are often less distressing to the animal, since unconsciousness is very quickly achieved. Death should be confirmed by exsanguination by severing major vessels or by destruction of the brain. Manual dexterity and an ability to handle the animal confidently are essential to minimise any apprehension. They should be practised first on dead animals, after careful observation of the method carried out by a competent and experienced person. Physical methods are appropriate for

small rodents, rabbits and birds and also for amphibians, reptiles and fishes. Dislocation of the neck causes extensive damage to the brainstem and instantaneous unconsciousness. Dislocation must be carried out quickly and with confidence, otherwise there might not be complete separation of the cervical vertebrae and the animal may experience distress or pain. It may be preferable to sedate or anaesthetise animals prior to cervical dislocation. It may be necessary to wrap birds to prevent involuntary flapping of the wings.

Concussing the animal by striking the back of the head renders the animal unconscious, following which death must be ensured by dislocation of the neck or by exsanguination. As with dislocation of the neck, confidence in handling the animal and manual dexterity are required to carry out this method without causing distress to the animal. Support the animal by the hindquarters and swing the body downwards such that the back of the head comes sharply into contact with a hard surface such as a work bench. Considerable training and practice on dead animals is required to ensure competence with this method, and it is difficult to ensure that animals are stunned consistently. For amphibia, reptiles and fishes the brain must be destroyed immediately following concussion, as in these species the brain is very tolerant to hypoxia, and it cannot otherwise be guaranteed that concussion is irreversible or that unconsciousness will last until death.

For ungulates the animal may be killed by one of the standard methods of slaughter, such as use of a free bullet, a captive bolt, or electrical stunning followed by destruction of the brain or exsanguination. However these methods are controlled by other legislation including control of firearms and will therefore only be available to those who have been appropriately trained and issued with the relevant licences.

For foetal, larval and embryonic forms there are other methods that can be used which take into account the degree of development of the nervous system in the various animals. Overdose of injectable anaesthetic may be used as for adult animals of all species. Refrigeration, disruption of membranes or maceration can be used for birds and reptiles, but the death of the reptile embryo must be ensured by overdose of anaesthetic, maceration or immersion in tissue fixative. Cooling of foetuses until movement has stopped followed by immersion in cold tissue fixative is appropriate for mouse, rat and rabbit foetuses. Decapitation can be used for foetal mammals and birds up to 50g weight, using a pair of sharp scissors. In some jurisdictions decapitation for neonatal rodents is considered an appropriate method of euthanasia.

### Other methods of euthanasia

Other methods of killing may be employed occasionally if there is a scientific need. Microwaves can be used to fix brain metabolites without losing anatomical integrity (Ikarashi *et al.* 1984; Stavinoha *et al.* 1978). Specialist apparatus and careful technique are required. The microwaves are focused on particular areas of the brain, producing death very rapidly. Electrical stunning may be used as in routine pre-slaughter stunning for ungulates and also for other species such as poultry or rabbits. It requires specialist equipment,

and death must be confirmed using another method. Pithing may be carried out in unconscious fish, amphibia or reptiles. A sharp needle is inserted through the foramen magnum and agitated to destroy the brain. This requires technical skill in order to ensure rapid death, and must not be carried out in conscious animals. Rapid freezing using liquid nitrogen can be used *in situ* or following decapitation to freeze the brain. The animal must be rendered unconscious first, as it can take up to 90s to freeze deep structures. Decapitation may not be humane in conscious animals, because of the length of time it takes for the decapitated head to lose consciousness, particularly in cold-blooded vertebrates. If this method is required for scientific reasons, there must be particular justification, and consideration given to sedating or anaesthetising the animal first.

### Confirmation of death and disposal of carcasses

After carrying out any method of euthanasia it is vital to check that the animal is really dead before disposing of the carcass. Thus the process of killing must be completed by one of the following six methods:

- confirm permanent cessation of the circulation, if possible by severing the major vessels;
- destruction of the brain with a permanent loss of brain function; all signs of reflex activity must have ceased;
- dislocation of the neck, following concussion or overdose of anaesthetic;
- exsanguination;
- onset of rigor mortis;
- mechanical disruption by destruction of the body in a macerator.

All animal carcasses are classed as clinical waste and as such must be disposed of correctly either by maceration or in clinical waste bags that are then incinerated. There should be local rules relating to the method of disposal in each animal unit.

### Alternatives to euthanasia

For most laboratory animals the carrying out of euthanasia is an integral part of the experimental procedure, as tissues are collected for examination and generation of critical data. However there are some procedures that can be completed and all necessary scientific data collected without necessitating the death of the animal. At the end of these procedures, some animals are then used as breeders, some are returned to stock for use in further procedures, some are moved out of being laboratory animals into other sectors such as agriculture as farm animals or rehomed as pets. The first critical decision is to ensure that the maximum amount of data has been generated from each individual, without causing additional harm, and thus prevent more animals having to be used. In the case of surplus ex-breeding or stock animals, it may be possible to harvest blood or tissue at euthanasia which can then be used in *in vitro* experiments which are increasingly being developed as replacement alternatives to the use of live animals in research. However a number of

laboratory species including dogs, rabbits and species of primates, such as common marmosets, squirrel monkeys, capuchins, stump-tailed macaques and chimpanzees, have been successfully retired to private homes, zoos, sanctuaries or professional collections in the UK, Europe and USA. This is reported to be beneficial for staff morale as well as the animals (Laboratory Animal Science Association (LASA) 2004) and can help further develop a culture of care.

Re-homing ex-laboratory animals must be considered very carefully since the re-homing facility must be able to accommodate the animals properly and there must be adequate resources to care for them in the longer term. Whoever will be caring for the animals must have suitable training and experience. Depending on the animal's age, state of health, previous experiences and the physical and social conditions in which they are to be kept, there are potentially significant welfare costs to laboratory animals that are rehomed. Re-homing should only be considered if it is clear that the process will be truly in the best interests of the individual animal, that it will not harm its welfare, and that the new home offers it a good quality of life. The factors that must be considered when re-homing dogs have been described in detail in the LASA (2004) guidance on re-homing and in the Joint Working Group on Refinement (JWGR) report (2004).

Re-use of animals in further experimental procedures in order to avoid euthanasia may result in a decrease in the total number of animals used thus applying the principle of reduction. However it also presents the specific ethical question of animal numbers versus animal suffering. The suffering (both contingent and direct) of an individual animal must be weighed against the welfare impact of obtaining, housing and preparing (surgically in some cases, or by training) a different animal. In the European Union re-use is subject to legal constraints defined in Council Directive no. 86/609/EEC and it is considered that a reduction in total number of animals used does not justify causing a significant increase in suffering for the individual animals involved.

Intuitively, longevity is an aim of most humans, provided that one remains in good health. However, for a laboratory animal, longevity may not be in its welfare interests. For a start, the laboratory environment may not be the ideal one in which to keep some species (Berdoy 2002). Limits should therefore be set on the length of time for which animals are maintained. It is not necessarily easy to define a set of temporal criteria and decisions may have to be made on a case-by-case basis. The points that should be considered include:

- The health of the animal. This should include both physical and psychological health and welfare and should be regularly reviewed by the animal care staff, veterinary staff and ethologist (as appropriate). Any abnormal behaviours should be noted as well as physiological indicators of poor well-being.
- The adequacy of animal's environment. Whatever the housing system there must be good quality and quantity of space, with attention to all three dimensions, and provision for social interactions, if appropriate for the species.

There should be a good reason for maintaining animals kept in the laboratory long term other than as subjects in experi-

ments or as breeders. For example, they may be kept as a companion for an experimental animal when using species such as sheep, dogs or primates. Additional resources such as enrichment, training and exercise will be necessary and there should be a written plan for such animals as well as for experimental ones.

As an example, ex-breeder primates are a particular case where there can be a tendency to allow animals to live out their natural lifespan but where arguments may be put forward for euthanasia once an animal reaches a specific age or has given birth a specified number of times. Again, decisions should be made on a case-by-case basis. In wild primate populations, as in most species, the cessation of breeding is frequently determined by the death of the individual (from disease, parasites, predation, fighting or a basic inability to feed sufficiently) and is quite likely to occur before any biological reproductive senescence occurs. In harem, or multi-male systems, males may breed for as long as they retain the required social status to maintain reproductive access to females, and females may breed for as long as they are able to achieve the necessary breeding condition.

There is no evidence for the existence of a menopause in New World primates and they appear to continue breeding, albeit with reduced frequency as they get older, well into old age with lifespans of typically 10–20 years (higher in some species: 40–45 in *Cebus* sp. and 30–35 in *Ateles* sp.) (Hendrickx & Dukelow 1995). In macaques, the menopause, including stopping of the menstrual cycle and ovulation, has been determined to be at about 25–30 years of age; and it may be accompanied by appearance changes, such as changes in face colouration and a greying and thinning of the hair. In addition to changes in the reproductive physiology and anatomy, post-menopausal changes may occur, for example to the skeletal and cardiac system (Hendrickx & Dukelow 1995). Although an aging individual may have ceased to breed frequently, and there may be an increase in the number of stillbirths in older females, this does not mean that this animal does not perform an extremely valuable social role within the group in which it lives. In captive populations removing older animals ranging from social perturbation (and hence stress) caused by removing a socially influential older animal to loss of any role they might have played in educating younger members of the group in parenting skills. This is particularly true of the removal of older, high-ranking females in matrilineal macaque societies.

The periodic change of the resident breeding male occurs naturally in macaque harem and multimale groups and this helps to maintain breeding production; avoiding female boredom with their partner. However, the removal (either culling or individual housing) of older females from their group should be avoided unless there are over-riding animal health concerns. In the interests of the animal's health and welfare it may be appropriate to embark upon a course of contraception for older females that are experiencing problems such as repeated stillbirths, but it is important for their welfare that they be allowed to remain with their social group.

The use of a welfare assessment grid can be helpful in balancing some of the difficult decisions about the future of an animal. The axis can be used to give a schematic represen-

tation of parameters including clinical condition, psychological well-being, behaviour and environmental conditions (Wolfensohn & Honess 2007).

### Concluding remarks

There is no doubt that the purposeful killing of animals by people, when done badly, can cause extreme suffering and it matters not whether the animal is being killed for food, for population management or as part of a research project. Its capacity to suffer is the same, whatever the purpose. There is an ethical obligation and a practical opportunity to minimise any associated suffering when animals are killed and this should be done each and every time (Mellor 2000). Whatever the answers to these questions might be, it is both worthwhile and ethically imperative to find scientifically based refinements to minimise suffering at euthanasia.

An animal's quality of life has been defined as being made up of three components: its value to itself, its value to science and its value to its peer group (Sandoe & Christensen 2007). Alternative views are that the animal has no value at all, has a value for that individual only, or that its value exceeds what is 'in it' for the animal in question. Any domestic species, whether farmstock, companion animal or laboratory animal is man's product, arguably for man's use and would not exist if man had not organised for it to do so (Allen 2007). The same author continues that since a post-weaning animal does not have grieving relatives, the most sensible, pragmatic, economic and humane solution whether it is sick and suffering, old and debilitated or simply no longer wanted for its intended use, is to kill it. However, animals, both domestic and wild have varied roles in society and their value can be economic, cultural, political, emotional or religious (Gardiner 2007). They are also attributed an inherent 'animal value' that exists by virtue of them being sentient beings. Antonites (2001) argues that while sentience is important it is not a sufficient condition and it is the demonstration of rational consciousness in animals that leads to the ethical and welfare implications. Kirkwood and Hubrecht (2001) expand on the meaning of consciousness and cognition and conclude that despite the diversity of opinion it is of great relevance to animal welfare. For further discussion on the ethics of killing animals which have an inherent value either to themselves or to others see Nuffield Council on Bioethics (2005).

Each individual's view of this will affect their attitude to choices made about treatment, endpoints and euthanasia method. Ethically driven scientific evaluations are used to improve the humaneness of livestock slaughter through such organisations as the Humane Slaughter Association<sup>1</sup>. Killing used in vertebrate pest control is also under discussion since many of the current methods of rodent control fall short of a humane ideal (Universities Federation for Animal Welfare (UFAW) 2006), but questions remain between the objective scientific evaluations and their interpretation as to how much suffering an animal experiences and the relativ-

<sup>1</sup><http://www.hsa.org.uk>

ties of different types of suffering. Specifically, how does one compare the intensity of suffering versus its duration? Or how can two different types of suffering be compared; for example Mellor and Litten (2004) give the example: is severe breathlessness a greater welfare insult than severe and unquenchable thirst? Moreover, there is the question of quality of life versus quantity of life. It is perhaps inevitable that a veterinary surgeon will have a different perspective on the value of an animal's life compared to the view of the pure scientist. The former has committed his/her professional life to the welfare of animals committed to his/her care, whereas for the latter the animal is a tool to formally investigate a hypothesis. But while we may not all agree on the value of an animal's life we should all agree on the significance of animal welfare and strive to maximise it.

# PART 2

## SPECIES KEPT IN THE LABORATORY

# Mammals

# 18 Wild mammals

Ian R. Inglis, Fiona Mathews and Anne Hudson

## Introduction

A range of wild mammal species is studied in the laboratory or other captive conditions. Many of the principles for keeping wild animals (eg, nutrition, climatic requirements) are similar to those for domesticated animals of the same species but, as emphasised below, it is very important to take careful account of behavioural and other differences to avoid stress or ill-health. This chapter touches on special requirements for a small selection of species kept for research in Europe but cannot provide detail on the very wide range of species kept worldwide.

As noted above, although some wild animals used in research are closely related to common laboratory animals, for example, the Norway rat (*Rattus norvegicus*), the house mouse (*Mus musculus*) and the European wild rabbit (*Orytolagus cuniculus*), their requirements can be profoundly different (see also Chapter 25). Applying the standard protocols and housing conditions developed for laboratory strains is likely not only to compromise their welfare, but also adversely affect the quality of the data collected. The process of domestication in laboratory strains has selected, both deliberately and accidentally, for traits such as docility and inquisitiveness. In addition, inbreeding has reduced the inter-individual variability that characterises natural populations. This means that laboratory animals are generally easier to handle than their wild counterparts, are less stressed by standard procedures and the close proximity of humans and are more predictable in their responses.

Many other wild animals studied in the laboratory have no domesticated relatives. Examples include Daubenton's bats (*Myotis daubentoni*), red fox (*Vulpes vulpes*), badger (*Meles meles*) or wild boar (*Sus scrofa*). The lack of relevant baseline information on 'normal' physiological profiles, such as haematological reference ranges, for most species presents significant challenges. Similarly, baseline data on 'normal' behaviour are frequently lacking. It can therefore be difficult to apply the conventional methods for scoring well-being familiar to researchers working with laboratory animals, or to define thresholds at which interventions to alleviate suffering should be implemented. The onus is therefore on researchers to familiarise themselves with relevant literature from a range of sources – for example from zoo medicine and conservation biology – and also to apply the precautionary principle when judging whether welfare is compromised.

It is useful to consider the evolutionary context of an animal's response in captivity: for example, for a mouse, sleeping in the open would be maladaptive in the wild, and this behaviour in the laboratory is more likely to indicate exhaustion than relaxation (Mathews *et al.* 2004). Taking evasive action to the threat of predation (such as a human entering the room) is an appropriate response, and does not, in itself, indicate compromised welfare. However, if efforts to escape are thwarted (for example if no hiding places are provided); if there is repeated exposure to the stressor; or several stressors are experienced simultaneously (such as exposure to humans and the provision of new food types) then psychological and physiological distress are likely (Moberg 2000).

Wild mammals are usually kept for applied research into: (1) methods of population control (eg, Shepherd & Inglis 1987, 1993; Smith *et al.* 1994); (2) the transmission of diseases and parasites (eg, Tesh & Arat 1967; Crouch *et al.* 1995); (3) environmental protection, where the animals are used to test for possible contamination (eg, Beardsley *et al.* 1978; Barber *et al.* 2003; Thompson 2007); and (4) for studies relating to conservation or breeding. However, wild mammals have also been used for more academic reasons, such as to investigate various forms of learning (eg, Shumake *et al.* 1971; Powell 1974; Cowan 1977; Inglis & Shepherd 1994) and behaviour (eg, Odberg 1987; Hurst 1990; Wurbel *et al.* 1998; Hendrie *et al.* 2001).

For many types of work, there can be good justification – from the perspective of animal welfare as well as research output – to undertake it in the laboratory rather than the field. In the UK, special dispensation is needed to release wild animals back into the wild after a procedure. This requires competent and authorised persons to judge that the animal is fit for release and that no long-term adverse implications are expected from the procedure. In many cases, research in the field or re-release to the wild would not be appropriate. For example, when testing new rodenticides, all subjects need to be monitored and humane endpoints applied. However, this is not always the case and, historically, work has often been conducted in the laboratory for reasons of convenience. Advances in methods of tracking, remote monitoring, non-invasive sampling (for example, using hormone profiles in faecal samples to judge reproductive status) and field anaesthesia mean that there is now much more scope to conduct research on wild animals in their natural environment. It is therefore important to

carefully evaluate the welfare costs of conducting the research in the laboratory versus the field. In some cases, the quality of the research may also be improved by working with wild mammals *in situ*: for example, captivity is likely to influence disease dynamics due to the effects of stress, alteration of population processes etc, and so field research may be preferred (eg, Mathews *et al.* 2006; Amengual *et al.* 2007; Vaz 2007; Beldomenico *et al.* 2008; see also Chapter 7).

This chapter discusses only those aspects of maintenance, care and handling of wild mammals that differ from the techniques usually employed with laboratory strains.

### Potential health hazards to humans

Working with wild mammals is hazardous. They frequently show aggressive behaviour when approached or handled. In addition, allergy to laboratory animals (ALA) is common particularly when, to avoid disturbance, cages and pens of wild mammals are less frequently cleaned than those of laboratory strains. The most common symptoms are blocked sinuses, sneezing and watering eyes. Particular attention must be paid to the potential transmission of zoonotic parasites and pathogens from wild animals to humans. It is important to recognise that screening of natural populations for parasites and pathogens is often somewhat haphazard. Screening is largely driven by concern for disease outbreaks important to the health of humans or their livestock. There has tended to be little proactive screening, and baseline information on the prevalence of most pathogens is scant or non-existent for many species (Mathews 2009). This chapter, therefore, is only able to highlight some of the better known parasites and pathogens that occur in European wildlife. Researchers must be alert to the possibility that other zoonoses are likely to be present, and the implications of these agents for human health may not be known; for example, most emerging infectious diseases appear to be zoonotic in origin (Taylor *et al.* 2001). Parasites and pathogens not only threaten the health of staff and of other animals in the facility, but they may also influence the animals' responses to experimental interventions. Recent evidence suggests that animals need not even be in direct contact with infected individuals in order to mount immune responses (eg, Curno *et al.* 2009). Particular care should, therefore, be taken whenever a new cohort of animals is brought to the laboratory.

One of the most serious diseases likely to be carried by wild rodents is Weil's disease or leptospirosis, caused by the spirochaete *Leptospira icterohaemorrhagiae*. Wild rats are the most common host but the house mouse (Twigg *et al.* 1969), water vole (pers. obs.) and other mammals including rabbit (Chalmers *et al.* 2009) and hedgehog (Dyachenko *et al.* In press) can also carry the organism. Once the spirochaete is contracted, a rat passes through a brief bacteraemic period of acute infection, which is not accompanied by obvious symptoms of disease. This is then followed by a chronic stage when the organism is harboured in the kidneys and is excreted in the urine throughout the remaining lifetime of the host without clinically affecting its health. *Leptospira icterohaemorrhagiae* enters the human body through abrasion in the skin, or via the mucous membranes of the eyes, nose, throat or lungs. It is uncertain whether the spirochaete can also be transmitted through unabraded skin. There have

been reports of mouse colonies infected with *Leptospira ballum* causing illness in personnel (eg, Stoenner & Maclean 1958). The early stages of Weil's disease produce general flu-like symptoms and it is, therefore, important that staff inform their doctors that they have contact with wild rodents.

Rat-bite fever in man is caused by two organisms that naturally inhabit the buccal cavities of wild rats (Somerville 1961). *Streptobacillus moniliformis* is pathogenic to mice, whereas both rats and mice are the normal host to *Spirillum minus*. The human diseases lead to local irritation followed by generalised febrile illness with a macular rash. As its name implies, rat-bite fever is usually contracted from a rodent bite.

*Pasteurella pestis*, the plague bacillus (Hudson *et al.* 1964), is transmitted through several species of fleas that parasitise wild mammals. As it is easy to control these insect vectors, the danger of human infection from a sanitised colony of wild rodents is small. *Pasteurella septica* may be of more practical importance. It is found in the respiratory tracts of many mammals and is transmitted to humans by bites.

*Salmonellae* are a common cause of food poisoning. *Salmonella typhimurium* and *Salmonella enteritidis* are the two types most frequently associated with colonies of wild mammals. Newly infected colonies can suffer high losses. Chronic infection leads to a prolonged carrier state in which the carriers show no symptoms but shed infective agents from the alimentary tract. Human infection occurs via the oral route and results, within hours or days, in fever and gastrointestinal distress.

Lymphocytic choriomeningitis is a viral disease of humans that in its rarest form may cause a fatal encephalitis. The virus is commonly found in house mice but rarely in other wild rodents (Maurer 1964). Laboratory personnel are thought to acquire the virus by ingestion.

*Toxoplasma gondii*, a parasitic protozoan, can be carried by many mammal species, (including humans who are 'dead end' hosts). This causative agent of the disease toxoplasmosis is usually minor and self-limiting but it can have serious, or even fatal, effects on a foetus whose mother contracts the disease during pregnancy. The life cycle of *T. gondii* has two phases. The sexual part of the life cycle takes place only in the members of the felidae family, whilst the asexual part of the life cycle can take place in any mammal. The early stages of toxoplasmosis can produce no symptoms, or mild fever, enlarged lymph nodes in the neck and muscle pains.

Cryptosporidiosis and giardiasis are protozoan diseases affecting the intestines of mammals. The parasites are spread by faecal-oral route. Symptoms appear from 2–10 days after infection and can last for up to 2 weeks. As well as watery diarrhoea there are often stomach pains or cramps and a low fever but not all individuals have symptoms. Infection can be life-threatening in immunocompromised people and animals.

Rabies is a very dangerous viral disease but one that is unlikely to pose a hazard in a well managed animal unit in Europe. The virus is geographically distributed in endemic pockets, which periodically erupt into neighbouring regions. Although carnivores and bats are the usual carriers, all mammals are susceptible. The virus enters through skin wounds usually caused by bites inflicted by infected animals in the virulent stage of the disease. Where wild mammals

have to be imported from regions with endemic rabies, vaccination in conjunction with quarantine should prove effective against carriers of the virus. European bat lyssavirus II (EBL 11) is endemic in Daubenton's bats in the UK (Brookes *et al.* 2005). Although passive surveillance has failed to identify bat rabies in other British bats caution should still be exercised, as a range of European bats is known to be naturally infected with EBL 1 and EBL 11 (Harris *et al.* 2006). It is important to note that infected bats may not exhibit symptoms of rabies for a considerable period. All staff working with bats must therefore be vaccinated against rabies, and appropriate gloves should be worn whenever handling the animals.

Dermatomycoses are frequently acquired by wild mammals. The affected regions on the animal develop bald circular patches, which gives the condition its vernacular name 'ringworm'. The causative agent is usually *Trichophyton mentagrophytes* and there can be a much higher proportion of carriers than of clinically infected animals, particularly in wild mice.

Cestode infection is an important hazard (eg, Gibson 1967). The tapeworm *Hymenolepis nana* is common in wild rodents and can infect humans via the oral route. *Hymenolepis diminuta* is also found in wild rodents but only rarely in humans.

Arthropod parasites are usually restricted to a few closely related hosts. Some, especially fleas and *Sarcoptes* mites, do attempt to invade humans but the infections are usually self-eliminating irritations of a duration that varies with the physiological sensitivity of the persons involved, and they are easy to control. However, in addition to being a nuisance, ectoparasites are potential vectors of disease; as discussed above, several flea species transmit *Pasteurella pestis*, the plague bacillus.

## Precautions

When working with any wild mammals, as with laboratory animals, scrupulous personal hygiene and adherence to all safety codes are essential. The following precautions reflect specific hazards associated with working with wild mammals.

1. Adequate protective clothing should be worn at all times (ie, a minimum of laboratory coat or overalls, overshoes or boots, masks and gloves) in the animal unit and removed before entering non-infective areas. If disposable clothing is not worn, provision must be made to isolate soiled garments from other laundry.
2. All clothing worn in the animal unit must be dealt with as a potential hazard. Even if clothing has not come into direct contact with wild mammals there could still be allergens present and hence it should not be taken out of the unit. Wherever possible, the laundering of protective clothing should be done within the animal unit.
3. All equipment should be thoroughly washed and disinfected or sterilised after use. Disinfectants with low odour, which are biodegradable, and are effective against a wide range of pathogens and parasites should be used. Note that some agents that infect wild animals are particularly resistant to disinfection (such as *Cryptosporidium parvum* and *Mycobacterium bovis*).

Care should be taken to ensure that appropriate disinfectants are used; many virucides are NOT effective against a sufficient range of pathogens.

4. Non-standard housing such as floor pens should be vacuumed rather than swept, or doused with water first, to reduce the risk of allergy.
5. All cuts, scratches and abrasions, particularly on the hands and forearms, must be covered with waterproof dressings before entering the animal unit.
6. Hands and forearms need to be thoroughly washed with adequate soap before entering areas outside the animal room.
7. Gloves should always be worn when cleaning out and washing cages, and when handling wild mammals.
8. When conducting experimental procedures with, or sexing, wild rodents, safety glasses should be worn in order to minimise the risk of urine passing through the mucous membranes of the eye.
9. Particularly when working with wild rodents, staff must report animal bites; it is essential that medical attention is given within 24h.
10. Risk assessments should be carried out laying down basic information on relevant zoonotic diseases (eg, Weil's disease). Staff should inform their doctor that they work with wild mammals.
11. Staff should undergo a course of anti-tetanus injections and regularly receive booster injections.
12. Staff should have annual checks carried out to make sure they are not developing symptoms of animal allergies.

## Capture of wild animals

Information on welfare issues relating to the capture and use of wild animals is given in Chapter 7. An important additional consideration when conducting laboratory research is that the animals are removed from the site of capture. Wild animals are parts of communities and ecosystems, and the removal of individuals therefore has consequences for the remaining animals. The effects may range from starvation of dependent young, to the removal of a predator or prey-base. The Three Rs principles can be applied to help minimise these effects. Reduction in the numbers of animals used may be possible through improved study design. Alternatively, impacts on the population may be reduced if smaller numbers of animals are caught at a greater number of sites (this strategy may also help avoid problems of pseudoreplication in the study design). Refinement to the protocol might include avoidance of capture during the breeding season and possibly (depending on the type of research) conducting the work in the field. Replacement could be achieved through the use of a related laboratory animal or a captive-bred wild-type animal; or, where there are conservation concerns, the use of a more common, related species.

## Transport of wild animals to the animal unit

Detailed information on the transport of laboratory animals is given in Chapter 13. Animals being transported in the UK are protected under the Animal Health Act 1981 (including

the Welfare of Animals During Transport Order 1997) and the Protection of Animals Acts 1911–2000.

Specific reference is made under the Animal Health Act 1981 Transit of Animals (General) Order 1973 to the transport of those wild species listed under CITES. Article 11 (2) states that: *'No person shall transport an animal to which the Convention on International Trade in Endangered Species refers except in compliance with the CITES guidelines for transport and preparation for shipment of live wild animals or in compliance with the standards set by the International Air Transport Association'*. Specific reference is also made in the Animal Health Act to the transportation of deer in velvet. Article (6) states that: *'No person shall transport a deer in velvet unless the journey is of 50km or less and special precautions are taken to protect it from injury or unnecessary suffering.'*

Every effort should be made to minimise transport times: as a general rule, the amount of stress experienced increases with journey length. Because the animals need to be captured prior to transport, a considerable time may have elapsed before arrival at the laboratory, even if the transport distance is short (for example, if some animals were trapped early in the night): the total amount of time for which the animal has lacked control over its environment must therefore be evaluated. The cumulative effects of several stressors (capture, transport, introduction to laboratory, etc) may result in high levels of stress or even distress, with consequences for the animal's psychological state and physiological function (Moberg 2000). Interventions such as the provision of high-energy foods to help prevent exhaustion, or the use of chemical sedatives may be necessary.

Wild rodents can be transported in the cage traps in which they were captured providing that these are covered to give the animals darkness and security. Preferably, cages with nest boxes should be used. Sufficient pelleted diet should be added to the traps together with a few cut potatoes or apples to provide moisture. Small groups of mice captured in the same locality may be transported together within large bins; as well as food, these bins should contain ample hay or straw to reduce the chance of fighting during transit. Some species that are caught in nets will need to be placed in suitable transport cages/bags, eg, bats can be placed in cloth bags. To transport some large mammals for very short distances it may be possible simply to securely fasten a hessian sack over the head. The transportation of several species requires expert assistance; for example, it is difficult to transport deer safely although they may be quietened and restrained if their heads and limbs are covered.

### Arrival of wild mammals at the animal unit

Wild animals are likely to have suffered considerable stress as a result of capture and transport, even under optimal conditions. For example, even short transport distances in badgers have important effects on innate immune responses, and a period of undisturbed recovery is required for the animals to return to normal profiles (McLaren *et al.* 2003).

The introduction of wild mammals into an animal unit poses the severe risk of spreading diseases and parasites to laboratory stocks. Ideally wild mammals should be housed in a separate building from laboratory stocks. If this is not

possible they must be removed as far as possible from laboratory strains; for example, in a separate isolated corridor. There are several key husbandry duties that are essential to prevent the spread of disease and parasites:

1. separate and complete sets of equipment must be kept for wild and laboratory stocks;
2. wild mammals should never be moved through areas containing laboratory strains;
3. it is essential that different personnel care for wild and laboratory animals;
4. experimental procedures that involve both laboratory and wild animals must be carried out first in the rooms containing the laboratory strains;
5. laboratory breeding stock must be health screened at least once per year.

Upon arrival at the animal facility, it may be necessary to treat the animals for ectoparasites and/or endoparasites (Tuffery & Innes 1963). Veterinary advice should be sought to develop appropriate preventative medicine programmes and procedures for each species kept. Some care should be taken in extrapolating treatments from related domesticated species as what can be safe for one species may not be for another (especially, for example, in the use of live vaccines). Whether the removal of the natural parasite burdens is required depends on the research question. For example, if the work is intended to study dominance or mating behaviour and extrapolate to wild populations, then removal of parasites could interfere with data interpretation since parasite loads influence social status and mate selection. Where parasite removal is desirable, care should be taken to choose an agent and method of application that does not harm the animal or interfere with experimental results. For example, a reliable method to rid wild rodents of ectoparasites is to immerse the animal, still inside the cage trap, in a solution of Amitraz 251 for a few seconds. The animals will need to be dipped again 14 days later. For bats, permethrin-based powders should be used and systemic spot-on treatments avoided due to their potential toxicity. Alternatively, the majority of mites can be removed without chemical treatment by placing the animals on light-coloured cotton cloths and changing these daily. In addition, several species will require inoculation; for example, wild rabbits should be vaccinated against myxomatosis and rabbit viral haemorrhagic disease, whilst red foxes in the UK need vaccination procedures against canine distemper, hepatitis, parvovirus, parainfluenza and canine leptospirosis. As noted above, vaccination of wild animals should be considered carefully as live vaccine strains safe for use in some species may cause severe disease in others.

### Monitoring the health and welfare of the animals

Health monitoring is a legal requirement in several countries, including the UK. Monitoring can be carried out in three ways: (1) the daily checking of each animal for signs of clinical disease; (2) the regular screening of a predetermined number of animals to determine what microorganisms are present and/or to which they have previously

been exposed; and (3) *post-mortem* examination of any animal that dies. Routine health screening is rarely carried out for wild mammals but should be conducted if health concerns arise or if it is important to assess the subclinical disease burden. A predetermined number of representative animals (preferably a mixture of sexes and ages) is selected for a detailed study of the micro-organisms and antibodies present. Larger species can be sampled at the institution and the resulting samples sent to the analytical laboratory; whilst for smaller species the whole body can be sent away for analysis. The samples that may be collected for analysis include: fresh faeces (or gut contents in small species) for signs of protozoa and parasite eggs/segments/larvae; hair and skin scrapes for signs of ectoparasites; ear swabs for signs of mites; and throat and nasal swabs for signs of bacteria and viruses. A clotted blood sample is taken for antibodies to listed micro-organisms and for serum biochemistry. It is important to recognise that the parasites and pathogens included in routine screening of standard laboratory species may not be those of most relevance to wild animals, and specific tests may therefore need to be requested.

There may be interactions between the health status of the animal and some aspects of the research work. Some of these interactions are obvious; for example, respiratory infection may result in high mortality when the animals are anaesthetised. Other interactions are subtler; for example, Sendai virus in rats causes immunosuppression and then permanently modulates the animal's immune response, and in mice the hepatitis virus also has major effects on immune responses.

Staff should be able to spot signs of illness, pain and distress in those wild mammals for which they are responsible. However, this is not always easy because it may be difficult to see or interpret signs of chronic pain, and indicators of chronic pain or distress are usually more insidious in the early stages. Although fundamental uncertainty exists when assessing subjective experiences such as pain and suffering in animals, nevertheless there are some reliable signs. For example, an animal may show protective behaviour towards an injured part, such as limping after an injury to a leg, going off feed because of abdominal injury, or actively seeking relief from pain by ingesting both opiate and non-opiate analgesics. Careful observation is often required to detect those changes in an animal's appearance and behaviour which indicate that deterioration has occurred. It must also be remembered that, particularly for wild animals in captivity, distress caused by fear should be considered as important as suffering induced by pain.

Although it is clear that animals can experience and suffer pain and stress, measuring the intensities of these states is very difficult. The UK National Centre for the Replacement, Refinement and Reduction of Animals in Research has suggested the following strategy, which is applicable to wild animals:

- If methods of pain assessment have been developed for the species used, then these should be adapted to the requirements of the particular research procedure being undertaken.
- If methods of pain assessment are not available, consider devoting resources to developing some form of scoring system.
- If pain scoring is not possible, determine the analgesic protocol based on clinical experience with other surgical procedures in that, or related, species.
- If possible, use dose rates that have been established using studies that have employed pain-scoring systems.
- When data on pain scoring is not available, estimate doses from results of analgesiometric studies using tonic (longer lasting) nociceptive stimuli (eg, late phase formalin test).
- Use pre-emptive analgesia and consider using multimodal strategies.
- Attempt to evaluate the efficacy of the analgesic regimen selected, if only by clinical assessment.

## Housing and handling

### General considerations

In the UK, wild mammals are not included within Schedule 2 of the Animals (Scientific Procedures) Act 1986 as far as the provision of light, heat etc is concerned. The housing and the animal unit environment for wild mammals should be appropriate for each species and, in the UK, professional help and advice must be sought from the Named Veterinary Officer (NVO) and the Named Animal Care and Welfare Officer (NACWO) of the animal unit.

Wild mammals should be kept in conditions that conform as far as is possible to their natural habitat. Whilst many of the larger mammals (eg, fox, deer) should be held only in outdoor facilities (see below), several of the smaller mammals can be successfully housed within indoor laboratory facilities (see below). Whilst housing requirements vary widely between wild species nevertheless there are some general guidelines.

The wild animals' exposure to humans should be minimised. Refuges should be provided that allow the animals to hide from view. 'Look out' places where animals can rest and spot the approach of humans are also environmental features that help to reduce stress. The animals should be provided with the materials required to perform natural behaviours such as nesting materials and substrates suitable for digging. For example, when given the opportunity, captive-bred bank voles will build straw nests and dig burrows in peat substrate.

Environmental enrichment must be provided (see Chapter 10). The form of such enrichment will depend on the species but should include not only objects that animals can manipulate but also static features that increase the complexity of movement throughout the cage/pen/enclosure. Hiding some of the animal's food helps to maintain more normal exploratory and foraging behaviour patterns and to prevent stereotypic behaviour. Species that are incompatible (for example, predator and prey, animals requiring different environmental conditions, animals of different health status) should not be housed in the same room nor, in some cases, within smell or earshot.

Standard housing and care regimes established for the commonly used laboratory animals are not necessarily suitable for wild mammals or for individuals of wild species born in captivity. For example, olfactory cues are extremely

important in communication in wild animals, and frequent removal of scent marks by cleaning of pens and cages will adversely affect the animals' welfare. Frequent cleaning will also entail the stress of exposure to humans and unfamiliar objects such as a holding cage and new bedding. A compromise between the need to prevent disease and the need to minimise stress is therefore required.

Many wild animals are unable to operate water bottles or other dispensing equipment, or require time to acquire the skill. Shallow drinking bowls should always be provided in the first instance, and removed only if there is evidence that the animals are able to use dispensers. Note that some species, such as the water vole or beaver, prefer to defecate in water, and so the resource should be provided for this purpose and refreshed regularly. Wild mammals can have difficulty recognising unfamiliar food (eg, laboratory chow). In addition, digestive problems can be produced by sudden changes in diet when the animals arrive in the laboratory (eg, the change from a grass-based diet to pelleted food in rabbits). Mortality can be markedly decreased by initially providing familiar foods and introducing novel foods slowly.

The temperature and humidity of indoor rooms housing wild mammals should be as carefully controlled as is the practice for laboratory strains of the same species. The control of such variables for wild mammals housed in outdoor facilities is not possible and it is essential that suitable shelter/refuge areas are provided.

Avoid high light levels; an intensity of 350–400 lux at bench level is adequate for routine experimental and laboratory activities. When nocturnal mammals are housed indoors, light-induced retinal damage can occur if the periods of darkness are too short to allow recovery. A daily cycle of 12:12h is suitable for the majority of mammals housed in indoor rooms. For observation and experimental purposes nocturnal animals may be housed under 'reverse photoperiod' conditions (ie, the light and dark periods are switched over and a dim red light is substituted for the dark period). Red light can also be used to provide appropriate 'twilight' periods for crepuscular animals. Changes in the lighting regime should always be conducted gradually, giving the animals time to habituate.

The control of noise is important in the care of all animals but particularly so for wild mammals. Loud, unexpected and unfamiliar sounds are more disruptive than constant sounds, regardless of whether the animal is housed inside or outside. There is no indication that constant background noise, such as that generated by air-conditioning and similar equipment, is harmful providing it is not too loud; indeed, having a radio playing at low volume for a few hours a day may assist the acclimatisation of wild mammals. The general background sound level in an empty indoor animal room should be kept below about 50dB. Some wild animals, particularly bats but also shrews and mice, hear and make use of ultrasound. Ultrasound is generated by a range of equipment (notably computers, but also burglar alarms, sensors, washing machines etc) and is not apparent to humans. It is therefore recommended that the range of ultrasound heard by the species in question is identified and compared with the ultrasound present in the laboratory (which can be cheaply monitored using a heterodyne bat detector). For

example, Daubenton's bats echolocate at 30–90kHz and are therefore particularly likely to be disturbed by sounds within this range.

### Specific examples

#### **Wild mice and voles (*Mus musculus*, *Apodemus sylvaticus*, *Apodemus flavicollis*, *Clethrionomys glareolus*, *Microtus agrestis*)**

Wild mice and voles can be kept and will breed in most types of cage but, as a general rule, the larger the cage area the more likely they are to breed. Males show high levels of aggression if housed together, unless they were litter mates and have been housed together continuously, but females provided they have been kept with other females during adolescence, are highly social and prefer to nest together. Wild adult females brought into the laboratory are highly likely to be pregnant, and need careful monitoring. Mice can breed extremely rapidly, and therefore need to be separated as soon as possible after weaning in order to avoid unwanted litters. Adjustment of photoperiod can be used as a method of bringing female bank voles into oestrus.

A range of bedding material can be used (eg, hay, paper-wool, shredded paper) and it is important to provide an ample supply of bedding because mice like to burrow and to cover their young. If possible, opportunities to burrow should be provided, for example through the use of peat substrate. The authors have successfully used deep polypropylene storage boxes (50cm × 50cm) filled with peat and covered with a lid made of wire mesh within a square wooden frame. A nest box should also be provided in the cage. The cages should not be frequently changed or washed because this removes the mouse pheromones that enable the animals to recognise their familiar environment, and as a result the animals become more stressed. Depending on the number of mice housed together, cleaning out should occur about once a fortnight, and certainly not more than once a week. Environmental enrichment (eg, toilet rolls, sputum cups, sticks, blocks of wood) should be provided. Wild mice, particularly when stressed, may gnaw continually at the diet in the hopper thereby forming a large pile of chewed food in the base of their cage. To help stop wastage of diet the food hoppers may only be filled half way.

Wild mice can also be housed in groups within indoor arenas that provide free movement within a large area. The mouse arenas used by the authors each consist of a wooden floor, 2m × 3m, with 1m high sheet metal walls. The floors and walls slot together enabling several arenas to be joined together to form a larger unit. The wooden floor is covered with a layer of shavings and/or hay. Food bowls, water fonts, nest boxes and enrichment objects are provided. A breeding colony is started with one male and two females and the authors have found that mice breed freely in such arenas. New mice cannot be introduced into an established colony, as the group members will kill them.

Wild mice are far less tractable than their laboratory relatives and, unfortunately, their small size means that it is not practicable to handle them wearing gloves that are strong enough to withstand the frequent bites that occur. Although

rubber gloves covered with cotton gloves are not thick enough to withstand a bite they do provide some protection since the slight gap between the glove and finger means that bites do not normally penetrate the skin, and they do provide protection against excreta, etc. A house mouse may be picked up by the base of its tail (although there is evidence that this is a stressful procedure) but the tip of the tail should not be held because the outer skin can be sloughed off as an anti-predator strategy. Make small circular movements whilst holding the mouse; this prevents it from climbing up its tail to bite you. Wood mice and yellow-necked mice have delicate tails, and these should be picked up by scruffing (holding a large pinch of loose skin from across the shoulder blades) which prevents the animal turning around and biting the handler, gently cupped in the palms of the hand rather than lifted by their tails (Figure 18.1). It is preferable to transport a wild mammal indirectly if at all possible, and short, 5 cm diameter tunnels made of plastic with a removable cap at one end can be used to transport wild mice (J.L. Hurst, personal communication). Mice will readily run into

such tunnels and their tails can then be grasped easily and the animal transferred within the tunnel. Mice in arenas take shelter in nest boxes when disturbed and, if these boxes are fitted with doors that can be firmly closed, they can be transported within the boxes.

#### Wild rat (*Rattus norvegicus*)

Wild rats are best kept in groups of related individuals within large arenas; they will readily breed under such conditions. Each group of rats is started using a male and female that have been trapped on the same local farm and then kept in quarantine for at least a month. Figure 18.2 shows one of the wild rat arenas used by the authors. These are housed within a large, bird-proofed agricultural building with roof lights to provide daylight. Each arena measures 10m 5m with 1.5m high walls made of zinc-coated steel. For the housing of small groups (ie, less than 10) it is possible to insert a partition down the centre of each arena, as shown in Figure 18.2. The tops of the walls are angled inwards to

prevent escapes. Wild rats climb extremely well and it is crucial that all joints between metal sheeting and wall surfaces do not leave vertical gaps. The floors are made of concrete and a drainage system is required. As well as food and water bowls, hay bales containing nest boxes are placed in the middle of the arena to provide nesting and harbourage. The food bowls can be placed upon the pans of balances set into the arena floors. A computer program has been developed that analyses the changes in weight of the various balances such that the amounts of food removed during feeding bouts can be measured in real time and assigned to individual rats, providing the animals differ sufficiently in their initial body weights. In this manner experimental studies have been conducted on undisturbed groups of wild rats (eg, Shepherd & Inglis 1987). As only healthy individuals are used to start colonies, the arenas can also be used as a source of animals for laboratory work. Baited cage traps are used to remove animals from the arenas.

Wild rats are able to chew through polypropylene and wood and it is therefore better if they are to be kept in the laboratory that they are housed in metal cages. It is difficult to clean cages of wild rats, as removing the animal from the cage is both hazardous to the operator and very stressful to the animal. The cages used by the authors therefore have bottoms made of a grid of thick bars with trays underneath which can be pulled out for cleaning. The trays lined with sawdust are placed under the cages and are changed twice a week. In order that the rat does not have to spend all the time on the grid floor, an area of solid substrate is provided by the floor of a metal box or hideaway that is clipped onto the back of the cage; this hideaway is open towards the back of the cage to allow observation. It is also helpful to be able to place a metal partition into the cage; for example this can be inserted vertically down a slot midway along the top of the cage. Thus when placing anything into the cage, such as a food pot, the rat can be confined in another part of the cage by inserting the partition. Shelters need to be provided, such as the inners from toilet rolls, or urine bottles, and paper strips.

If arenas are not available, wild rats can be successfully bred in the animal unit. Stainless steel mesh cages (each 60 cm × 35 cm × 25 cm) are used (Figure 18.3). These cages

have doors at either end and allow two metal partitions to be inserted; the cage can thus be divided into three sections should it be necessary to separate the members of the pair. Two nest boxes are provided, one at either end of the cage, so that male and female can have their own space. As there must be minimal human disturbance the male is not removed during the breeding programme. The second nest box provides him with shelter when the female is pregnant, or rearing young. Having two nest boxes is also essential when the pair are first placed together because there will inevitably be some fighting during the first 2 days. The animals must be observed closely during this period to ensure that they can, if necessary, be separated to prevent serious injury. Noises coming from the female's nest box indicates that a litter has been born, and after a further 10 days it is possible to inspect the inside of the nest box without risking death to the litter.

Wild rats should never be handled directly without first having been anaesthetised. They can bite viciously without warning and can carry a number of serious diseases (see earlier in this chapter). A safe, indirect way method to handle a wild rat involves the use of a strong, black, cloth bag which should be large enough to fit over the end of a cage and long enough to allow the rat to move well into the bag (at least 75 cm × 45 cm). The partition is placed into the cage to confine the rat to the end opposite the door that will be opened. The mouth of a black cloth bag is secured tightly over the opening end of the cage so that when the cage door is opened it is completely enveloped by the bag (Figure 18.4). The partition is then removed and the rat will normally enter the darkness of the bag with little delay. Once the rat is well inside the bag one hand is placed across the bag to stop the rat moving back towards the cage whilst the other hand removes the mouth of the bag from the cage and ties it securely. The rat will normally remain sufficiently quiet for a number of tasks, such as weighing, to be carried out. To place the rat back into the cage, the bag is placed in the cage, the neck of the bag is untied and the door of the cage firmly held closed. The bag is then carefully pulled through a small gap between door and cage (Figure 18.5). This will force the rat towards the mouth of the bag and into the cage. The cage door is then made secure. Cardboard and

plastic tubes with one blind end have also been successfully used by the authors for rats and water voles. The animals readily enter the tube, the end of which can be rapidly covered. This method is particularly useful if the animal needs to be anaesthetised, as the tube can serve as an induction chamber.

#### **Wild rabbit (*Oryctolagus cuniculus*)**

Wild rabbits should not be housed in plastic/metal cages indoors as they tend to injure themselves. Weak backs also become a serious problem when wild rabbits are housed in cages; this is thought to be due to lack of exercise. If it is necessary to keep wild rabbits indoors, they can be housed in floor pens (eg, the authors keep individual rabbits floor pens measuring 1.1 m × 1.3 m × 1.1 m). The floor of the pen should be covered with sand or straw; if the floor is just a hard substrate like concrete the animals will become stressed. Raised platforms or boxes that can be used as 'lookout posts' should be provided. Environmental enrichment in the form of tubes and large cardboard boxes filled with paper or straw for burrowing and nesting, should also be provided because,

without environmental enrichment, rabbits tend not to use empty floor space and fail to get sufficient exercise.

Rabbits can be housed in groups/pair/singles. However they are social animals, and much better standards of welfare are achieved by group housing. This can be achieved easily if youngsters, between 4 and 8 weeks of age, or female littermates are housed together. Neutering of male rabbits is likely to be required if they are to be group-housed successfully. Otherwise they will need to be separated at puberty in order to avoid fighting. It can be difficult to introduce older unfamiliar rabbits to each other. The introduction needs to be very carefully monitored, and adequate shelter and refuges must be provided (see Chapter 28). The use of a new pen (rather than introducing one animal to another's 'home' enclosure), prior familiarisation with the scent of the new individuals by introducing soiled bedding, and neutering, can all help to improve the success rate.

Rabbits held in outside accommodation require wooden boxes that provide refuge from hot sunshine and protection from small predators like stoats and weasels. Groups of rabbits can be held outside in grassed paddocks enclosed with heavy gauge, small mesh, wire netting fences to prevent

entry by rodents, stoats and weasels. The fencing should go below ground level to at least 75 cm to stop the rabbits burrowing out. A single strand electric wire can be strung between insulators just above the fence to prevent entry by foxes. Pairs and single rabbits can be housed in smaller grassed pens with a concrete area at one end where wooden nest boxes, food and water bowls are placed.

Great care is required when handling a wild rabbit because violent struggling can result in not only in deep scratches for the handler but also the animal breaking its back. The technique of handling a wild rabbit is basically the same as that used for a laboratory rabbit (see Chapter 28). The animal must be well supported or it will begin to thrash its hindlegs thereby causing serious back injuries. When disturbed, wild rabbits will usually retreat to their wooden nest boxes and the handler can then close the entrance door of the box and gain access to the animal by removing the roof of the box. The rabbit should be lifted by grasping over the flattened ears and nape of the neck with one hand whilst the other hand is placed around the hindquarters and the animal is drawn against the handler's body. The rabbit is then placed into a large, cotton, drawstring bag. Rabbits will normally rest quietly in these bags and can conveniently be carried in them. Many common procedures can also be conducted whilst the animal is in the bag (for example, weighing, extracting blood from the marginal ear veins) providing that care is taken to ensure that only the body part in question is out of the bag; the rest of the body, in particular the eyes, should remain inside the bag.

#### Grey squirrel (*Sciurus carolinensis*)

In the UK, a licence is required to hold grey squirrels in captivity because they are classed as a non-native species. In order to obtain the licence you will need to demonstrate that the squirrels are unable to escape from captivity. A licence is also required if the intention is to release the animal back into the wild, as might, for example, be needed

by an ecological study. This exemplifies the need to consider local biosecurity laws and regulations for the containment of non-native species. Where containment requirements are strict, this may impose constraints on husbandry methods that may be in conflict with health and welfare interests and plans will need to be developed to deal with or mitigate this situation.

Squirrels are less stressed if housed in groups but, if required, can be kept singly. A large space with plenty of foliage and branches is required to provide the animals with shelter and environment enrichment. Figure 18.6 shows the enclosures used by the authors. Each enclosure is 2.5 m × 9.8 m × 2.8 m, with a substrate of part grass and part concrete upon which the food and water bowls are placed. Ideally the floor should provide some opportunity for digging; if not then containers filled with soil or shavings must be provided. Even though squirrels can share nest boxes there should be at least one nest box per squirrel fixed high on the walls of the enclosure.

Grey squirrels can give serious bites and the handler should wear thick, protective gloves. Upon entering the enclosure all the squirrels are likely to retreat into their nest boxes. The roof of a nest box is removed and the squirrel is gently pinned down with a gloved hand. The handler must then feel around the animal's body until he or she can put their finger and thumb round its neck; the squirrel must be held securely above its shoulders in order to prevent it biting. Once the handler has a firm hold around the squirrel's neck with one hand and the other hand is supporting the animal's rump, the squirrel can be lifted out of the nest box. As well as supporting the rump it is a good idea to gently grip the back legs to prevent the squirrel from kicking. The squirrel can now be placed into a large cotton bag. Before letting go of the squirrel ensure that the bag is closed closely around the arm that is gripping the animal's neck. The neck can then be released and the arm slowly pulled out of the bag whilst ensuring that the squirrel can not escape before the bag can be closed.

**Figure 18.6** Squirrel enclosure. Courtesy of The Food and Environment Research Agency, British Crown Copyright, 2009.

### Stoat (*Mustela erminea*) and weasel (*Mustela nivalis*)

Weasels and stoats should be housed singly to avoid fighting. A wooden and wire mesh cage approximately 75 cm × 105 cm × 45 cm is suitable. The authors use a cage that has a door at the side to enable cleaning out and a metal chute used when feeding the animal. The metal chute is placed through the mesh of the top of the cage with approximately 8 cm protruding above the cage. The chute has a shutter at both ends; the bottom shutter (ie, the one inside the cage) can be operated from outside the cage by using a wire. With the bottom shutter closed, the top shutter is opened and food placed within the chute. The top shutter is then closed and the bottom shutter opened, thereby allowing the food to drop onto the floor of the cage. A nest box is also provided with a door that can be operated remotely from outside the cage. In this way the stoat or weasel may be confined within the nest box when the cage is cleaned, and the animal can be transported within the nest box if required.

Thick protective gloves must be worn for handling these animals. The live trap or nest box containing the stoat or weasel is placed in a deep trough and the animal is released into the bottom of the trough. The animal is firmly held down by placing fingers and thumb round its neck; it must be held above the shoulders or it will be able to turn and bite the handler. The animal is then lifted out of the trough by supporting its rump/hindquarters with the other hand.

### Fox (*Vulpes vulpes*)

The authors house foxes within enclosures approximately 4.5 m × 6.0 m (Figure 18.7). The animals are usually housed singly; although foxes from the same litter that were captured as cubs can be kept together. Each pen has a concrete floor and 1 m high concrete walls supporting thick wire mesh walls and a wire mesh roof. A wooden outer roof above the wire mesh roof provides shelter and protection from the elements. The concrete floor is sloped providing good drainage and the drains lead to a separate septic tank

that is emptied periodically. Shelves are placed on the top of the concrete walls to enable the fox to lie out (Figure 18.7). Nest boxes, foliage and other objects are provided for environmental enrichment. The pen has a door leading into a grassed paddock (completely enclosed by wire mesh) measuring approximately 4.5 m × 10 m that also contains foliage and enrichment objects.

Handling a fox normally requires two people. The animal is encouraged into a nest box, the roof of the box removed, and the noose from a dog-catcher placed over its head and around its neck; the slack in the noose is then gently taken up and the noose locked. This will enable the fox to be inspected within the nest box or moved.

### Wild boar (*Sus scrofa*)

Wild boar are secretive and largely nocturnal animals that will shy away from humans. However, when the sows are defending their young they can attack and can be very dangerous due to their size (150+ kg), speed, agility and aggressive defence of their young. In the UK wild boar are listed as dangerous animals under the Dangerous Wild Animals Act 1976. Although in captivity boar will, over time, become habituated to the presence of people it must be remembered that they will never become as docile as the domestic pig. The UK Farm Animal Welfare Council (FAWC) describes them as '*highly strung nervous animals, which can be easily excited or frightened and thus become highly aggressive*'.

The authors keep wild boar within two grassed paddock areas, each 27 m × 80 m in size, enclosed by a double fence consisting of an external 2 m high galvanised wire mesh fencing and an internal 8500 V three-tier electric fence (Figure 18.8). A metal race is used to move boar from one paddock to the other, or to restrain one or more boar when required. Pig arcs and basic sun shelters are provided. The pig arcs need to be capable of housing a sow and the many piglets she can have. The arcs have solid sides and provide good shelter from the weather but afford little visibility into

**Figure 18.7** Fox enclosure. Courtesy of The Food and Environment Research Agency, British Crown Copyright, 2009.

**Figure 18.8** Wild boar enclosure showing a pig arc and the surrounding double fence consisting of a wire mesh fence and a three-tier electric fence. Courtesy of The Food and Environment Research Agency, British Crown Copyright, 2009.

the rest of the paddock. The sun shelters give the boar both a place to rest and a good view of the paddocks and the other sows and piglets, whilst reducing their exposure to the sun. Foliage is also provided within each paddock to enable the wild boar to build nests, to lie in or to chew. It is essential that an area of the paddock is designated as a wallow; the animals lie in the wet mud to protect themselves from sunburn and external parasites, and to cool down on hot days. Rubbing posts are also placed in various locations around the paddock. The only safe way to handle wild boar is to sedate and then anaesthetise them.

### Laboratory procedures

Procedures and principles are generally the same for wild and conventional laboratory animals, but it is necessary to take note of special handling requirements, of the often unknown disease and reproductive history, and of specific differences that there may be in physiology, behaviour and responses to drug doses. In the UK, the majority of procedures must be conducted under a Home Office Project Licence by suitably qualified staff who hold the necessary Personal Licence. Most wild animals of conservation concern, for example bats and otters are also covered by additional regulations such as, in the UK, The Wildlife and Countryside Act 1981 and The Conservation (Natural Habitats, &C) Regulations 1994. This means that all procedures, as well as the removal of animals from the wild, must be licensed by the appropriate authority (in England this is Natural England), and this procedure is independent of the Home Office Licensing system. Because changes in wildlife law occur quite frequently, researchers are advised to consult the appropriate licensing authorities in their countries for species-specific advice.

### Marking

In general, the range of marking techniques that are available for laboratory strains, such as implantation of trans-

ponders or 'smart tags', can also be used on wild species (eg, Ball *et al.* 1991). Short-term marks such as clipping the guard hairs (fur clipping) may also be used if an enduring mark is not necessary. Helpful information is provided by Beausoleil *et al.* (2004) and Mellor *et al.* (2004).

### Anaesthesia

Small wild mammals are most easily anaesthetised using gaseous anaesthetics, especially isoflurane or sevoflurane. These must be delivered through a metered system, being much too volatile to be used safely with other techniques. Larger mammals can be anaesthetised using injectable anaesthetics and, since with wild species intravenous injection is usually not practical, the drugs are delivered intramuscularly. To allow maximum control over the depth and duration of anaesthesia, anaesthesia induced by an injectable agent can be maintained by gaseous anaesthetics. If the animal is free-ranging, then remote delivery of the sedative by dart-gun will be necessary and this, in the UK, requires a prohibited weapon licence, which specifies that the gun and ammunition are only to be used for the treatment of animals. There are similar arrangements for people who need pistols or revolvers to kill animals humanely. Darting is a skilled and dangerous business. The size of needle, volume and viscosity of the fluid and the amount of power used to project the dart need to be appropriate to the size of the muscle mass and thickness of the skin of the target species. Obviously, the use of inappropriate equipment and materials can cause serious damage to the animal. Darting usually requires a drug mixture containing various proportions of medetomidine, butorphanol and ketamine. In larger mammals such a drug cocktail may result in too large a volume of liquid, and in such cases alternative drugs like Tiletamine or Immobilon may have to be used. Specialist veterinary advice is needed in the development of protocols for chemical capture, sedation and anaesthesia. Information on latest methods for such procedures are available from specialist veterinary texts and series such as Fowler and Miller (2008).

## Collection of blood

General advice on blood sampling is provided in the report by the Joint Working Group on Refinement (JWGR 1993). Blood is taken from wild small mammals, rats and water voles from the coccygeal or tail vein of the anaesthetised animal. Although the scales on the tails make it difficult to see the vein, this technique can be perfected with little difficulty. A temporary tourniquet and the use of a vasodilator help to raise the vein. Disposable plastic hypodermic syringes with 0.50 mm needles are used for wild rats and with 0.25 mm for wild mice. These can be flushed with sodium citrate solution to prevent clotting. The needle is inserted pointing towards the anterior end of the animal. With small animals, the suction from a syringe will tend to make the vein collapse and so better success may be achieved by allowing the blood to drip out into a collecting pot. Alternatively, heparinised capillary tubes can be used to gather sample volumes of up to 100 µl. The authors have also successfully gathered high-quality samples from water voles using the Multivette 600 capillary blood collecting system (Sartstedt Inc.), which not only maximises sample volumes but reduces the risk of contamination. Sampling from the orbital sinus should be avoided because of the high risk of adverse sequelae. Similarly, sequential sampling from the tail tip (by cutting off the tip of the tail) is contraindicated, and should never be used in rats because the vertebrae extend to the tail tip.

Anaesthetised squirrels can be bled from the jugular vein. However, if the animal is held in a squeeze tube it is possible, by restraining it on its back and holding its hindlimbs apart, to take blood from the medial femoral vein of conscious squirrels. Stoats and weasels are difficult to blood sample and so blood has to be taken from the jugular vein under general anaesthetic. Sedated foxes can be blood sampled like a dog; the cephalic, jugular and lateral saphenous veins are all easily accessible. Badgers can be bled from the jugular vein under anaesthetic. Anaesthetised wild boar should have blood samples removed from a superficial vein of the medial branch of the saphenous vein that is located on the medial surface of the leg just proximal and anterior to the hock.

No anaesthesia is required to collect blood from the marginal ear vein of the wild rabbit. The rabbit is held in a cotton bag with one ear protruding. A patch of fur above the ear vein is shaved with a scalpel blade and the area wiped with cotton wool soaked in 70% ethanol. A small nick is made in the peripheral ear vein with the point of a sterile surgical blade (no. 11 size) and the drops of blood are collected in a hand-held tube. It is rarely necessary but if required, light pressure applied to the area with a cotton wool pad will stop the bleeding at the end of the procedure. Alternatively, blood can be withdrawn from the vein using a needle and hypodermic syringe.

Blood can be drawn from the veins that run semi-parallel to the tail in the interfemoral (tail) membrane of bats. The brachial vein near the elbow may also be used, but this carries greater risk of muscle damage. Note that the handling of wild-caught bats in the UK requires special authorisation from the statutory licensing authority. The vein should be raised using light pressure, and an incision made

with a small needle (25 mm). Blood drops can then be collected using a heparinised capillary tube. Haemostasis is achieved by applying light pressure, and if necessary by the application of a clotting agent. The small body size of bats places a significant constraint on the volume of blood that may be collected. The total volume sampled should not exceed 1% of the body weight. For most European species, volumes of 50–100 µl are recommended.

## Collection of urine

Urine can be a useful biological sample in which to measure a range of metabolites as well as some infectious agents (eg, *Leptospira*). In most larger mammals (>100 g), samples can be obtained from anaesthetised animals by using external manual palpation of the bladder. Samples can also be collected from small to medium-sized animals by placing the animal in a cage with a mesh floor. The mesh should be small enough to prevent faeces from falling into the collecting chamber below. To minimise the risk of contamination, the urine should be removed as soon as possible after it has been voided.

## Euthanasia

The primary aim of all methods of euthanasia is to bring about death in a rapid and painless manner (see Chapter 17). Guidelines for euthanasia of non-domesticated animals are provided by the American Association of Zoo Veterinarians (2006). Methods that are inherently humane may nevertheless cause suffering if practised by nervous or unskilled individuals and not performed with deliberation and purpose. Developing the required skill in methods of euthanasia should be obtained by practice on dead animals, where possible, after observation of the technique by trained personnel.

A frequently used method of euthanasia for laboratory strains is the administration of an overdose of a general anaesthetic, leading to cardiac and respiratory arrest and the death of the animal. Intravenous or intraperitoneal injection of pentobarbital (100–150 mg/kg) is commonly used because it is rapidly acting, easy to administer and relatively inexpensive. However, in wild animals both of these routes may be difficult and inhalation anaesthesia is frequently used instead.

Carbon dioxide is commonly used as an inhalation agent for euthanasia. However, the sudden exposure of animals to 100% carbon dioxide can induce severe dyspnoea and cause distress, and the technique is therefore not recommended (Conlee *et al.* 2005). Whenever practicable, the animal should be exsanguinated, or have its neck dislocated, before disposal of the body.

When dispatching a large wild animal it is usually necessary to first administer a sedative, often by darting (see earlier in this chapter), and then to give a follow-up injection of the anaesthetic overdose. (It is important to remember that in the UK if an animal is to be sedated before overdosing with an anaesthetic this requires specific permission on the relevant Project and Personal Licences of the operative.)

# 19 The laboratory opossum

John L. VandeBerg and Sarah Williams-Blangero

## Biological overview

### General biology of marsupials

The term marsupial derives from the Latin word *marsupium*, meaning little pouch. However, the word is somewhat deceptive because males of most species and even females of some species, including *Monodelphis* species, have no pouch.

Fossil evidence suggests that marsupials originated in North America, and dispersed to South America and then Australia. However, it has been argued that marsupials may have arisen on the ancient Southern continent of Gondwana (O'Brien & Graves 1990). In any case, it is generally accepted that the Australian forms were separated from the South American forms well before Australia split off from Antarctica 45 million years ago.

Marsupial lineages had disappeared from North America by 25 million years ago, as had the single species that reached Europe. The Virginia opossum (*Didelphis virginiana*), which is the only indigenous marsupial in North America today, is a recent arrival, having come from South America only about 4 million years ago. Of the other 291 extant marsupial species recognised by Nowak (1999), 73 are indigenous to South and Central America, 217 are indigenous to Australia and New Guinea and one (the Tasmanian tiger, *Thylacinus cynocephalus*) is probably extinct.

The most important feature of marsupials from the standpoint of unique research opportunities is the early developmental stage at which all marsupials are born. The gross anatomy of a neonate resembles that of a mouse at 12.5 days of gestation and that of a human at 6 weeks of gestation. Each neonate quickly attaches to a teat which swells in the mouth. The neonate is unable to release the teat until considerable further development has occurred. This early developmental stage at birth is common to all marsupials and renders the newborn marsupial, in essence, an extrauterine foetus that can be manipulated and observed in ways not possible with eutherian mammals.

In addition, marsupials have a variety of unique anatomical characteristics of the jaw, skull, teeth and reproductive system (Tyndale-Biscoe 1973). The early developmental stage of marsupials at birth and their distinctive anatomy are interpreted not as reflecting a more primitive stage in evolutionary development than eutherians, but rather as alternative strategies for achieving an equally adaptive endpoint. Thus, marsupials are useful for comparative research

designed to improve understanding of the evolution of genetic and physiological mechanisms in mammals. *Monodelphis domestica* is a marsupial species that is well suited to research and the laboratory environment.

There are three orders of American marsupials: Didelphimorphia (American opossums) with 15 genera and 66 species; Paucituberculata (shrew opossums) with two genera and seven species; and Microbiotheria with one species (the monito del monte) (Nowak 1999). Only four species, all American opossums, have been used extensively as laboratory animals, although the adaptability of many others to laboratory conditions has never been explored. Two of the four species are large pouched opossums (family Didelphidae), and two are small pouchless opossums (family Marmosidae).

### Marsupials in the laboratory

*Didelphis virginiana* has been used extensively as a laboratory animal in North America, and its close relative *Didelphis marsupialis* has been used in South America. The care, experimental manipulation and use of these species in laboratory research were reviewed in detail by Jurgelski (1987). However, *Didelphis* have limited utility because they are relatively large (1.0–5.5 kg), are aggressive towards one another and are seasonal breeders. Furthermore, reproductive success is low among captive-born animals, particularly males (VandeBerg 1990). No one has developed a long-term, self-propagating breeding colony of *Didelphis*. Therefore, experimental animals or breeders needed to produce first-generation captive progeny are usually captured from the wild. These animals have additional disadvantages in that they are of unknown age and health status, and generally carry a heavy parasite load. Furthermore, they are a potential source of pathogens that are causal agents of a variety of serious human diseases (Jurgelski 1987). Despite the shortcomings of these two species, they are likely to continue to be used as experimental animals for research that requires a relatively large marsupial or depends on the unique characteristics of these species.

*Marmosa robinsoni*, a small American opossum (40–70 g for females and 60–130 g for males) that appeared to have promise as a laboratory marsupial, was bred in captivity for several generations during the 1960s and 1970s (Barnes & Barthold 1969; Barnes 1977). However, fecundity decreased with each successive generation, and satisfactory conditions

for long-term propagation of this species were never identified.

### *Monodelphis domestica*

The grey short-tailed opossum (*Monodelphis domestica*) is the only American marsupial species that has proven to be successful as a self-perpetuating population in captivity. It has many characteristics that render it ideally suited as a laboratory animal, and it is widely used in North America and Europe. Breeding colonies have also been established in Australia and Brazil for specific experimental applications. Some stocks of this species have been produced in captivity for as many as 43 generations with no apparent detrimental effects on fertility, fecundity or health status. Because of the selection that has undoubtedly taken place over these generations, *Monodelphis domestica* presently in captive colonies may be quite different from their wild counterparts. For these reasons, laboratory stocks of this species are now referred to as the laboratory opossum. Figure 19.1 shows an adult female laboratory opossum.

*Monodelphis domestica* has been inappropriately described as the Brazilian opossum or grey opossum in the literature. The term Brazilian opossum is incorrect because many opossum species are native to Brazil, and *Monodelphis domestica* is also found in Bolivia and Paraguay. The grey opossum is also not an appropriate designation for *Monodelphis domestica* because some other opossum species also have grey pelage. Appropriate common names for this species are grey short-tailed opossum, laboratory opossum (when used in reference to laboratory stocks rather than wild animals) and *Monodelphis domestica*. However, the confusion demonstrates the importance of using scientific names where appropriate. The genus name *Monodelphis* may be used as an abbreviation without the species name when it is clear that *Monodelphis domestica* is implied, much as *Drosophila* is often used in reference to *Drosophila melanogaster*.

**Figure 19.1** An adult female laboratory opossum.

The 15 species of the genus *Monodelphis* (short-tailed opossums) are distributed from Panama to Argentina. Linnaeus in 1758 coined the term *Didelphis* meaning two wombs, because it was known that the females of this species have an internal uterus like other mammals, as well as a pouch in which much of early ('foetal') development takes place (Tyndale-Biscoe 1973). The short-tailed opossums were named *Monodelphis* by Burnett in 1830 (Pine & Handley 2008) who recognised them as being closely related to *Didelphis* but lacking a pouch.

The omnivorous *Monodelphis domestica* is nocturnal and individuals are most active during the first few hours of the evening (Streilein 1982). Under natural conditions, they consume insects and other invertebrates, small vertebrates and various fruits. They are efficient predators, particularly adept at killing scorpions and cockroaches. They reproduce throughout the year in their natural habitat.

### Size range and lifespan

*Monodelphis domestica* is among the largest of the short-tailed opossums. Adult laboratory-reared females typically weigh 60–100 g and males 90–150 g, although individuals of some stocks tend to be larger, and individuals within many stocks may exceed these ranges (VandeBerg 1990). Laboratory opossums begin to show physical signs of aging at approximately 3 years of age and generally die during the fourth year of life. The oldest individual in the colony maintained at the Southwest Foundation for Biomedical Research (San Antonio, Texas) reached the age of 4 years and 7.5 months (unpublished data). Reproductive and developmental data are summarised in Table 19.1.

### Social organisation

Little is known about the natural social organisation of *Monodelphis domestica*. Individuals are difficult to capture because they are solitary and nomadic, and the estimated population density is less than four per hectare (2.47 acres) in areas where the animals are most common (Streilein 1982). Furthermore, they are terrestrial and do not congregate at isolated trees where species of semi-arboreal marsupials are more easily found.

Fully enclosed nests with an opening just large enough to allow entry are built by both males and females in hollow logs, fallen tree trunks or among rocks (Nowak 1999). Both males and females use their slightly prehensile tails to carry nesting material to the nest.

It has been stated in the literature that the species was named *domestica* because it frequently inhabits human households and plays a welcome role in controlling insect and rodent populations. However, human dwellings are not considered to be a frequent habitation site for these animals (I. Santos, personal communication).

### Reproduction

In both the wild and captivity, *Monodelphis domestica* is a non-seasonal breeder. Female laboratory opossums reach

**Table 19.1** Laboratory opossum: reproductive and developmental data.

Parameter	Normal value
Weight at birth (mg)	~100
Weight at 2 weeks (mg)	~840
Weight at 8 weeks (g)	~20
Weight of adult female (g)	60–100
Weight of adult male (g)	90–150
Dental formula	$I^5_4C^1Pm^3M^4_4$
Range of litter size	4–13
Typical litter size	7–8
Age at weaning (weeks)	8
First oestrus (in presence of a male) (days)	140
Full sexual maturity (months)	6
Time of ovulation after exposure to male (days)	5–10
Time of copulation to fertilisation (days)	1
Gestation (days)	13.5
Minimum interbirth interval (with successful weaning) (weeks)	11
Typical age of reproductive failure, females (months)	18–24
Typical age of reproductive failure, males (months)	24–30
Typical lifespan (months)	36–42

sexual maturity by 5 months of age (Stonebrook & Harder 1992) and males achieve sexual maturity 2–3 weeks later. The youngest female reported to have given birth was 141 days old, but few females conceive prior to 140 days of age. For most females, the prime reproductive period is prior to 18 months. Not all successful breeders continue to reproduce that long, and most females cease to reproduce by 24 months of age. Males are frequently successful breeders until 24–30 months of age and sometimes for several months more.

### Standard biological data

The body temperature of *Monodelphis domestica* is 32.6°C (Dawson & Olson 1988), respiratory rate at rest is approximately 54 breaths per minute, systolic blood pressure is approximately 188 mmHg and heart rate is approximately 345 beats per minute (Kraus & Fadem 1987). Maximal hearing sensitivity is from 8–64 kHz (Frost & Masterton 1994). The dental formula for *Monodelphis domestica* follows the standard opossum pattern of  $I^5_4C^1Pm^3M^4_4$  (Reig *et al.* 1987; Macrini 2004; van Nievelt and Smith 2005).

### Genetics

The karyotype of *Monodelphis domestica* contains  $2n = 18$  chromosomes. The autosomes are large and easily distinguished from one another. Two hundred and thirty-three

bands can be observed in the G-banded karyotype (Pathak *et al.* 1993). The X chromosome is much smaller than the autosomes, and the Y is much smaller than the X. The karyotype is ideally suited for cytogenetic investigations.

Early surveys of genetic variants among laboratory opossums revealed 13 polymorphic proteins and two polymorphisms at the DNA level (Perelygin *et al.* 1996; reviewed by VandeBerg and Robinson 1997). The laboratory populations derived from the four founding sites in Brazil had significantly different gene frequencies for these early markers, and some alleles are specific to one population or another (van Oorschot *et al.* 1992a).

### Breeds and strains

The laboratory opossum, like the Syrian hamster, differs from other laboratory animals in that the details of its origins are precisely known and well documented (Table 19.2) (VandeBerg & Robinson 1997). The first captive animals ancestral to the present laboratory population were four males and five females captured in 1978 near the town of Exu in the state of Pernambuco, Brazil. They were shipped to the National Zoological Park in Washington DC, where all of them reproduced. Twenty pedigreed first- and second-generation descendants were provided to one of the authors (JLV) in 1979. These animals were used to establish the initial breeding colony of laboratory opossums at the Southwest Foundation for Biomedical Research. Genetic material from all nine of the original wild-caught founders from Exu is present in the laboratory stock known as Purebred Population 1.

Table 19.2 summarises the populations present in the Southwest Foundation laboratory opossum colony. These populations are the source of most, if not all, the other laboratory colonies of *M. domestica* in the world.

A single shipment of 40 fully pedigreed laboratory opossums, all derived from the nine original founders from Exu (Purebred Population 1), was sent from the Southwest Foundation to the Zoological Society of London, Regent's Park, London, in 1983. A successful breeding colony was established there and became a source of animals for European investigators. Several shipments totalling 56 descendants of the founders of Populations 1 and 2 were also made from the Southwest Foundation to German institutions during the 1980s. It is believed that all populations of *Monodelphis domestica* in Europe are derived from these shipments to London and Germany.

More recently, laboratory opossums were exported from the UK to Australia. The Australian animals were descended from the 40 individuals sent to London in 1983, and thus all trace their ancestry to the original nine founders of Purebred Population 1.

An additional colony established outside North America was initiated in 2007 with 16 descendants of the founders of Population 1 shipped from the Southwest Foundation to the Federal University of Mato Grosso do Sul in Campo Grande, Brazil. Previously, there had been no self-sustaining captive colonies of this species in Brazil.

Because the number of founders is limited, most laboratory opossums are partially inbred. However, several stocks

**Table 19.2** Laboratory stocks of *Monodelphis domestica*.

Laboratory code for wild populations	Year of importation to the USA	Town of origin	Number of founders	Purebred laboratory population (no. of founders)	Admixed populations	
					Laboratory designation	Proportionate genetic contribution to each individual
1	1978	Exu	9	Yes (9)	–	–
2	1984–1988	Piraua	14	Yes (7)	Admixed Population 2	≥78% Pop. 2, ≤22% Pop. 1
3	1990	Joaima	2	No (0)	Admixed Population 3	≥64% Pop. 3, ≤36% Pop. 1
4	1992	Conselheiro Mota	1	No (0)	Admixed Population 4	50% Pop. 4, 50% Pop. 1
5	1993	Brecha (Bolivia)	2	No (0)	Admixed Population 5	≥54% Pop. 5, ≤46% Pop. 1

exist that have no shared relatives with Purebred Population 2 (Table 19.2). Therefore, animals with an inbreeding coefficient of zero can be produced by matings between animals from Purebred Population 2 and any animals of Purebred Population 1, Admixed Population 3, Admixed Population 4 or Admixed Population 5.

### Sources of supply (conservation status)

The species *Monodelphis domestica* is broadly distributed in much of eastern and central Brazil and in Bolivia and Paraguay. The natural habitat of *Monodelphis domestica* encompasses the relatively dry Chaco, Cerrado and Caatinga biomes, where they are most frequently found among rock outcrops (Streilein 1982). The species is not endangered or threatened. However, wild-caught animals are difficult to obtain because their population densities are low, making them somewhat difficult to trap.

The laboratory opossum colony at the Southwest Foundation for Biomedical Research is the source population for all of the captive colonies of *Monodelphis domestica* in the world, although a limited number of descendants of the nine founders from Exu (Population 1) were distributed directly by the National Zoological Park in the late 1970s and early 1980s.

### Uses in the laboratory

The continuous availability and non-seasonal reproduction of laboratory opossums have made possible, for the first time in history, the large-scale experimental use of a marsupial species. Consequently, the laboratory opossum has become by far the most extensively used marsupial in research. A total of 895 publications citing *Monodelphis domestica* were indexed in BIOSIS Previews (all life science subjects) between 1978, the year in which the first *Monodelphis domestica* arrived in the USA, and 2006 (two in 1978 and 50 in 2006). In comparison, the numbers of publications citing other marsupial species have remained approximately constant and at a much lower level for any one species (VandeBerg & Robinson

**Figure 19.2** A newborn laboratory opossum.

1997). The diversity of research topics is too great to allow a detailed summary in this chapter, but several major areas of research are summarised below.

The most obvious distinctive feature of marsupials, the birth at such an early stage of development, was a major driving force for establishing a laboratory marsupial. The features of the newborn laboratory opossum (Figure 19.2) have been exploited in research on function of the embryonic nervous system in long-term cell culture (Stewart *et al.* 1991), healing of the neonatal spinal cord after complete transection or crushing (Fry & Saunders 2000; Mladinic *et al.* 2005; Lane *et al.* 2007), effects of oestrogen on testicular development (Fadem & Tesoriero 1986), ontogeny of skin healing and development of capacity for scarring (Armstrong & Ferguson 1995), and development of neuropeptides, steroid receptors, and the visual system (reviewed by Kuehl-Kovarik *et al.* 1995).

Research in immunobiology provides an example of the use of laboratory opossums in a comparative approach to answer questions about function and evolution (Stone *et al.* 1996). Both the cellular (Stone *et al.* 1997) and humoral (Croix *et al.* 1989; Shearer *et al.* 1995) immune responses have been investigated. Evidence from those early studies suggested that the immunobiological characteristics of *Monodelphis* are

similar in many respects to those of eutherian mammals. For example, skin graft responses are similar to those of eutherian mammals, suggesting considerable polymorphism of the MHC class I locus. However, *Monodelphis* exhibits a limited mixed lymphocyte culture (MLC) response, suggesting that class II loci may be highly restricted in extent of variability (Stone *et al.* 1998). An additional difference between *Monodelphis* and eutherian mammals is that the primary humoral response is mediated equally by IgM and IgG, as compared with predominantly IgM in eutherian mammals. It had been suggested that marsupials may have a less complex immune system than eutherian mammals, but recent findings have established that the genomic regions that specify key elements of the immune system are highly similar in the marsupial and eutherian lineages (Wong *et al.* 2006; Belov *et al.* 2007).

The laboratory opossum is also uniquely suited as a model for some human diseases. It is the only mammal other than humans known to be susceptible to malignant melanoma as a consequence of ultraviolet (UV) radiation alone; that is, in the absence of chemical promoters (Robinson *et al.* 1994, 1998). It also is susceptible to a form of corneal cancer induced by UV radiation, and susceptibility is highly heritable (VandeBerg *et al.* 1994; Kusewitt *et al.* 2000). Although corneal cancer is rare in humans, the high heritability of this disease in laboratory opossums makes it a potentially valuable model for investigating genetic mechanisms in carcinogenesis. A third disease for which the laboratory opossum has become a valuable model is dietary-induced hypercholesterolaemia. A single recessive gene is primarily responsible for determining that some individuals are resistant to this condition and others are susceptible (Rainwater *et al.* 2001). Recent work has shown that the gene for dietary response affects response to dietary cholesterol but not to saturated fat (Kushwaha *et al.* 2004a), and that factors associated with different dietary responses are absorption of dietary cholesterol, production of apolipoprotein B and expression of hepatic genes involved in cholesterol homeostasis (Kushwaha *et al.* 2004b, 2005; Chan *et al.* in press).

*Monodelphis domestica* displays considerable promise for research on allografting and xenografting, the interactions between graft and host and the development of tolerance. Allogeneic grafts of melanoma cells into opossum pups lead to tumour growth and systemic metastasis (Robinson & Dooley 1995). Remarkably, even mouse and human cancer cells can cause tumours to develop, some of which metastasise when implanted into pups (Fadem *et al.* 1988; Wang *et al.* 2003). Immunotolerance of xenografts can be induced by injecting multiple desensitising doses of cancer cells (Wang & VandeBerg 2005). These findings establish a foundation for exploiting *Monodelphis domestica* in research on the cascade of interactions between host and tumour cells, and the immunobiological mechanisms that are involved.

A xenograft model has also been developed for investigating cell transplant strategies to repair diseased or injured retinas (Sakaguchi *et al.* 2004). This model involves transplanting murine brain progenitor cells and retinal progenitor cells into the eyes of 5–10-day-old *Monodelphis* pups.

One of the primary reasons for developing *Monodelphis domestica* as a laboratory animal was the need for a small

marsupial that could be produced in large numbers for research on the marsupial system of sex chromosome dosage compensation: paternal X-chromosome inactivation in somatic cells of females (VandeBerg 1983; VandeBerg *et al.* 1983). It took more than two decades for molecular technologies to advance to the state where they could be brought to bear on understanding the reasons for the difference between paternal X inactivation in the opossum model and the random inactivation that is characteristic of eutherian mammals. However, a flurry of recently published manuscripts has established that marsupials lack the inactivation centre that is present on eutherian X chromosomes; these reports have provided details about inactivation of the X-chromosome in X-bearing spermatozoa prior to fertilisation (Davidow *et al.* 2007; Hornecker *et al.* 2007; Mikkelsen *et al.* 2007; Namekawa *et al.* 2007; Shevchenko *et al.* 2007). However, since the mechanism by which paternal X inactivation occurs is still not understood, this field of research is likely to continue providing new insights into this unusual form of regulation of gene expression at the level of the whole chromosome.

*Monodelphis domestica* exhibits a variety of interesting genetic and physiological characteristics. For example, females exhibit greatly reduced rates of recombination in comparison with males (and with eutherian females) (van Oorschot *et al.* 1992b, 1993; Samollow *et al.* 2007); *Monodelphis* has a photolyase capable of repairing UV-induced DNA damage (cyclobutane pyrimidine dimers) (reviewed by Ley *et al.* 2000), whereas eutherian mammals do not; and the sperm heads of *Monodelphis* precisely align in pairs during passage through the epididymis and possibly achieve maximal progressive motility via this adaptation (Taggart *et al.* 1993). Some other marsupial species are known to share one or more of these characteristics with *Monodelphis*, but none provides such a convenient and economical opportunity for further investigation.

Cells from *Monodelphis* have been cultured for a variety of research purposes under conditions suitable for culture of cells from eutherians, but the optimal temperature for cell culture is less than 37°C. Cell types that have been cultured include lymphocytes (Robinson *et al.* 1996), fibroblasts (Merry *et al.* 1983; Robinson *et al.* 1994), melanocytes (Dooley *et al.* 1995) and melanoma cells (Robinson *et al.* 1994).

Procedures for long-term (10-day) culture of the intact central nervous system of 2-day-old pups have been developed and used to investigate the actions of amines and transmitters, and the activation and inactivation of gamma-aminobutyric acid (GABA) receptors (Stewart *et al.* 1991; Mollgard *et al.* 1994).

Embryos have been cultured by several groups (Moore & Taggart 1993; Johnston *et al.* 1994; Selwood *et al.* 1997). Embryos cultured at 32.6°C, the body temperature of *Monodelphis domestica*, progress further than those cultured at 37°C (Selwood & VandeBerg 1992). Parthenogenic development to the two-cell stage occurred in 8% of oocytes cultured at 32.6°C.

The recent development of high-quality genomic tools specific to *Monodelphis domestica* (Samollow 2006) is certain to stimulate an acceleration of research with this species in many biological disciplines. These tools include a physically anchored genetic linkage map with 150 highly polymorphic

loci (Samollow *et al.* 2007), a cytogenetic BAC map (Duke *et al.* 2007) and a high-quality draft of the genome sequence (Mikkelsen *et al.* 2007). The laboratory opossum was the first marsupial selected for genome sequencing by the National Human Genome Research Institute. This first marsupial gene sequence has been instrumental in revealing the complexities of the marsupial immune system, and a prominent role for the evolution non-protein-coding sequences in mammalian diversification (Mikkelsen *et al.* 2007; Lemos 2007). A genomic tool that is not yet available for *Monodelphis domestica* is a species-specific microarray. However, cross-species applications of mouse and human microarrays have been successfully used to profile gene expression changes during melanomagenesis and spinal cord development (Wang *et al.* 2004; Lane *et al.* 2007).

## Laboratory management and breeding

### General husbandry

#### Housing

Polypropylene and polycarbonate cages (mouse shoebox cages) of two standard sizes are generally used: a 'large cage' sized 43 cm × 22 cm × 13 cm (l × w × h); and a 'small cage' sized 27 cm × 17 cm × 12 cm. Each cage is fitted with a standard stainless steel top used for rodents. However, the tops used in breeding colonies must fit within 0.75 cm of the cage edges, and the space between the bars on the top must not exceed 0.75 cm. Pre-weanlings can escape through openings as small as 1.0 cm, which is a standard distance between bars on some tops sold for use with rodents. Filter covers may be used to protect against airborne pathogens, but they are not essential in a well managed colony. Multiple cages are kept in racks (Figure 19.3). There have been no recent studies on housing requirements for this species.

#### Environmental provisions and enrichment

The cage bottom is covered with aspen or pine shavings to a depth of approximately 2.5 cm. The animals are hygienic and generally choose a single corner of their cage as a toilet area. In addition to bedding, each cage is provided with paper towelling, cut into 5 mm × 18 cm strips by a paper shredder, for nesting material. The amount of nesting material provided is about 3 g for a single animal, 5–6 g for a pair or a female with a litter and 10–12 g for a group of weanlings caged together. The early stage of development at birth, incapability of thermoregulation at birth and lack of a maternal pouch make nesting material especially important for neonatal survival.

Nest boxes are provided in cages that contain breeding pairs, a female with a litter or a group of weanlings. Nest boxes can be constructed of any material that can be easily cleaned and permit a female to be checked for the presence of a litter with minimal disruption. Polypropylene or plastic food storage boxes with removable lids and an entrance hole cut from one side will suffice. In the authors' colony, aluminium nest boxes (18 cm × 13 cm × 10 cm) are generally used which are constructed locally. Each box has a remov-

**Figure 19.3** A rack of large cages, each containing a pair of animals and a nest box. The life history record of each animal is kept in a spiral notebook affixed to a clipboard on the front of each cage.

able 'shoe box' type lid and an entrance measuring 5 cm × 4.5 cm (w × h). A convenient alternative to a nest box is a round glass jar 16.5 cm long, 8.9 cm in diameter, with an opening 8.3 cm in diameter. However, it is easier to check females for the presence of litters if a nest box with a removable lid is used (Figure 19.4).

From the perspectives of psychological well-being and environmental enrichment, ample nesting material is essential for all animals whether they are single- or pair-housed, and at least one nest box is essential for pair-housed animals. Both males and females may spend many hours per day assembling bundles of nesting material, curling their semi-prehensile tails around a bundle and carrying it around the cage. In some instances, bundles of nesting material are woven into elaborate nests, even by animals that are not in breeding situations. A nest box is essential for paired animals in order to provide a haven in which one member of the pair may be able to protect itself from an aggressive mate, and for providing seclusion for mothers with litters. There have been no recent publications on enrichment for this species.

#### Social grouping

Litters are weaned at 8 weeks of age and under optimal conditions the animals are caged individually (a small cage is sufficient). Littermates may be caged communally in a large cage containing a nest box, but there is risk of aggression. If caged communally beyond 4 months of age, many animals become aggressive towards one another and severe

**Figure 19.4** A female with a 4-week-old litter in a nest box from which the lid has been removed. The nest is well formed except across the top where the lid contacted the sides of the nest itself.

injuries or death are likely outcomes. Therefore, individual caging is mandatory after 4 months of age.

#### Presentation of food and water

Feeders designed for rodents are unsatisfactory for laboratory opossums; Rather, food pellets are placed directly on the bedding in a clean area of the cage. To ensure *ad libitum* feeding, a sufficient quantity of pellets is added three times a week.

Water is provided in glass, polycarbonate or polypropylene bottles fitted with rubber stoppers and stainless steel sipper tubes. Automatic waterers are not recommended because *Monodelphis* are unable to adapt to any of several designs that have been tested.

#### Identification and sexing

Littermates are separated into individual cages by 4 months of age and the only contact between animals after that age occurs during pairing of females and males. Therefore, after the separation of littermates, each individual can be tracked by an ID number that is recorded in a record booklet or on a cage card that is maintained with each animal as it is moved from cage to cage.

Ear punching and the shearing of identification patterns on the back are practical methods of identifying individuals if there is a need to do so with group-housed littermates, provided the identification patterns are monitored and renewed as needed. Subcutaneous transponders may also provide an efficient means for identification of individual *Monodelphis*.

*Monodelphis* can be easily sexed long before weaning because the testicles are contained in a pendulous scrotum attached to the body by a thin stalk.

#### Physical environment and hygiene

Room temperature is maintained at 23.5–26.5°C, slightly higher than that recommended for rodents. Although no controlled experiments have been reported, the neonatal survival rate is suspected to be higher at this slightly elevated temperature.

Fluorescent lighting is used in a cycle of 14 h light and 10 h dark, and humidity is maintained at 55–60%. Humidity levels below 35% lead to desiccation and necrosis of the ears and tails of some individuals.

The animal rooms should be kept as quiet as practicable. Loud noises such as those that occur during construction cause stress that may lead to increased levels of aggression and cannibalism. Additionally, *Monodelphis domestica* can hear at ultrasound frequencies inaudible to humans and sources of high-frequency noise should be minimized.

Once a week, all animals are moved to clean cages with fresh bedding. Nest boxes and well constructed nests are moved to the new cage if they are not soiled. Care is taken to disturb as little as possible the nests of mothers with litters less than 3 weeks old in order to discourage cannibalism. Nest boxes are generally washed in a cage washer every 2 weeks when litters are not present.

#### Health monitoring and quarantine

*Monodelphis* is an exceptionally healthy laboratory animal and has required no health monitoring procedures other than routine daily observation.

Animals captured from wild populations typically carry endoparasites and should be kept in quarantine while the bedding is changed three times per week to break the life cycle of these parasites. Endoparasites are generally eliminated within a few weeks by this procedure. Ectoparasites have not been documented on newly captured animals.

#### Transport

For general advice on transport see Chapter 13. Local transportation in a climate-controlled vehicle suited for animal transport is safely conducted with the animals in their standard cages. Temperature should be maintained as constant as is practical. For trips during which the temperature might drop below the normal laboratory range for this species (23.5–26.5°C), the animals should be transported in cages with nest boxes and several days after the addition of nesting material so that ample nests will have been constructed.

For shipping by air, animals can be placed in standard mouse shipping boxes purchased from commercial mouse suppliers, into which plywood partitions have been placed (International Air Transport Association 2008). Each animal must be placed singly within a partitioned enclosure to prevent fighting en route. Even littermates that have been caged together since weaning are likely to be aggressive during transport. Care must be taken in constructing partitions to ensure that a portion of each compartment has open access to at least one ventilation opening.

The authors typically partition each box into six compartments (Figure 19.5), the dimensions of which are 18 cm × 13 cm × 18 cm (l × w × h). The box is divided into four compartments if fewer than five animals are to be transported.

The floor of each compartment is covered with about 2.5 cm of shavings and about 15 g of nesting material is provided for each animal. Two quarters of one orange are usually provided at one end of each compartment, and apple quarters or pieces of watermelon have also been used successfully. Alternatively, water gel packs can be used, especially for trips of extended duration.

Attempts to ship females with suckling pups have had limited success because of cannibalism. However, no problems have been encountered in shipping pregnant females, even in the late stages of pregnancy.

Animals should be acclimatised to a new environment in solitary cages. Pairings of breeders should not occur less than 1 week after arrival to minimise the risk of aggressive behaviour.

**Figure 19.5** Top: a shipping box ready for six animals to be placed inside. Note the nesting material on top of the wood shavings and the two orange quarters in each. Bottom: a plywood cover with holes for air exchange is placed inside the box before closing the cardboard top to ensure that animals cannot gain access to an adjacent compartment and to facilitate putting individual animals into, and retrieving them from, the compartments.

## Breeding

### Condition of adults

Females are biologically capable of rearing up to four litters per year, although this level of success is rare. More than four litters can be produced by a single female in a year if the pups are removed for experimental purposes prior to weaning and the female is returned immediately to breeding. One female subjected to this protocol produced 67 progeny in 1 year. The largest number of progeny weaned by a female in the Southwest Foundation colony is 49.

A single male can be paired with a different female every 2 weeks, and could in theory sire up to 26 litters per year. The largest number of weaned progeny sired by a male in the Southwest Foundation colony is 105.

Female laboratory opossums reach sexual maturity by 5 months of age (Stonebrook & Harder 1992), 2–3 weeks earlier than males. Oestrus is induced at any time of the year by the presence of a strange male, generally 5–10 days after the animals are caged together. The induction of oestrus occurs even immediately after a litter dies or is removed prior to weaning, if a female is provided with a male. This characteristic is highly advantageous in comparison to many marsupial species that are seasonal breeders. This characteristic also facilitates timed pregnancies and the collection of staged embryos.

The only practical strategy for determining if an animal is fertile is to pair it with a member of the opposite sex which has a recent history of fertility. If an animal does not reproduce after four such opportunities, it is judged to be infertile.

### Pairing

Monogamous pairings are made to minimise aggressive behaviour and to prevent interference with mating. Under normal conditions, a mature male and female are placed together in a large cage (with a nest box and nesting material). Pairing should be done early in the day so that animal care staff can be alert for undue aggression for at least a few hours after pairing. A low level of aggression is common and does not pose a high risk, but occasionally the animals must be separated due to aggressive fighting.

Conceptions are not likely to occur more than 10–12 days after pairing, so males are typically removed after 2 weeks, at which time they may be paired with another female. After removal of the male from the cage, the female is kept solitary for at least 2 weeks (the gestation period), usually in a small cage. If a litter has not been born (or has died or been removed), the female may be paired again with the same or a different male. If a litter is born, the mother and her nest are carefully transferred to a large cage and the nest is placed in the nest box if it was not constructed inside the box.

The day of mating cannot be precisely ascertained by techniques that are used for rodents. There is no vaginal plug and sperm are rarely detected in vaginal smears. Furthermore, the time of ovulation is difficult to predict from vaginal smears because cornified cells from the lateral vaginae may infiltrate the posterior vaginal sinus, masking changes in the cytology of the cells that line the posterior vaginal sinus

(Fadem & Rayve 1985). Therefore, several laboratories have adapted video systems to determine the precise timing of mating (Baggott & Moore 1990; Mate *et al.* 1994; Kuehl-Kovarik *et al.* 1995). Generally, a group of cages is filmed under red light during the dark phase when most matings occur. The film can be fast forwarded for examination each day to identify the exact time of copulations. Another strategy has been to keep the paired animals separated by a perforated plexiglass partition except for 1–2 h at the end of the light period and at 12 h intervals after that until mating occurs (Kuehl-Kovarik *et al.* 1995). Mating usually takes place within 20 minutes of removal of the partition.

Generally, no harm arises from leaving a male paired with a female longer than 2 weeks, provided he is removed within the first 2 weeks after a litter is born to prevent him from eating the pups when they are left alone by the mother. However, there is little chance of conception from a prolonged pairing and there is always risk of aggression.

### Fertility decline and aggression

Risk of aggression is especially high among older animals, particularly females. For most females, the prime reproductive age is up to 18 months, and most cease to reproduce by 24 months of age. Cessation of reproductive success is often accompanied by aggressive behaviour toward prospective mates. Females in the authors' colony are routinely removed from the breeding programme at between 18 and 24 months of age depending on their reproductive history, history of aggression towards potential mates and importance of the particular animal to its breeding programme. However, the oldest female that produced a litter in the authors' colony was 34 months old at the time of conception and she succeeded in rearing the litter to weaning.

Some elderly males become aggressive to their potential mates, so a judgement is made as to which males are allowed to continue as studs beyond 2 years of age. The oldest male that sired a litter in the authors' colony was 40 months old at the time the litter was conceived.

### Embryonic development

The embryonic development of *Monodelphis* has been described in detail (Baggott & Moore 1990; Mate *et al.* 1994; Selwood *et al.* 1997). According to Mate *et al.* (1994), ovulation and fertilisation occur about 24 h after mating. Between 2 and 3 days later (days 3 and 4 after mating), most embryos are at the four-cell stage, and on day 5 most are at the 16–32-cell stage. Complete unilaminar blastocysts are present on day 7 and bilaminar blastocysts on day 8. The first somites are formed in the primitive streak by day 10, the heart and blood vessels by day 11 and paddle-shaped forelimbs by day 12. By day 14, the forearm is well developed with claws on the digits, and birth occurs on day 15. Thus, development from the bilaminar blastocyst stage to birth takes place in a mere 7 days.

### Production

At the time of pairing, a male and a female are placed together in a large cage containing bedding, nesting mate-

**Figure 19.6** A large cage ready for a pair of animals. Fox chow is placed on the bedding near the front of the cage. Nesting material is divided into two portions to limit competition for it. Typically, one animal builds a nest inside the nesting box and the other builds a nest outside.

rial, a nest box and fresh feed and water (Figure 19.6). Both males and females build nests.

Birth occurs approximately 14.5 days after copulation and 13.5 days after ovulation and fertilisation (Mate *et al.* 1994). Under normal circumstances, birth probably occurs in the seclusion of the nest and nesting material should be provided to allow for this behaviour. Pregnant females may be observed or filmed giving birth if deprived of nests.

Females may become more active for a few minutes before birth. At the moment of birth, the female places one side of the dorsal surface of her rump on the floor, with hindfeet in the air; props the anterior part of her body by placing a forepaw on the floor; and curves her spine so her head is near the urogenital opening, which is raised to extrude the neonates on to the mammary area.

As many as 15 neonates have been observed in a newborn litter. However, the maximum number of newborns that are capable of surviving is equal to the number of teats of the mother; that number is 13 in most individuals, but may be only 11 or 12 (Robinson *et al.* 1991). Typical litter size (determined after attachment to the nipples) varies among stocks, but 7–8 is common for many stocks, and 9–12 is not unusual. Occasionally, a litter of 13 is reared to weaning.

The neonates are light grey at birth and are licked vigorously by the mother while they flail from side to side in worm-like movements. Attachment to the nipples generally occurs within seconds, or a few minutes at most, and the colour of the skin turns to a bright pink shortly thereafter. Neonates that do not find a teat continue crawling, generally in an upward direction and remain light grey. After the unattached neonates reach the dorsal side of the mother, they are cannibalised.

### The young

Litter survival is highly variable, depending on the breeding stock, the age and reproductive experience of the dam and the size of the litter. In general it exceeds 50%, but survival is reduced in highly inbred litters and in litters born to older

females (approaching 2 years of age and beyond). Small litters tend to be lost more frequently than large litters; litters of three or less rarely survive to weaning, so, if it is necessary to return the female immediately to breeding, the litter has to be euthanased. It is important that extraneous noise be kept to a minimum in breeding colonies to reduce the risk of cannibalism of litters by their mothers.

The newborn marsupial has an embryonic two-layered forebrain, no cerebellum, embryonic eyes, no ears and hindlimbs at the paddle stage of development. Anatomically, it resembles a mouse at 12.5 days of gestation. The newborn *Monodelphis* weighs about 100 mg and is approximately 1 cm in length. It attaches to a teat within seconds or minutes of birth. Each newborn remains attached to the same nipple for at least the first week of life. At 2 weeks of age, each pup weighs about 840 mg (VandeBerg 1990) and may be left alone in the nest, although pups are frequently present on the nipples during the third week of life both when the mother is resting and when she is active. The pups begin to grow fur during the third week of life and their eyes open about 1 month postnatally.

Laboratory opossums are routinely weaned at 8 weeks of age, when they weigh about 20 g. Occasionally, when the size of the young is judged to be smaller than normal at that age, they are left with the mother until 9–11 weeks postpartum, when lactation usually ceases. Weaning is accomplished simply by placing littermates in a large cage by themselves or by placing each one in a small cage. The weanlings continue to grow rapidly for 200–250 days, after which growth plateaus (see growth curves in Cothran *et al.* 1985). Growth of females and onset of puberty may be stimulated if they are paired with males prior to 6 months of age (Stonebrook & Harder 1992). Conversely, females exhibit pronounced growth retardation if they are deprived of mates after about 6 months of age (Cothran *et al.* 1985; VandeBerg 1990).

### Breeding systems

Most aspects of breeding systems are similar to those for mice and rats, with the exception of inbreeding.

For stocks where the number of animals and reproductive success are especially limited, a useful practice is to pair proven breeders with animals that are virgin or have failed to reproduce. This practice helps to ensure that animals capable of reproduction are provided the best opportunity for success before they are culled on the basis of reproductive performance.

At the Southwest Foundation for Biomedical Research, more than 95 000 laboratory opossums have been produced and weaned. Pedigree data are maintained for each individual in a computerised database, and the inbreeding coefficient of each individual is calculated using software developed at the institution (Dyke 1989). Because the number of founders was small, all individuals are partially inbred except those that can be produced by intercrosses between several stocks (as discussed under Breeds, strains and genetics).

Initial attempts were made to develop inbred strains by full sibling matings, but all lines were eventually lost as a consequence of reduced fecundity, as well as high mortality of litters within the first 2 weeks of life. One line achieved

an inbreeding coefficient (F) of 0.911 (equivalent to just over 11 generations of full sibling matings) before it was lost (VandeBerg & Robinson 1997).

More recently, a series of partially inbred stocks has been developed by matings involving full siblings interspersed with matings between relatives less closely related than full siblings (VandeBerg & Robinson 1997). Six of these stocks currently have inbreeding coefficients in excess of 0.90. Selective breeding practices are being employed to increase the inbreeding coefficients gradually while maintaining satisfactory levels of fecundity and litter survival rates, and two stocks have inbreeding coefficients in the range of 0.95–0.96 (equivalent to 14–15 generations of full sibling matings).

The partially inbred stocks have been derived from Purebred Population 1 and Admixed Population 2. Despite not having achieved the status of fully inbred strains (F = 0.986, equivalent to 20 generations of full sibling matings), these partially inbred stocks are useful for research where uniform experimental subjects are desired, for research on histocompatibility and for intercross and backcross mating strategies for gene mapping and other genetic objectives.

### Feeding

#### Natural and laboratory diets

In captivity, *Monodelphis* will consume virtually any small animal, such as cockroaches, crickets, earth worms, scorpions, mice, lizards, snakes and *Tenebrio* larvae. They will also eat most fruits. However, the recommended diet is a reproduction grade of dried pelleted fox chow (reviewed by VandeBerg 1990) for which no supplements are required.

#### Dietary requirements

Dietary experiments have been conducted with commercially prepared foods for cats, dogs, marmosets, mink and foxes, as well as more natural diets containing meat, insects, eggs, milk, infant mice and fruit. The optimal diet of those that have been rigorously tested experimentally was found to be the reproductive grade of fox chow as noted above (VandeBerg 1990). The diet currently used at Southwest Foundation for Biomedical Research contains not less than 35% crude protein 13% crude fat and 4.5% crude fibre (dry weight). Specific dietary requirements have not been defined.

#### Water

All animals should have access to fresh water *ad libitum*. At the authors' facility, tap water is provided in bottles that were sanitised on the same day. A freshly sanitised bottle of water is provided weekly when the cage is changed.

### Laboratory procedures

#### Handling

*Monodelphis domestica* is a most gentle and docile wild mammal in response to human handling. Even individuals

captured from wild populations can be picked up by experienced handlers with little risk of being bitten. At the Southwest Foundation facility, the only hand coverings used are latex disposable gloves. Under most circumstances the animal is picked up by the tail, as is typically done with laboratory mice (Figure 19.7). Animals may also be picked up by placing the fingers under the midsection and the thumb over the back, just behind the front legs of the animal, as shown in Figure 19.8.

If a *Monodelphis* is not handled properly, it is likely to bite. The animals have sharp, needle-like teeth, and most adults, particularly the larger males, are capable of puncturing human skin. Inexperienced or careless handlers are generally bitten under either of two circumstances. One is when they move their hand too fast in attempting to capture an animal. *Monodelphis* has an extremely fast reflex to bite anything that moves rapidly, whether it be prey (presumably a hunting adaptation) or a human hand. The biting reflex is often quicker than the initial movement of the human hand to grab the tail (or animal). In contrast, moving the hand slowly to the animal and picking the animal up slowly will almost never elicit a bite, even though some animals back into the corner of the cage hissing with an open mouth and displaying their teeth. The second circumstance in which an inexperienced or careless handler is likely to be bitten is when an attempt is made to restrain any part of the body of the animal. If the body of an unanaesthetised animal must be restrained, light leather gloves, such as golf gloves, should be used.

**Figure 19.7** Picking up an animal by the tail. This female has a newborn litter.

## Physiological monitoring

Body temperature can be assessed by thermocouples as a deep colonic measure at an insertion depth of 3–4 cm (Dawson & Olson 1988). A temperature-sensitive microchip transponder also could be used.

General advice on refinement of blood collection, within the Three Rs framework, is provided by the Joint Working Group on Refinement (JWGR) (1993). Blood can be collected easily and routinely by cardiac puncture of animals anaesthetised with isoflurane. A 1.27 cm, 27G (0.406 mm nominal outside diameter) needle on a 1 ml tuberculin syringe is typically used, although a larger syringe may be used for collecting larger volumes of blood. Experienced technical staff collecting blood routinely are able to obtain 0.8–1.0 ml of blood in 95% of attempts, with no obvious adverse impact on health (Robinson & VandeBerg 1994).

Cardiac puncture, under anaesthetic, has been conducted repeatedly over time on an animal without apparent ill effects. In an investigation of the effects of chronic blood loss, 2 ml of blood was removed weekly from each of 20 animals for 13 weeks (Manis *et al.* 1992). No apparent changes in health status occurred, although haematopoietic characteristics were altered.

Another procedure for collecting blood is to make an incision through the ventral tail artery of an anaesthetised animal after a heat lamp has been placed above it to dilate the blood vessels (Kraus & Fadem 1987). This procedure can yield 1–2 ml of blood. The wound is cauterised upon completion of the procedure and sealed with flexible collodion.

Large volumes of blood can be collected by exsanguination using the cardiac puncture method. Experienced personnel can routinely collect at least 5 ml and often as much as 6–7 ml from each animal that weighs 100 g or more (Robinson & VandeBerg 1994).

Urine may be collected by putting individual animals in cages with wire mesh bottoms placed over collection pans

**Figure 19.8** Picking up an animal by placing the fingers under the midsection with thumb and index finger just behind the front legs of the animals.

as described by Christian (1983). The collection pans should contain a layer of mineral oil to prevent evaporation of urine and faeces.

For milk collection within 2 weeks postpartum, the sucklings must be pulled off the teats and euthanased. For older litters, the mothers can simply be separated from their litters temporarily. Two hours after the separation of mothers from their litters, dams are anaesthetised with isoflurane and injected intramuscularly with 0.75 ml oxytocin (Samples *et al.* 1986). Milk droplets are exuded by manually squeezing the mammary glands, and they are collected in capillary tubes. Between 5 and 10  $\mu$ l of milk can be collected during the first few days of lactation, and up to 80  $\mu$ l during the later stages (Crisp *et al.* 1989).

### Administration of medicines

General advice on refinement of the administration of medicines or test substances can be found in JWGR (2001).

### Anaesthesia and analgesia

Light anaesthesia by inhalation is recommended for all injections because it is difficult to restrain *Monodelphis*. The procedures for injections of *Monodelphis* are the same as those for rodents. Subcutaneous injections are generally given in the shoulder area, intramuscular injections in the hindleg area and intraperitoneal injections in the caudal abdomen.

Detailed procedures for anaesthesia were described by Robinson and VandeBerg (1994). However, procedures for anaesthesia by inhalation have been further optimised in recent years.

The most satisfactory inhaled anaesthetic in the authors' experience is isoflurane. Although considerable care must be taken to maintain depth of anaesthesia without killing the animal, isoflurane is relatively safe in the hands of experienced personnel for short-term anaesthesia (up to 1 h). Animals are provided with water but no food overnight prior to anaesthesia, in order to minimise the risk of vomiting and aspirating stomach contents during or after sedation. In the authors' laboratory, animals are placed in a chamber with six individual compartments lined with paper towels. The chamber is flooded with a mixture of isoflurane/oxygen delivered from an anaesthesia machine. The oxygen flow rate is set at 0.8 l/min and the isoflurane level is set at 4% V/V. The animals can be monitored through the clear acrylic sides of the chamber. The length of time required to sedate the animals is variable, but most animals are thoroughly sedated within 5 minutes. Animals are removed from the chamber based on their appearance.

Depth of anaesthesia can best be judged by toe pinching and respiratory rate. Deep anaesthesia sufficient for cardiac puncture or surgical procedures is indicated by failure to withdraw a foot in response to a pinch. Respiratory rate should be watched continuously during the procedure and during the recovery period; a sudden reduction in rate of breathing or sporadic breathing indicates that an animal is at high risk of death. If respiration ceases, an animal can often be resuscitated by placing one or two drops of doxa-

pram hydrochloride (20 mg/ml) on the tongue of the animal. If respiration does not commence within a few seconds, one end of a 20 cm length of plastic tubing is placed over the animal's nostrils and snout, firmly against the skin, and the person conducting the procedure blows into the other end at intervals of 1–2 s so that the animal's lungs inflate on each occasion. The tubing has an external diameter of 15 mm and an inside diameter of 11 mm.

For recovery from anaesthesia, an animal is placed into an acrylic chamber on its ventral surface on a heating pad covered with absorbent paper and maintained at 30°C. If there is any sign of respiratory distress, the procedures for resuscitation are immediately performed. Most animals are fully recovered and able to walk without losing balance within 10–30 minutes, when they are returned to their cages.

For inducing deep anaesthesia for a prolonged period of time, a combination of inhalation and injection anaesthesia was developed in the early 1990s (Robinson & VandeBerg 1994). In this protocol, the animal was lightly anaesthetised with isoflurane and then injected subcutaneously with 0.0025 ml (= 50  $\mu$ g) per gram of body weight of sodium pentobarbitone (pentobarbital) (20 mg/ml) followed by an intramuscular injection of 0.0054 ml (= 2  $\mu$ g atropine and 40  $\mu$ g ketamine) per gram of body weight of an atropine/ketamine mixture (1.25 ml atropine (0.4 mg/ml) + 0.1 ml ketamine HCl (100 mg/ml)). Occasionally during prolonged anaesthesia, one or two additional injections of sodium pentobarbitone (pentobarbital) were required to maintain deep anaesthesia. The authors have not used this protocol in their laboratory for many years, but would recommend now that isoflurane replace halothane, and that a more advanced injectable anaesthetic be considered as a replacement for sodium pentobarbital. Telazol (30 mg/kg) or a mixture of medetomidine (100  $\mu$ g/kg), butorphanol (0.2 mg/kg) and ketamine HCl (10 mg/kg) have been used to immobilise Virginia opossums (*Didelphis virginiana*) for short periods of time (Stoskopf *et al.* 1999), suggesting possible replacements of sodium pentobarbital. More research is required to establish an up-to-date protocol for long-term anaesthesia of laboratory opossums.

Light anaesthesia of dams and litters with halothane or isoflurane has been used for procedures that can be completed quickly. However, litter loss is unacceptably high when dams with litters are subjected to deep anaesthesia with isoflurane. Deep and prolonged anaesthesia with the combination inhalation and injection anaesthesia protocol causes minimal loss of litters (E.S. Robinson, personal communication). Halothane/nitrous oxide anaesthesia has also been used successfully to anaesthetise dams and pups for the conduct of neonatal surgery (Armstrong & Ferguson 1995). It has been reported that feeding a mother mealworms immediately after recovery from anaesthesia may reduce the incidence of cannibalism (Saunders *et al.* 1995).

Another approach to anaesthesia of a mother with attached pups is to anaesthetise it lightly using a 50 ml conical tube delivering the regulated anaesthetic mixture over the head of the mother (Wang & VandeBerg 2003). This procedure enables anaesthesia of the dam without affecting the pups, greatly reducing the risk of losing the litter.

Anaesthesia of sucklings within the first 2 weeks of life has been accomplished by cooling them with ice (Morykwas

*et al.* 1991; Stewart *et al.* 1991) or by using a series of puffs of dry ice dust (Taylor & Guillery 1995). The methods are effective because the neonates are not capable of thermoregulation; furthermore, the nervous system is poorly developed with an embryonic forebrain and no cerebellum. Because neurones in mammals cease to function when body temperature is reduced to 20 °C, as compared with 0–4 °C in poikilotherms, cooling is an effective form of anaesthesia for altricial mammalian neonates which are incapable of thermoregulation. Hypothermia is recommended for surgical procedures on altricial neonates by the Institute of Laboratory Animal Research (ILAR) (1992) and the Canadian Council on Animal Care (1993), and the subject was reviewed by Martin in 1995.

Procedures for ovariectomy, castration, partial hepatectomy, unilateral hysterectomy, vasectomy and embryo transfer have been described in detail (Kraus & Fadem 1987; Robinson & VandeBerg 1994). In addition, procedures have been developed for tail amputations and eye removals, which are sometimes necessary following trauma (usually fighting) or infection (Robinson *et al.* 1994). The procedure for anaesthesia by inhalation and injection is generally used for major surgery, but simple procedures can be conducted under isoflurane anaesthesia alone. Techniques are similar to those used for rodent surgery. However, incisions must be closed with sutures rather than surgical clips, because the animals are adept at removing the clips.

Buprenorphine is used as a post-surgical analgesic. Immediately after surgery, 0.1 mg/kg is injected subcutaneously along the lateral abdomen. For the next 2 days, buprenorphine is administered orally at 0.18 mg/kg twice a day. If the animal appears to be experiencing discomfort, the dose is increased to 0.25 mg/kg.

### Euthanasia

Euthanasia is most easily accomplished by inhalation because the animals are difficult to restrain for physical methods of euthanasia. Carbon dioxide or isoflurane are suitable inhalants for the purpose of euthanasia (see also Chapter 17). After the animal has ceased to breathe, cervical dislocation is performed to ensure that it is dead. Alternatively, after induction of anaesthesia using injectable agents (eg, tiletamine/zolazepam mixture), animals can be euthanased with an overdose of intravenous or intracardiac barbiturates (Pye 2006).

Young animals within the first 2 weeks of life are resistant to carbon dioxide and isoflurane, and are easy to restrain. Therefore, decapitation is an appropriate form of euthanasia for this age group.

## Common welfare problems

### Disease

Laboratory opossums are relatively free of infectious disease so little is known about appropriate treatments or medicines. As is standard procedure with other small readily available laboratory animals, a colony can be protected from transmissible diseases by euthanasing animals suspected of

being infected, and conducting a complete pathological and microbiological evaluation. Appropriate prevention measures can be implemented on the basis of the results. Comprehensive texts on wild animal medicine are available (eg, Holz 2003).

### Prophylaxis

Infectious diseases are virtually non-existent in animals that are properly managed and fed a nutritionally adequate diet. However, some of the animals involved in early dietary trials were prone to opportunistic respiratory infections. The affected animals were restricted to groups receiving diets that turned out to be nutritionally suboptimal.

### Signs of disease

Common clinical signs of disease include rapid breathing, poor coat condition and loss of body weight. If an animal suspected of having an infectious disease is discovered in a colony, it should be necropsied by a veterinary pathologist, and all husbandry procedures and conditions, including nutritional adequacy of the diet, should be carefully assessed.

Loss of hair near the tail on the rump occurs commonly in females, especially when they are lactating, and rarely in males. There is no apparent detriment to health from hair loss which is thought to be due to hormonal changes.

Haematological and serum chemical values have been determined for healthy laboratory opossums maintained under standard conditions (VandeBerg *et al.* 1986; Cothran *et al.* 1990). These values may be useful as reference values in instances where health problems are suspected.

### Common diseases

Wild-caught animals may harbour a variety of endoparasites, including *Capillaria*, *Trichuris*, *Cruzia*, *Strongylus* and fluke-like and *Hymenolepis*-like species, although no disease states induced by these parasites have been observed (Hubbard *et al.* 1997). There have been no reports of ectoparasites in wild or captive populations of *Monodelphis domestica*.

Based on 150 necropsies of *Monodelphis* that became ill or died spontaneously at the Southwest Foundation for Biomedical Research, the most prevalent pathological changes were in the digestive (38%), urogenital (19%), cardiovascular (12%) and respiratory (19%) systems (Hubbard *et al.* 1997). The primary disease problems were rectal prolapse, congestive heart failure and dermatitis. Rectal prolapse was a common problem in laboratory opossum females in earlier years (Cothran *et al.* 1985), but for unknown reasons this condition has become rare. It is likely that animals resistant to this condition under laboratory conditions have been highly favoured by selection.

The most common neoplasia is pituitary adenoma, followed by uterine lesions and cutaneous lipomas (Kuehl-Kovarik *et al.* 1994; Hubbard *et al.* 1997).

No zoonoses have been identified and, as far as the authors are aware, abnormal behaviours related to housing conditions have not been reported.

## Reproductive problems

In addition to those animals that fail to reproduce (see Breeding), some females that readily produce litters routinely lose them during the first 2 weeks after parturition. In the authors' colony, females that fail to wean three consecutive litters are generally culled.

When the mother of a valuable litter dies, fostering can be employed to rear the litter to weaning if the pups are old enough to release the teat. However, milk production may not be sufficient for survival of members of an existing litter in addition to foster pups. Therefore, fostering is generally practised only when the mother of an especially valuable litter dies. In that case, a foster mother is required whose pups are at the same age as the orphaned litter, and whose litter size is at least as large as the litter to be fostered. The foster mother's pups are euthanased and replaced in the nest by the foster pups.

Fostering has been successful for litters between 2 and 4 weeks of age. Beyond that age, orphaned litters can be reared by feeding fox chow liquefied with tap water; it is fed via an eye dropper three to four times per day. In addition, half-and-half cow's milk is provided in a shallow dish, such as a Petri dish. As the animals mature, the amount of water added to the fox chow is gradually reduced until it has a pasty consistency by the time the animals are 6 weeks old. By 6–7 weeks of age, the animals can eat moistened fox chow in a shallow dish. By 7–8 weeks, they are able to consume fox chow pellets.

# 20 Tree shrews

Eberhard Fuchs and Silke Corbach-Söhle

## Biological overview

### General biology

The first report of tree shrews dates back to 1780. The description and an accompanying sketch were from William Ellis who maintained a naturalist's journal during Captain's Cook's third Pacific voyage of the ship *Discovery*. Uncertainties concerning the taxonomic affinities of tree shrews originated with this description in which tree shrews were designated 'squirrels', a confusion that still occasionally persists today. About 80 years ago, a variety of reports described similarities between tree shrews and primates, and the conclusion that there was a direct phylogenetic relationship between modern tree shrews and primates was predominantly made by Le Gros Clark (1924), largely on the basis of brain anatomy. His view was endorsed in G.G. Simpson's classification of the mammals (Simpson 1945). In the following years, several authorities (see eg, Luckett 1980) had doubts about this phylogenetic link and, as a result, excluded tree shrews from primates. An intensive discussion of tree shrews and their phylogenetic relationships is provided in Luckett (1980), Martin (1990) and Emmons (2000). Today, tree shrews are placed in their own order, Scandentia, and according to very recent molecular phylogenetic studies they are placed together with primates and dermoptera within the clade Euarchonta (Kriegs *et al.* 2007). Currently the tree shrew genome is being cloned as part of the Mammalian Genome Project, funded by the National Institutes of Health (NIH).

Tree shrews (family Tupaiidae) are subdivided in two subfamilies: the diurnal subfamily Tupaiinae containing five genera (*Tupaia*, *Anathana*, *Dendrogale*, *Lyonogale*, *Urogale*) and the nocturnal subfamily Ptilocercinae, with a single genus, the pen-tailed tree shrew *Ptilocercus*. The geographic distribution of the Tupaiidae extends from India to the Philippines, and from Southern China to Java, Borneo, Sumatra and Bali. Natural habitats are tropical forests and plantation areas (Table 20.1).

In general, tree shrews are similar to squirrels in their external appearance and habits and the Malay word 'tupai' (from which the name *Tupaia* is derived) is used for both tree shrews and squirrels, whereas the Malay word 'tana' (found in the species *Lyonogale tana*) is used only for tree shrews. Despite their name, tree shrews have nothing to do with real shrews and most species of tree shrews are much

more active on the ground than in trees. Although there are clear differences between tree shrew species, they share a basic common pattern that can be described with reference to the relatively well known Belanger's tree shrew *Tupaia belangeri* (Figure 20.1). All are relatively small, agile and, in general, omnivorous with a preference for small fruits and invertebrates, especially arthropods. Tree shrews range from the predominantly arboreal (*Dendrogale*, *Tupaia minor*, *Ptilocercus*) to the predominantly terrestrial (*Lyonogale*, *Urogale*), but most tree shrew species are semi-arboreal and usually forage on the ground. The terrestrial tree shrews have a long snout and sharp claws both of which are used to obtain food by rooting through the leaf litter on the forest floor. Species which are more arboreal are smaller than the terrestrial species. They have shorter snouts, smaller or poorly developed claws, long tails and more forward-facing eyes. When eating, all species will hold food between the front paws. In general, tree shrews have a well developed visual system and, for some species, colour vision has been documented. The vocal repertoire of *Tupaia belangeri* consists of eight distinct sounds. Within this repertoire, four basic acoustic structures can be distinguished which can be associated with functional categories such as alarm, attention contact and defence (Binz & Zimmermann 1989). No ultrasonic vocalisations could be found in *Tupaia belangeri* (Kirchhof *et al.* 2001). The same authors report that during agonistic encounters, adult males elicit five distinct call types, partially with graded variants. The calls show harmonic or noisy spectra ranging from 0.4–20 kHz. The call structure depends on the dominant status and the motivation of the individuals. Increasing pitch indicates increasing fear, while decreasing pitch and larger frequency range indicate increasing aggression (Kirchhof *et al.* 2001).

All tree shrews seem to use nests both for sleeping and rearing of offspring. Nests may be located in trees or on the ground level. Even tree shrews, which spend most of their time in trees, avoid climbing on fine branches and do not leap within or between trees. Typically, they use broad branches as support and trees as a vertical extension of the terrestrial substrate (Martin 1990).

### Size range and lifespan

Depending on the species, the body weight of tree shrews ranges between 45 and 350 g (see Table 20.1) with adult

**Table 20.1** Tree shrews, Scandentia, their biological data and distribution (with modifications from von Holst (1988)) (BW, body weight; HBL, head-body length; TL, tail length; NN, number of nipples; GP, gestation period; LS, litter size; BIW, birth weight; W, weaning; P, puberty; L, longevity in captivity).

	Body	Reproduction	Life history	Distribution
Subfamily Tupaiinae <i>Tupaia</i> (tree shrews) <i>T. belangeri</i> , <i>T. glis</i> , <i>T. gracilis</i> , <i>T. javanica</i> , <i>T. longipes</i> , <i>T. minor</i> , <i>T. montana</i> , <i>T. nicobaria</i> , <i>T. palawanensis</i> , <i>T. picta</i> , <i>T. splendidula</i>	BW: 50–270 g HBL: 12–21 cm TL: 14–20 cm NN: 1–3 pairs	GP: 41–55 days LS: 1–5 BIW: 6–10 g	W: around 30 days P: around 2 months L: 9–12 years	Tropical forests, semi-terrestrial

males being usually heavier than adult females (own observation). Their lifespan in the wild is still unknown but in captivity, *Tupaia glis* (Bever & Sprankel 1986) and *Tupaia belangeri* (own observations) can live 10 years or more.

### Social organisation

Despite extensive morphological description and behavioural studies in the laboratory, remarkably little is known about the behaviour and the ecological roles of tree shrews in the wild (Emmons 1991, 2000; Emmons & Biun 1991). Based on observations of Kawamichi and Kawamichi (1979), males of the common tree shrew *Tupaia glis*, which are close relatives to the Belanger's tree shrew, have relatively stable home ranges of about 2 acres. The territory of an adult male overlaps to a certain extent with the home range of one adult female and also includes the ranges of a small number of juveniles. This suggests that common tree shrews are basically monogamous in the wild, which is in agreement with observations made in the laboratory where tree shrews can be effectively maintained in pairs. The same authors also reported territorial marking behaviour using the chest gland, and territorial fights between adults of the same sex. Chemical signals play an important role in territorial behaviour of male tree shrews. Scent substances are found in glandular secretions, urine, faeces and saliva, and contain

information concerning the identity and physiological state of the individual. Laboratory experiments have shown that in males, both the production of the scent substances and the marking behaviour are controlled by androgens (von Holst & Buerger-Goodwin 1975; von Holst & Eichmann 1998; Eichmann & von Holst 1999).

### Standard biological data

The dental formula of the Tupaiidae is:  $I^2_3C^1Pm^3M^3_3$  (Butler 1980). Core body temperature and its circadian rhythm have been studied by telemetry in *Tupaia belangeri*. Minimal body temperature during the night was about 35°C while during day time the core temperature increased to a maximum of about 40°C (Refinetti & Menaker 1992 and own observations). This day/night difference of about 5°C is much larger than that of most endotherms. Since body temperature rhythm is synchronised with the rhythm of locomotor activity, the diurnal temperature curve shows a bimodal shape which clearly differs from the cosine waveform that characterises the temperature rhythms of other species (Figure 20.2).

Systolic blood pressure recorded using the tail-cuff method similar to that often used in rats yielded a mean systolic blood pressure of 125 mmHg (Fuchs *et al.* 1993). When using this technique it is not necessary, as is the

case with rats, to warm the tree shrew's tail before measurement.

Heart rates in tree shrews show a surprising pattern of variance. Telemetric analysis has revealed that heart rate is strictly correlated with the behaviour and the emotional status of the animals. A heart rate between 240 and 300 beats/min (own observations) is characteristic of resting periods, while during physical activity, heart rate is in the range of 250–350 beats/min and can increase up to 650 beats/min in emotionally exciting situations (Stohr 1988; Muller & Hub 1992). *Tupaia belangeri* shows a high locomo-

**Figure 20.1** Adult male *Tupaia belangeri* from the German Primate Center.

tor activity revealing a clear bimodal pattern with a clear trough in the early afternoon (Kurre & Fuchs 1988) (Figure 20.2).

Reliable data on serum constituents are only available for *Tupaia belangeri*. Table 20.2 summarises serum values reported by Schwaier (1975). An overview of serum and endocrine data is given by von Holst (1977). Erythrocyte numbers are in the range of  $8 \times 10^6/\text{mm}^3$ , leucocytes in the range of  $3 \times 10^3/\text{mm}^3$  and mean thrombocyte numbers in the range of  $170 \times 10^3/\text{mm}^3$  (Zou *et al.* 1983). Basal concentrations for plasma norepinephrine (noradrenaline) range from 2.8–36.3 ng/ml and for epinephrine (adrenaline) from 1.3–19.1 ng/ml (Fuchs 1984). Corticosterone is the principal corticosteroid (mean 9 ng/ml) in the peripheral plasma and in unstressed animals the corticosterone:cortisol ratio is 4.5:1 (Collins *et al.* 1984). Values of urinary hormones for *Tupaia belangeri* are summarised in Table 20.2.

### Breeds, strains and genetics

When selecting a breeding stock for tree shrews, it is important to know the exact origin of the animals. Sometimes, it can be extremely difficult to distinguish between closely related species since traditional classifications do not provide substantial help. Based on their external morphology alone, *Tupaia glis* and *Tupaia belangeri* are very difficult to distinguish from one another. The exact taxonomic classification could be ascertained by means of geographical origin, morphological criteria, cytogenetic analysis and analysis of acoustic signals (Toder *et al.* 1992).

### Sources of supply

The Three Rs are a fundamental ethical requirement in laboratory animal science (see Chapter 2). To refine animal experiments and to reduce the number of animal subjects to a minimum, full control over the genetic background and lifespan of the subjects is required. Therefore, it is strongly recommended that animals should only be purchased from laboratory breeding colonies. Information on sources of

### Uses in the laboratory

Evidence derived from studies on the brain of *Tupaia* by Sir Wilfred Le Gros Clark played a major role in the acceptance

of the classification of Tupaiids as primates. Their popularity as experimental subjects in neurobiology, in particular neuroanatomy, has been a direct consequence of their former phylogenetic status in which they were classified as primitive primates (Campbell 1980). The vast majority of experimental work with *Tupaia* has been on the visual system since they were considered ideal subjects to gain insight into the organisation of the early primate visual system. However, it became clear from comparative studies that *Tupaia* possesses none of the features characteristic of primate visual systems (Campbell 1980).

<sup>1</sup><http://www.dpz.eu>

Tree shrews have proved to be useful animal models in many instances where a small omnivorous non-rodent species is required (Cao *et al.* 2003). Of course, they should only be used where it is appropriate and necessary for the study. They can be used in many fields of preclinical research such as toxicology and virology, in particular in studies investigating herpes and hepatitis viruses (Hunt 1993; Xu *et al.* 2007). Further, various aspects of behaviour, infant development, communication and social structures can be studied in tree shrews (Martin 1968a, 1968b; Hertenstein *et al.* 1987). Based on a study by von Holst (1972), psychosocially stressed male tree shrews were thought to be a suitable model to study the mechanisms of acute renal failure. However, the authors and others (Steinhausen *et al.* 1978) were unable to replicate these results.

Tree Shrews' pronounced territoriality, especially that of males, can be used to establish natural challenging situations under experimental control in the laboratory. When living in visual and olfactory contact with a male conspecific by which it has been defeated, the subordinate Belanger's tree shrew shows dramatic behavioural, physiological and neuroendocrine changes. As we know today, these stress-induced alterations result entirely from the continuous visual presence of the dominant conspecific. In contrast, dominant tree shrews show no noticeable biobehavioural alterations. It is an interesting aspect of preclinical research that many of the alterations in subordinate tree shrews are similar to the symptoms observed in depressed patients and can be counteracted by several classes of antidepressant drugs (Fuchs 2005).

There is a high degree of genetic homology between tree shrews and primates for several receptor proteins of neuro-modulators (Fuchs & Flugge 2002) and the amyloid-beta precursor protein (Pawlik *et al.* 1999); this and the three to four times longer lifespan of tree shrews than that of rodents (Keuker *et al.* 2005), suggest that this species may possibly come to be used in future studies focusing on aging-related brain changes in socially homogeneous and stable cohorts.

## Laboratory management and breeding

### General husbandry

#### Housing

Tree shrews have been housed in enclosures of various sizes. Cages and cage equipment should be adapted to the natural behaviour patterns of the animals, providing enough space for their locomotor activities. The cage equipment thus should include substrates for climbing, such as suitable branches and wire mesh. A broad branch (diameter approximately 7 cm), board or tube should be fixed near the top of the cage where the animals can rest during their siestas. Objects for scent marking such as branches, and pasteboard tubes for hiding and marking should also be offered. Outside the cages, wooden sleeping boxes and, for breeding pairs, a separate nest box and nesting material should be provided. Schwaier (1973) recommended the installation of tunnels made out of flexible plastic tubing, of suitable diameter, which can be fixed outside the cages allowing opportunities

for greater travel. When cages are side by side they must be separated by opaque screens, which prevent interactions other than the exchange of calls and dispersed odours. Cages face to face separated by a corridor are quite satisfactory because they allow visual interactions without the threat of an immediate attack. Below the cages are waste trays with sawdust or paper to catch excrement and food. In general, the caging conditions should allow control and observation of the animals during the active period by the animal care staff. Construction of the animal facilities should allow each room to be emptied of animals from time to time to allow for cleaning, disinfection and repairs. In the rooms all possible routes of escape must be screened with small diameter wire mesh. To avoid startling the animals, it is recommended that staff should give a sign to the animals before entering an animal room, for example, by knocking on the door.

Tree shrews are best housed at a temperature of approximately 25 °C. Temperatures less than 20 °C can be dangerous for the offspring. Humidity is also critical. Experience suggests that minimal levels required are in the range of 45–50%.

Little systematic research has been carried out on housing of tree shrews; a description of a successful facility is provided here. In the German Primate Center, Göttingen, *Tupaia belangeri* are housed in steel cages (size 50 cm × 80 cm × 130 cm (w × d × h) (Figure 20.3), or 65 cm × 85 cm × 85 cm (w × d × h)). Outside the cages are wooden nest boxes with removable covers (18 cm × 15 cm × 15 cm (w × d × h); entrance 6 cm diameter). These boxes are made from waterproof plywood, which is highly resistant to water and heat and can be effectively cleaned. As the animals stay in the box all night, moisture arises and the animals become damp unless open-pored material is used for the nest box. Therefore, boxes made of plastic or metal are inappropriate. The animals can be locked in the box by a shutter and the box can be removed from the cage. Breeding pairs are housed in modular units (two units with nest boxes) which can be separated by a wire mesh frame.

The animal quarters are air-conditioned with a relative humidity of 60 ± 7%, a temperature of 27 ± 1 °C, and a 10-fold air-exchange per hour. The animal rooms are illuminated (L:D = 12:12) from 8:00 am to 8:00 pm with six neon lamps (58 W each, light intensity about 900 lux). After lights are on and before lights are shut down a 30 minute 'sun rise' and a 30 minute 'sun set' with reduced light intensity are programmed. In addition to the neon lamps, each room is equipped with two ultraviolet lamps, which are regulated by a separate timer. The total UV exposure time per day is 2 h (four intervals of 30 minutes each). During the night there is no natural or artificial illumination of the rooms. Each animal room is equipped with one loudspeaker, which is active from 8:30 am to 7:30 pm broadcasting news, reports and some music at low volume. Cages are cleaned once a week with water, the paper under the cages is changed daily, and the waste trays with sawdust are cleaned once a week. No detergents are used in the animal rooms.

#### Presentation of food and water

Food is supplied in glazed stoneware or stainless steel dishes (diameter about 8 cm, height about 3 cm) which are

**Figure 20.3** Housing and rearing *Tupaia belangeri* in the German Primate Center. Upper row: Animal room, a single cage and a nest box closed with a slider. Middle row: Catching a tree shrew from its nest box with a cloth. Lower row: Housing for newborn tree shrews.

changed and cleaned daily. Tap water is provided in bottles or in dishes.

#### Identification and sexing

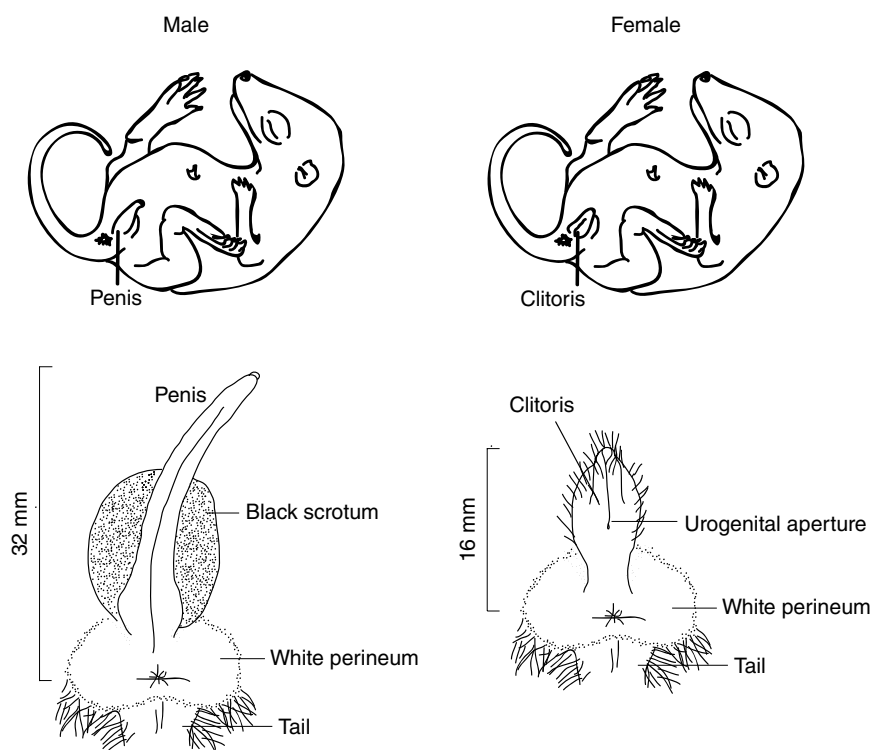

Animals should be individually marked, which can be achieved by subcutaneous implantation of transponders or by cutting patterns into the tail hair. Tattooing is hard to perform and the marks often do not last long. Other methods such as notching the inside of the ear or even amputation of claws are prohibited by law in most countries.

The external genitalia of adult male tree shrews consist of a slender and elongate penis, which is posterior to scrotal testes. Retraction of the testes into the abdominal cavity can occur under experimental conditions of stress. In female *Tupaia*, *Lyonogale*, *Urogale* and *Dendrogale*, the clitoris is greatly elongated and grooved on its ventral surface. In neonatal *Tupaia*, the urethra enters the clitoris and extends throughout its length as the clitoral urethra, whereas in the adult the urethra opens together with the vagina as a urogenital sinus at the base of the clitoris. Therefore, infant and

juvenile females and males might sometimes be mixed up because the vaginal orifice at the base of the clitoris is sealed. In contrast to the penis, the clitoris does not have a tubular sheath (Figure 20.4).

#### Health monitoring, quarantine and barrier systems

From the information available to date, the maintenance of tree shrews involves very little risk to human health but, nevertheless, they should be handled with caution. Routine colony health-screening procedures should be carried out and veterinary assistance must be available. Newly acquired animals must be kept in quarantine and require veterinary treatment for external and internal parasites. As pointed out earlier, environmental and social stressors may be a cause of health problems in tree shrews. They may induce sudden and dramatic weight loss or even wounds. Therefore, animal care staff should routinely monitor the animals for signs of illness, such as no food and water intake,

**Figure 20.4** Ventral view of the external genitalia of infant and adult tree shrews (*Tupaia belangeri*). Note the penis of the infant tree shrew is twice as long as the clitoris and the anterior position of the scrotum in the adult male tree shrew (Bearder & Pitts 1987, adapted from Martin 1968a).

diarrhoea, weight loss, aberrant body posture or movements, rough fur and lethargy or apathy. When the animals are handled for the routine weighing procedure (at least once a month), they should also be checked for signs of cataracts or tumours.

### Transport

For shipment, each individual should be confined to a small dark wooden compartment or its nest box. The size of the compartment is determined by the body weight of the animal and both national and international regulations. It must have openings for sufficient ventilation and should be lined with nesting material. Moist fruits, cooked moist rice and water in a gel form (available commercially) should be provided. Before shipping, animals should be habituated to water provided in gel form. See also Chapter 13.

Due to the high metabolic rate and the sensitivity of tree shrews to disturbances, newly arrived animals are often quite exhausted. For recovery, they should be supplied with sugar water or apple juice and a high-calorie diet. The sleeping boxes should be warmed with an electric cushion (30 °C), lights in the room should be dimmed and disturbances should be avoided.

### Breeding

#### Adults

Females can give birth to their first litter at an age of about 4 months. Males become fertile between 4 and 5 months. The best age for first pregnancy seems to be between 6 and 9

months. If the animal is older, problems such as infertility, stillbirth, cannibalism or abortion occur more often. In males, stress can result in testicular inactivity (Fischer *et al.* 1985; Brack & Fuchs 2000).

#### Identifying fertile state

Based on the length of the intervals between copulation periods observed in captivity, several authors have suggested an 8–12 day (anovulatory) oestrous cycle in various species of *Tupaia* and ovulation is supposed to be induced by copulation (Martin 1990). However, it is still a matter of discussion whether ovulation is triggered by copulation (induced ovulation) and/or whether an oestrus cycle exists. No cyclic changes in vaginal smears have been detected by the authors or others. In addition, the authors could not find any cyclic alterations in urinary excretion of sex hormones. According to Cao *et al.* (2001) ovulation can be induced by combined injections of pregnant mare serum gonadotrophin and human chorionic gonadotrophin.

#### Mating systems

In tree shrews, mating is one of the critical and in many cases most difficult part of breeding. If a female accepts a male, copulation may be observed within a few hours. In many cases, however, placing an adult male and an adult female together in one cage will result in aggressive interactions. There are two main reasons for these fights. One is that the individuals just do not like each other; 'love at first sight' and its cardiovascular consequences have been described by von Holst (1987). Another reason is territoriality. If the mating cage is the territory of one partner, this animal –

male or female – defends its area against the intruder. In many cases the animals become gradually familiar with another and amicable physical attractions can be observed at the 'border' between the cages so that the partition can be removed after some days. However, if aggressive interactions or fights do not cease, other partners have to be tested. When a well matched couple is found and stable pair-bonding is established, constant reproductive success is guaranteed. Under natural and laboratory conditions, breeding may occur at any time of the year and no seasonal breeding peaks have been described.

When the female leaves the nest after giving birth and having suckled the young, copulation with the male usually occurs within a few hours. Therefore, leaving a couple together is convenient and ensures regular births. Repeated pregnancy cycles are typical of a highly successful breeding colony of *Tupaia belangeri*, and female receptivity and copulation are often confined to the post-partum oestrus (Martin 1968a, 1968b).

### Conception and pregnancy

In *Tupaia belangeri*, pregnancy can be detected by palpation from the second week of gestation onwards. Significant weight gain (30–50 g) and marked swelling of the abdomen are observed within 2 weeks before term. Duration of pregnancy in regular breeding pairs is in the range of 41–45 days. Breeding success is a good indicator of the general condition of the colony. Even with harmonious, healthy and well nourished breeders, successful breeding can be disrupted by a variety of disturbances. Tree shrews are highly susceptible to stress and many of the problems in housing them are related to this. Loud noises, strange persons and unfamiliar care staff, overcleaning, inadequate furnishing of the cages and crowding have all been shown to be the reasons for abortion, shortened pregnancies, cannibalism or reduced amounts of milk resulting in starvation of the offspring.

### Nesting

About 1 week before term, the female starts to carry nesting material into one of the two nesting boxes. For nesting material, we offer shredded paper, wood-wool or dry leaves. If no nesting material is available, the females will use pellets.

### Parturition

After a relatively short gestation period, tree shrews give birth to naked and altricial pups. In most cases births occur in the morning hours, but sometimes they also occur in the afternoon.

### Early development

The infants are born without fur; their ears open at around 10 days and their eyes after 20 days. The development strongly depends on the milk supply and health condition. The nipple count for all species of tupaiids falls within the range of one to three pairs. Field and laboratory studies indicate that the number of pups per litter is one to four (in some cases in the authors' colony there were five young per

litter which were successfully raised). The birth weight is about 10 g.

Immediately after birth, the young are nursed and the weight of optimally fed babies is in the range of 14–20 g. Females tend to be a little heavier than males. Schwaier (1973) reports a litter size of 2.23 and sex ratio of 0.82 (males: females). For another colony of *Tupaia belangeri*, a sex ratio of 1.8 and a litter size of 2.4 was reported (Hertenstein *et al.* 1987). A survey of the *Tupaia belangeri* colony at the German Primate Center, Göttingen (1984–2007, total 2962 animals) revealed a sex ratio of 0.95 (m:f) and the following litter sizes: singletons: 158; twins: 462; triplets: 461; quadruplets: 113; quintuplets: 9.

A detailed description of growth and reproductive development in *Tupaia belangeri* from birth to sexual maturity is given by Collins and Tsang (1987) and Hertenstein *et al.* (1987).

The maternal behaviour in *Tupaia* is unusual among mammals and has been described in detail by Martin (1968a, 1968b). The tree shrew species that have been investigated (*Tupaia belangeri*, *Tupaia minor*, *Lyonogale tana*) all show an unusual nursing schedule with the infants kept in separate nests and visited by the mother for suckling only once every 48 h.

The pups receive about 5–10 ml milk. Due to the thin skin the dilated stomach appears as a light patch in the abdomen (Figure 20.5). The fat content in tree shrew milk is very high (about 25%) while the sugar concentration is low. The energy content of the tree shrew milk lies within the range of other mammals which is in general related to body size (Martin 1990). Since any suckling visit takes only 5–10 minutes, a tree shrew infant will be in contact with its mother less than 2 h during the 30 day nest phase, following which the infant is independent of its mother for milk supply. Thus, tree shrews have the lowest mother–infant contact and parental investment yet described for viviparous mammals (Martin 1990). The pattern of minimal mother–infant contact is strikingly different from the characteristic primate pattern of elaborated maternal care, juvenile dependence and enhanced social organisation (Martin 1990). In a recent field study, Emmons and Biun (1991) investigated the maternal behaviour of the Malaysian tree shrew *Tupaia (Lyonogale) tana*. Their observations confirmed the peculiar 'absentee' system previously demonstrated only in the laboratory. For the first month of life, the pups stay in a nest apart from the mother, who visits them every other day to nurse them for about 2 minutes. After they leave the nest, the mother spends a lot of time with them daily for at least 3 weeks. The male that shared the mother's territory frequently interacted with the mother during the nestling phase of the pups, but had no contact with them.

Death of young is due to premature birth (non-inflated lungs, interstitial pneumonia), cannibalism or starvation. Cannibalism of the new-born young by the mother or other adults occurs under stressful laboratory conditions which contribute to high mortality and also leads to modifications of maternal suckling behaviour. It has been observed by von Holst (1969) that increasing stress in the group modifies the suckling intervals and led to increased cannibalism of young *Tupaia belangeri* under experimental conditions.

**Figure 20.5** Newborn *Tupaia belangeri* before (left) and after suckling (right). Due to the thin skin the dilated stomachs appear as light patches (\*) in the abdomen.

According to reports in the literature, newborn *Tupaia belangeri* are marked by a maternal scent substance which protects against cannibalism (von Stralendorff 1982). In contrast to these observations, the authors were successful with cross-fostering strategies in cases where the mothers were unable to suckle and raise their offspring.

In order to avoid cannibalism and to control suckling success the authors separate the neonates from the parents immediately after birth. For the next 3 weeks they are kept in a nest box elsewhere in the animal facility (Figure 20.3). Since temperature regulation is immature in newborn tree shrews the floor of the nest box is warmed by a temperature-controlled heating cushion (eye heating cushion, temperature about 27°C) during the first 10 days (Figure 20.3). If they are kept too warm, they will develop a lighter fur colour; as they get older, the animals turn to their normal colour. Mothers are transferred to their litter every day for a maximum of 30 minutes. It is important to note that some females suckle their young only every second day; others have very clear daily time windows within which suckling will take place. The best suckling rhythm for each breeder can only be found by careful observation of individual animals.

#### Hand rearing

The extremely high fat content of the tree shrew milk is probably one reason why hand rearing is regarded as being very difficult. For successful hand rearing Tsang and Collins (1985) developed a liquid formula and a protocol which conforms to the natural weaning pattern of *Tupaia belangeri*.

#### Weaning and rearing

*Tupaia belangeri* can be weaned around day 35. In the authors' colony the young are separated from the parents at 50–60 days of age. Weaned *Tupaia* of the same sex and about equal age can be housed in peer groups (up to 10 animals depend-

ing on the size of the cage and the number of nest boxes). At 8–10 weeks of age, females and males gradually become fertile and consequently aggressive interactions increase. It is then time to separate the animals. In many cases smaller all-female groups (three animals) are stable. Males are housed singly or together with a female.

#### Feeding

##### Natural and laboratory diets

Tree shrews of the genus *Tupaia* are predominantly insectivorous. Besides insects they use fruit to add extra calories or nutrients such as calcium to a high-protein diet.

At the authors' colony, as basic food *Tupaia belangeri* are provided with a specially developed pelleted *Tupaia* diet. In addition, the animals get small pieces of fruit (such as apples, oranges, bananas, grapes, kiwi) and vegetables twice a week. Once a week, they get fruit juice and vitamins, cooked eggs or baby food and on weekends, small pieces of crisp bread. As rewards they get meal-worms, raisins, pieces of banana, dates and figs. Breeding pairs or recovering animals get, in addition to the standard food, cat chow or mashed bananas.

In the laboratory, tree shrews are reported to eat almost anything. Therefore, when pellets are not available they can be fed with steamed rice and chopped beef heart; they especially prefer soft, fat and sweet food, and all kinds of fruits and vegetables. There are, however, indications for allergic mechanisms against soybean products and oat flakes (Brack *et al.* 1990).

#### Water

As judged from the water content of their faeces, tree shrews absorb little water from their ingesta and they cannot stay without water for more than 1 day without serious problems. Consequently, water bottles must be controlled daily

and water must always be present *ad libitum*; the mean water intake is 350 ml/kg. Tap water should be changed at least once a week. Bottles and nipples should be washed with hot water or sterilised between changes. No detergents should be used.

## Laboratory procedures

### Handling and training

For quick and easy catching tree shrews can be locked in their nesting boxes as the animals usually slip into the boxes as soon as somebody enters the room. When removing the animals and to protect the experimenter's hands, the animal is gently wrapped in a cloth (40 cm × 40 cm) (Figure 20.3). Since their teeth are small, bites are not dangerous but can be painful. Using this technique, no difficulties occur with the usual procedures such as daily external body inspection, weighing, urine and blood collection, temperature and blood pressure recording, and application of substances by different routes. Tree shrews can be easily trained for memory tests, for example, by positive reinforcement techniques (Ohl *et al.* 1998; Bartolomucci *et al.* 2001; see also Chapter 16).

### Physiological monitoring

Rectal temperature can easily be measured by thermometers of the type used in humans. Transmitters can be implanted for long-term studies.

### Collection of specimens – blood, urine

Blood withdrawal (about 500 µl) by puncturing the venous plexus at the lower side of the tail with a small scalpel is recommended by some authors. Prior to puncture, the tail should be shaved and rubbed with a silicon paste which improves the blood collection. Blood flow can be enhanced by holding the tail under a heating lamp. This technique, however, requires experience and is therefore often unsatisfactory. Another approach is described by Schwaier (1974), taking blood from the saphenous vein. Following the recommendations of GV-SOLAS for small laboratory animals, not more than 0.7 ml blood per 100 g body weight at a time should be collected. In cases of repeated blood sampling (eg, over 2 weeks) not more than 0.07 ml/100 g body weight should be collected within 24 h. Despite being completely relaxed during blood sampling, the procedure *per se* seems to be stressful for the animals as documented by increased basal heart rate over several days after one blood sampling procedure (Stohr 1988).

Morning urine can easily be collected from animals that have been confined to their nest box shortly before the lights turn on in the animal rooms. A slight massage of the hypogastrium gives between 1 and 7 ml of urine. Another approach is to place plastic mats with wells under the cages and to collect the urine later with a pipette out of the wells.

Urine analysis has proved to be a stress-free and reliable procedure for long-term monitoring of the physiological status of *Tupaia belangeri*. Among these are parameters for metabolic activity (Johren *et al.* 1991), various bioactive compounds (Collins *et al.* 1989; Fuchs & Schumacher 1990; Fuchs *et al.* 1992) and urinary proteins which play a crucial role in olfactory communication (Weber & Fuchs 1988). Age and time of the day may have an impact on the values (Fuchs 1988; van Kampen & Fuchs 1998). For urinary data see Table 20.2.

### Administration of medicines

Most routes of applications, such as subcutaneous, intramuscular, intraperitoneal or oral, are easy to perform. For intravenous injections it is recommended to use the saphenous vein (Schwaier 1974).

### Anaesthesia

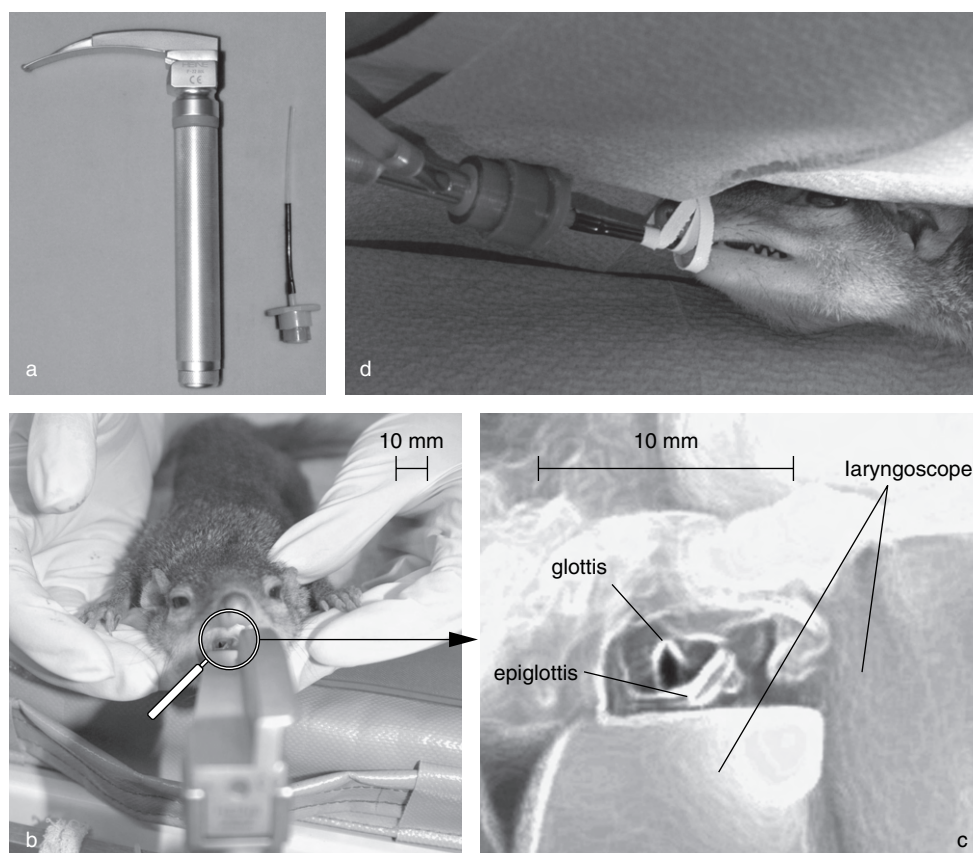

Adequate anaesthesia is a prerequisite for using an animal species in the laboratory for a wide range of experiments. Early studies used pentobarbital in a comparatively high dose of 75 mg/kg.

A quick and safe injection anaesthetic is the so called Goettinger Mixture II (GM II) consisting of ketamine (50 mg/ml), xylazine (10 mg/ml) and atropine (0.1 mg/ml). The dosage is 0.1 ml/100 g body weight. Anaesthesia usually occurs within 5 minutes of the intramuscular injection, and general anaesthesia lasts about 20–45 minutes. For longer general anaesthesia, inhalation anaesthesia is recommended. For inhalation anaesthesia, animals had to be artificially ventilated through an endotracheal tube (home-made from high-med-PE-micro-tube, inner diameter 1.75 mm, outer diameter 2.08 mm). Our experiences with a respirator for small animals show that 0.5–2% isoflurane in a mixture of 30% oxygen and 70% N<sub>2</sub>O, with a respiration rate of 35 per minute with an inspiratory phase of 35% and plateau phase of 5% work fine for *Tupaia belangeri*.

Inhalation anaesthesia is used following induction by injection anaesthesia (eg, GMII). The jaw bone is placed on the fingers and the head is fixed by placing the thumbs behind the skull. The mouth is opened by introducing the laryngoscope. Sometimes the epiglottis can be held down with the tip. After inserting the endotracheal tube, correct placement must be checked by auscultation; once correct placement is confirmed, the tube can be held in place with a strip of adhesive tape (Figure 20.6).

### Euthanasia

The use of animals in research, including euthanasia, is a sensitive issue. Because of differences in national regulations, each researcher will be required to obtain clearance from the local or national ethical committee for research prior to conducting euthanasia. In our opinion, cervical dislocation is not an appropriate method of euthanasia for tree shrews. We recommend either an overdose of sodium

**Figure 20.6** Intubation of a tree shrew (*Tupaia belangeri*) for inhalation anaesthesia. (a) Laryngoscope and homemade micro-tube (for details see text). (b) Fixation of the head and position of the laryngoscope. (c) Enlarged view of (b) showing glottis and epiglottis. (d) After successful intubation, the tube is held in place with a strip of adhesive tape.

pentobarbital, for example, or decapitation. Carbon dioxide has been used on tree shrews and has proven to be an appropriate means of euthanasia. In any case, after exposing animals to an overdose of anaesthetics it is always mandatory to confirm death by, for example, cervical dislocation, as an appropriate secondary means of euthanasia.

## Common welfare problems

### Health problems

Tree shrews experience relatively few health problems. However, our experience shows that gastritis can be a frequent problem. In this case, animals stop eating and a lack of faeces can also be observed. Gastritis can be effectively treated with cimetidine (10 mg/kg body weight, twice daily orally).

Diarrhoea is another symptom often seen in a colony. Mostly *Escherichia coli* *variatio haemolytica*, *Klebsiella pneumonia* or protozoa (*Giardia*, *Trichomonas*, *Entamoeba*) are the cause of this symptom. Before antibiotic treatment of diarrhoea, appropriate diagnostic and resistance tests are strongly recommended.

Infection with the cestode *Tupaia taenia quentini* was successfully treated with praziquantel (Brack *et al.* 1987). Intestinal trichomoniasis with *Tritrichomonas mobilensis*

(mostly in the caecum) has also been described as well (Brack *et al.* 1995). Enteropathy of the upper digestive tract was due to a foodstuff allergy against oat flakes and soybean products (Brack *et al.* 1990).

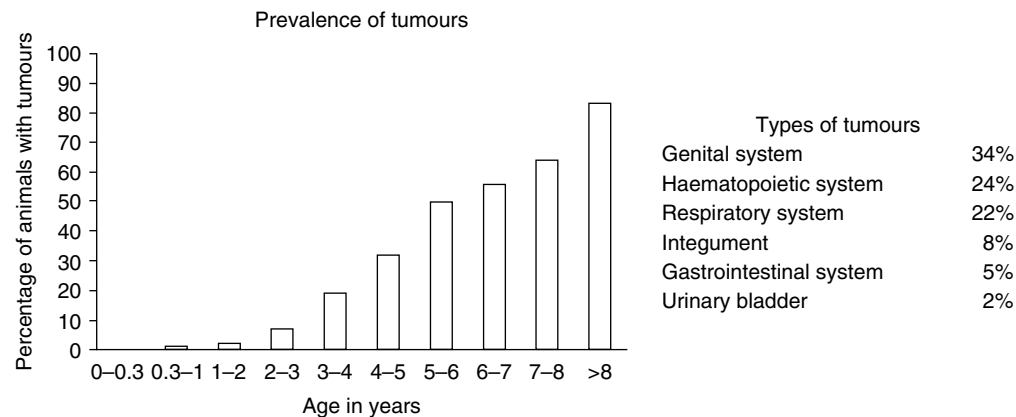

Penis prolapse is another possible health problem. We found this in several males of different ages with unknown cause. The prolapse is not lethal by itself, but since there is no effective treatment and the penis becomes irritated and swollen, in most cases, the animal has to be euthanased.

Automutilation can often occur if the cages are too small, overcrowded or the animals are disturbed too much. Moving the animal to a bigger or quieter area in the facility is the first step in treatment. In some cases, standard antibiotic treatment and amputation of the affected body part (eg, a toe or the distal part of the tail) is necessary.

*Tupaia* seem to be prone to the spontaneous development of gallstones with fatty and cholesterol-rich diets (Schwaier 1979). In two reports mite infestations were described (Bever 1985; Brack *et al.* 1989).

Most tumours of the genital system of male animals have a Leydig cell origin and occur unilaterally. Tumours of the female genital system are predominantly mammary tumours or sometimes ovarian tumours. Tumours of the haematopoietic system are malignant lymphomas; tumours of the integument occur mostly in the jugulo-sternal gland. Similar to humans, the incidence of tumours increases with age (Brack

**Figure 20.7** Common spontaneous tumours and incidence of tumours, which rises with age (with modifications from Brack 1998).

1998). The most common spontaneous tumours are summarised in Figure 20.7.

Two tree shrew specific viruses are known and reported in the literature so far: the *Tupaia herpes virus* (THV) (five different types), which might be a cause for tumours (Darai *et al.* 1982), and the potentially non-pathogenic *Tupaia paramyxovirus* (TPMV) (Tidona *et al.* 1999).

### Concluding remarks

Despite their obvious attractiveness there are limitations to the use of tree shrews in research. Major limitations are housing and breeding, both of which are time consuming and expensive. Obviously, this constraint explains why many laboratories are not capable of using these animals for their study programmes. Further research is required to collect basic data on tree shrews to inform their housing and care.

# Rodentia and Lagomorpha

## 21 The laboratory mouse

Vera Baumans

### Biological overview

#### General biology

The house mouse is a cosmopolitan species, which is commensal with man and is capable of adapting to a wide variety of environmental conditions. Its laboratory counterpart originated from wild mice caught and bred by mouse fanciers for their behaviour or coat colours. During the early twentieth century, they were also increasingly bred for scientific purposes. The increase of biomedical research at this time, the interest in Mendelian genetics and the advantage of a small, inexpensive mammal that could be easily housed and bred were crucial to the development of the laboratory mouse.

Like most rodents, the mouse is a nocturnal burrowing and climbing animal, which shows a clear circadian rhythm with peaks of activity during the dark period (Figure 21.1). Maintenance behaviour, such as eating and drinking, occurs mostly during the night (Schlingmann *et al.* 1998).

Mice have acute hearing and respond to a range of ultrasonic frequencies; for example, the retrieval response of the female is elicited by ultrasonic calls from pups that are out of the nest. The sense of smell is also highly developed in mice, and is not only used to detect food and predators. Mice have a wide repertoire of olfactory social signals that include pheromones and the creation of patterns of urine marks on the substrates of their environments. Mice normally excrete large amounts of protein in the urine. In contrast to their olfactory and auditory acuity, vision is poor in mice, especially in albinos (see section on Environmental provisions section).

Selected physiological data for mice are summarised in Table 21.1. Sex, strain, age, reproductive phase and environment can have a dramatic influence on physiological and behavioural data. Body weight and growth curves are also influenced by these factors. Body weights of both sexes increase rapidly during the first 6–8 weeks, but they grow more slowly after this until 6 months of age, when a plateau is reached for a few months, followed by a decline. As small animals, mice have a relatively large surface area per gram of body weight. This results in dramatic physiological changes in their response to fluctuations in the ambient temperature (Fox *et al.* 2002). In general, they cannot regulate body temperature as well as other mammals and do not tolerate heat well; they have no sweat glands, they cannot

pant and their ability to salivate is limited (Fallon 1996; Fox *et al.* 2002). There is some evidence that the tail has a thermoregulatory function in small rodents (Joint Working Group on Refinement (JWGR) 1993).

The mouse is an omnivorous animal. Each half of the jaw contains one incisor and three molars (dental formula:  $I_1^1 C_0^0 Pm_0^0 M_3^3$ ). Canine teeth and premolars are absent, resulting in an open space, the diastema. The incisors and molars grow continuously and are worn down by mastication.

The proximal part of the stomach is squamous and non-glandular, whereas the distal part is glandular (Fox *et al.* 2002; Havenaar *et al.* 2001). In females the urethra ends in the ventral wall of the vagina. She has three pairs of mammary glands in the cervicothoracic region and two pairs in the inguinoabdominal region (Figure 21.2).

#### Size range and lifespan

Adult mice are 12–15 cm long from the nose to the tip of the tail, with the length of the tail approximately equalling that of the body. The newborn mouse weighs between 1 g and 2 g, and gains weight very rapidly during the 3 week suckling period. Intrinsic variables such as genotype, sex, strain and age of the mouse and extrinsic variables such as diet, number of mice per cage and environmental temperature account for the variation in adult body size (Cunliffe-Beamer & Les 1987).

Many environmental and genetic factors influence the lifespan of the mouse. These include diet, number of animals per cage, subclinical infections, husbandry procedures, genetic predisposition to tumours, strain, gender and the presence or absence of deleterious mutant genes (Cunliffe-Beamer & Les 1987). Mice from short-lived strains (eg, CBA) have a life expectancy of between 5 and 16 months, while mice from long-lived strains (eg, C57BL6) often survive to 24 or even 36 months of age.

#### Social organisation

Mice are social animals, which live in compatible, single male dominated groups that are mostly family based. The organisation of a mouse colony tends to be a dominance hierarchy under confined or crowded conditions but is

**Figure 21.1** Circadian rhythm in the mouse. Black bars indicate the dark period (Schlingmann *et al.* 1988).

territorial under less restricted ones (Mackintosh 1981; van Loo *et al.* 2003; Latham & Mason 2004; Barnett 2007). Differences in behaviour between inbred strains may reflect behavioural adaptations to different habitats of the feral populations from which the ancestors of the inbred strain originated; for example, BALB/c mice appear to be well adapted to surface living, making superficial nests and showing territorial behaviour, while C57BL mice are more adapted to living in holes and do not show clear territorial behaviour (van Oortmerssen 1971; Busser *et al.* 1974).

Pheromones serve as a principal mechanism for communication and affect developmental and reproductive processes (Fox *et al.* 2002; Latham & Mason 2004). Mice use a variety of specialised scent glands, together with urine, faeces and vaginal secretions for olfactory communication. Urine is a particularly important source of odour (Hurst *et al.* 1993).

## Reproduction

Sexual maturity in mice occurs very early in life. Oestrogen-dependent cornification of the epithelium at the vaginal opening may occur as early as 24–28 days (Fox *et al.* 2002), but sexual maturation varies with strain and environmental influences. Ovarian follicle development begins at 3 weeks of age and matures by 30 days. Puberty in males occurs up to 2 weeks later.

Female mice are polyoestrous, spontaneous ovulators and they cycle every 4–5 days. Factors such as season, diet, genetic background and environmental factors influence the oestrous cycle. The cyclicity of oestrus and ovulation are controlled by the diurnal rhythm of the photoperiod, and oestrus and ovulation most often occur during the dark phase (Fox *et al.* 2002). Light cycles of 12–14 h light and 10–12 h dark are necessary to maintain regular oestrous cycles. Light intensities in the range commonly encountered in animal rooms can affect the oestrous cycle (Clough 1984), eg, too much light or a too long period of dark will cause irregularities in the oestrous cycle. Pheromones and the social environment also affect the oestrous cycle. Female mice housed in groups become dioestrous, anoestrous or pseudopregnant (the Lee-Boot effect), while the introduction of a male into such a group synchronises their oestrous cycles (the Whitten effect). If the female is housed with a second male within 24 h after a successful mating, implantation of fertile egg cells will be prevented and the female will return to oestrus in 4–5 days (the Bruce effect). These effects are mediated by pheromones in the urine of the males (Cunliffe-Beamer & Les 1987).

Mating also often occurs during the dark phase (Fox *et al.* 2002), and can be detected within 24 h after copulation by the formation of a waxy vaginal plug (a mixture of sperm and secretions from the seminal vesicles and the coagulating glands of the male). As this detection method is not always reliable it is often combined with detection of spermatozoa in the vaginal fluid after flushing. Elevated environmental temperatures (>28°C) and high noise levels can reduce female fertility (Cunliffe-Beamer & Les 1987).

The gestation period of non-lactating females is 19–21 days, depending on the strain. Pregnancy can be diagnosed

**Table 21.1** Standard biological data environmental requirements and physiological parameters of mice (partly from Scott 1991; Wolfensohn & Lloyd 2003; Fox *et al.* 2002; Havenaar *et al.* 2001).

<b>Environmental requirements<sup>a</sup></b>

early by abdominal palpation between the 7th and 10th day of gestation, when the uterus feels like a string with knots in it. At days 15 and 16 the uterus feels uniformly enlarged. At the end of pregnancy, the skulls of the foetuses become firm and can be palpated. Towards parturition, pregnant females also build nests for giving birth (see later).

Litter size commonly ranges from 1–14 pups, depending on the strain. During parturition, pups and placentas are delivered simultaneously. Nursing females usually lactate for 3 weeks. Post-partum oestrus occurs within 24h of parturition, but results less frequently in fertile matings, possibly because lactation delays implantation and prolongs gestation after post-partum oestrus for up to 12 days (Havenaar *et al.* 2001; Fox *et al.* 2002; Hedrich & Bullock 2004). Cannibalism (which is strain-dependent) can be minimised in most cases by providing a quiet place with reduced light intensity and nesting material.

The effective reproductive life of a female mouse approaches 2 years but, as litter size decreases with aging, females are usually retired by 1 year of age.

### Uses in the laboratory

The mouse is the most widely used vertebrate species in biomedical research. Their short reproductive cycle, short lifespan, small size and low cost of maintenance make them suitable models for humans and animals in many aspects of biomedical research, including cancer and drug research, vaccine and monoclonal antibody preparation and evaluation of the safety and effectiveness of pharmaceutical products. As a result of the rapid advances in biotechnology, new strains expressing novel genetic characteristics are being created at a remarkable rate, so that there are now

more than 1000 genetically defined inbred strains of laboratory mice.

### Genetics, strains and stocks

See also Chapter 4.

Laboratory mice have 40 chromosomes that are differentiated by the size and pattern of transverse bands. Genetic mapping in mice began in the early 1900s, and the first linkage in the mouse was discovered by Haldane *et al.* (1915). Extensive linkage maps and an impressive array of inbred strains are now available to expedite sophisticated genetic research.

The most thoroughly studied genetic systems of the mouse are the histocompatibility loci. Histocompatibility (H) loci control expression of cell surface molecules that modulate major immunological phenomena, such as the recognition of foreign tissue. For example, the time, onset and speed of skin graft rejection are controlled by two groups of H loci. The group of major H loci is called H2 and is located on chromosome 17. These genes cause rapid rejection (10–20 days) of grafts that display foreign H2 antigens. The group of minor H loci consists of genes scattered throughout the genome. These genes are responsible for delayed graft rejection. Genes associated with the H2 complex also control other immunological functions, such as cell–cell interactions in primary immune responses and the level of response to a given antigen. Immune-mediated responses to infectious agents such as viruses and complement activity are influenced directly or indirectly by the H2 complex (Fox *et al.* 2002; Hedrich & Bullock 2004).

Inbred mice are widely used for research in fields such as immunology, oncology, microbiology, biochemistry, pharmacology, physiology, anatomy and radiobiology and offer a high degree of genetic uniformity. Clarence C. Little developed the first inbred mouse strain, DBA, in 1909. Animals of an inbred strain are homozygous and genetically very similar to other mice of the same strain and sex. They are produced by brother × sister matings for at least 20 generations (Fox *et al.* 2002; van Zutphen *et al.* 2001). At this stage, the inbreeding coefficient should be ~ 0.99 (ie, residual heterozygosity approximately 1%). The assumption that all sources of the same inbred strain provide genetically identical mice is not valid, as animals maintained at different institutions for many generations may show genetic drift, even though they originate from the same source. Therefore, genetic monitoring of colonies is a prerequisite for standardisation of laboratory animals resulting in a reduction in the number of animals used.

Inbred strains can be created with very specific characteristics, enabling researchers to develop very specific animal models for biomedical research. Thus, they might be highly sensitive to, for example, tumour development or be immunodeficient (the athymic nude or the severe combined immunodeficient (SCID) mouse). It is obvious that the welfare of these strains might be easily compromised as they might be more sensitive to bacterial, viral and fungal infections than outbred mice or they might suffer from their induced diseases (Baumans 2004).

By contrast, outbred mice are genetically heterogeneous and are often produced by breeding systems that minimise inbreeding. Random pairing is best planned with the aid of tables of randomised numbers or a randomising device (see Chapter 4). However, a small colony may become inbred, or at least not that genetically heterogeneous, as eventually all animals will become genetically related. In a population of 25 breeding pairs, for example, heterozygosity will decrease by 1% per generation with standard randomisation techniques. A stock is regarded as outbred when it has been maintained as a closed colony for at least four generations. To minimise changes caused by inbreeding and genetic drift, the population should be maintained in such numbers as to give less than 1% inbreeding per generation.

### Symbols

Rules for the nomenclature of different 'breeds' of mice are well defined. The term 'stock' is used to denote an outbred population of mice while the term 'strain' is used to denote an inbred population. The outbred stock designation consists of a symbol indicating the current breeder/holder of the stock, followed by a colon and the stock symbol consisting of two to four capital letters (eg, CrI:NMRI).

Inbred strains should be designated according to the rules for the nomenclature by one to four capital letters (eg, A; DBA) or for some old strains by a combination of capital letters and numbers (eg, C57BL; 129). Inbred strains can be divided into substrains. The strain designation is followed by a slash and the substrain designation which may consist of a combination of numbers and letters. The letters usually represent the laboratory code. For example, C57BL/6J means that this strain originated from female 57 at the Cold Spring Harbor Laboratory (C) and was the black line (BL). The 6 indicates subline number 6 and bred at the Jackson laboratory (J).

F1 hybrids are animals resulting from a cross between two inbred strains. They are genetically uniform and heterozygous for those genes for which the two parental strains differ. A coisogenic strain is a subline which differs from the original inbred strain by only one gene which is the result of a mutation. The symbol for a coisogenic strain must consist of the full strain and substrain designation, followed by a hyphen and the symbol of the mutant gene (eg, C3H/HeJ-Lps, a mutant substrain of C3H with a gene causing resistance to bacterial lipopolysaccharide).

A congenic strain is an inbred strain where a genetic trait has been introduced by repeated backcrossing with an inbred strain. The designation of congenic strains is similar to that of coisogenic strains. However, if congenic strains differ at the major histocompatibility locus, it is acceptable to give an abbreviated strain name, followed by a full stop and the abbreviation of the name of the donor strain (eg, B10.D2, which refers to a C57BL/10 carrying the H2 haplotype of the DBA/2 inbred strain) (van Zutphen *et al.* 2001).

Recombinant inbred (RI) strains are produced by brother × sister mating of individuals from the F2 generation of a cross between two (unrelated) inbred strains which are termed progenitor strains. The RI strains can be regarded as established after a minimum of 20 generations of brother × sister matings and will then form a set or series of

RI strains. They are designated by combining abbreviated names of both the parental strains which are separated by a capital X. The parallel lines are given numbers (eg B6XH-1 which is the first recombinant inbred strain derived from the progenitor strains C57BL/6J and C3H/HeJ). RI strains represent a fixed set of randomly assorted genes of both progenitors. These strains are very valuable for genetic research, in particular for studies on linkage analysis and for the identification and genetic analysis of complex genetic traits (van Zutphen *et al.* 2001; Hedrich & Bullock 2004).

The sequence of the mouse genome is a key informational tool for understanding the contents of the human genome. The availability of more than 50 commonly used laboratory inbred strains of mice, each with its own phenotype for multiple variable traits, has provided an important opportunity to map quantitative trait loci (QTLs) that underlie heritable phenotypic variation (Mouse Genome Sequencing Consortium, 2002). A system to define parameters as body weight, behavioural patterns and disease susceptibility among a number of inbred lines is under construction in the Mouse Phenome Database<sup>1</sup> (Mouse Genome Sequencing Consortium, 2002).

### Transgenic animals

See also Chapter 4.

Genetically engineered or modified mice are those with induced mutations, including mice with transgenes, with targeted mutations (knockouts) and with retroviral, proviral or chemically induced mutations<sup>2</sup>. Transgenic technology focuses on the introduction or exclusion (knockouts) of functional genetic material in the germ line of an animal, thus changing the genetic characteristics of an organism and its progeny. The most frequently used methods for genetic transformation of the germ line are microinjection of DNA into the pronucleus of fertilised oocytes and the injection of transfected embryonic stem (ES) cells into normal mouse blastocysts, resulting in a subsequent generation of chimeras. These techniques have led to the rapid development of a variety of animal models, designed for the study of gene regulation, gene expression, pathogenesis and the treatment of human and animal diseases (eg, Alzheimer's disease, growth hormone disturbances, poliovirus vaccine testing in humans or mastitis in cows).

Although there may be numerous benefits of producing transgenic lines, this development does raise some ethical and welfare issues. For example, the increase in the use of genetically modified animals has caused an increase in numbers of mice used of more than 23% per year; this is not only due to growth in the numbers of these animals in research but also to the large number of mice necessary to create each genetically modified line, such as breeding males, donor females, vasectomised males and pseudopregnant recipient females. Furthermore, non-transgenic and wild-type littermates may be produced that are not suitable for research or further breeding (Dennis 2002).

<sup>1</sup><http://www.jax.org/>

<sup>2</sup><http://www.jax.org/jaxmice>

Moreover, the process of transgenesis by microinjection may compromise welfare through the experimental procedures used during the process of transgenesis. The donor animals, vasectomised males and foster mothers which are needed for the production of the transgenic offspring may experience discomfort from procedures, such as early mating (from 3 weeks onwards), anaesthesia, surgery and injections (JWGR 2003).

At the level of integration of the microinjected DNA into the genome, unintentional insertional mutations may occur, potentially also resulting in welfare problems. At the level of expression of the introduced gene detrimental side effects may occur. For example, the giant mouse that over-produced growth hormone suffered from chronic kidney and liver dysfunction (Poole 1995; Crawley 2000). In this mouse the presence of a both functional and non-functional microinjected DNA construct increased mortality and body weight of the pups in the first 2–3 days after birth, whereas no significant differences in behaviour and morphological development were observed later on (van der Meer *et al.* 2001a).

From an ethical point of view it might be argued that the integrity of the animal is compromised as the genome is modified (van der Meer *et al.* 1996, 2001b). Furthermore, concern has been expressed with respect to the patentability of transgenic animals, such as the oncomouse. Finally, it has been suggested that the escape of transgenic animals could impose a risk for animal populations in the wild. However, escapes from modern, well built laboratories are unlikely and it appears that laboratory animals are not very viable in the wild (van der Meer *et al.* 1996, 2001).

In conclusion, transgenic technology has a great potential for increasing the understanding of the role of genes and may provide suitable animal models for human and animal disease, but the welfare of transgenic animals has to be carefully monitored, at least until the second generation of offspring. A surveillance system including score sheets can be helpful in identifying welfare problems, and can be used together with humane endpoints, in order to prevent unnecessary suffering through euthanasia of severely affected animals (Mertens & Rulicke 1999; van der Meer *et al.* 2001). Data banks from existing genetically modified animals will be useful to help predict potential impairments in new genetically modified lines yet to be created (Baumans 2005a). See also Chapter 5 for further information on phenotyping.

## Sources of supply

Laboratory mice can be obtained in several ways (see also Chapter 12). Commercial laboratory animal breeders can supply a vast array of well defined, high-quality animals of outbred, inbred, hybrid or mutant bearing strains or stocks. In-house breeding is now mostly limited to strains or stocks which are not commercially available and/or to the maintenance of colonies associated with studies of reproduction and genetics, such as the production of transgenic animals (see also see Chapter 4). In-house breeding may often seem cheaper, but many costs may be hidden, such as those of husbandry, quality control and overheads, including maintenance costs and salaries of the animal staff. In-house

breeding may result in less efficient use of animals as large-scale breeders can even out fluctuations in demand. However, in-house breeding may be necessary for developmental studies.

The assumption that all sources of the same strain provide genetically identical mice is not valid, as animals maintained at different institutions for many generations may show genetic drift, although they originate from the same source (Cunliffe-Beamer & Les 1987). Therefore, genetic monitoring of colonies is a prerequisite for standardisation of laboratory animals.

Also, it should not be assumed that clinically normal mice from different sources are comparable with respect to their health status, as there may be the potential for even clinically 'healthy' mice to introduce unwanted pathogens such as mouse hepatitis virus and Sendai, which could jeopardise research results (Cunliffe-Beamer & Les 1987).

## Laboratory management and breeding

### General husbandry

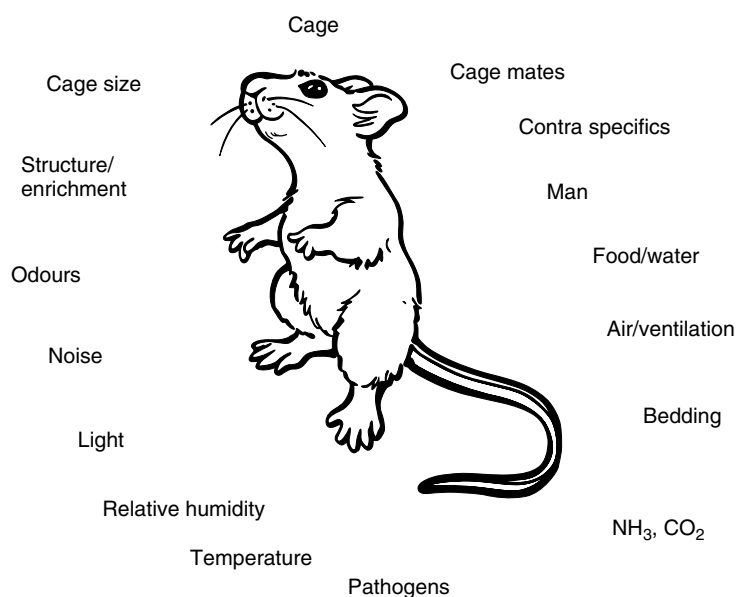

#### Housing

The laboratory mouse has partially adapted to captive life, but still shows similarities to its wild counterparts. Mice are active, highly explorative animals, which, in the wild, spend considerable time foraging, seeking a wide variety of food. They construct elaborate nests and burrows and form complex social structures. All these behaviours, which they remain strongly motivated to perform, are still present in the laboratory mouse. Housing systems for laboratory animals have often been designed on the basis of economic and ergonomic aspects (such as equipment, costs, space, work load, ability to observe the animals and to maintain a certain degree of hygiene) with little or no consideration for animal welfare.

Such conditions deprive animals of the possibility of performing a full repertoire of normal behaviour, such as exploring, resting, climbing, grooming, foraging, nesting and social behaviour. This may then lead to frustration and suffering (Dawkins 1990; Sherwin 2000) expressed in abnormal behaviour such as stereotypies, due to lack of stimulation (van de Weerd & Baumans 1995; Würbel 2001). The environment of a mouse should consist of a wide range of stimuli, including the social environment of conspecifics and humans and the physical environment, such as the cage and its contents (Figure 21.3).

Laboratory mice are usually bred and housed in shoe-box shaped cages made of polycarbonate, polypropylene or stainless steel with solid or wire-mesh floors (Figure 21.4). Wire-mesh floors are used if experiments require continuous collection of faeces and/or urine or elimination of contact between the animal and bedding material. However, since mice are nesting animals, in a choice test they prefer solid floors with sawdust for digging, nesting and resting rather than grid floors (Blom *et al.* 1996); solid bottom cages containing bedding and nesting materials should therefore be used whenever possible (Council of Europe 2006; European Commission 2007).

**Figure 21.3** Stimuli in the environment of laboratory animals.

**Figure 21.4** Polycarbonate cages for mice with sawdust-covered solid floors. (Photo: T.P. Rooymans.)

Boxes made of plastics may have varying degrees of translucency and also different abilities to withstand steam sterilisation. Cage lids are usually made of stainless steel and have an indentation forming a food hopper. Mice eat directly from the hopper through spaces about 3–5 mm wide. It is important to appreciate that small mice can escape through spaces more than 6 mm in width. Water can be provided from a bottle attached to each cage or by an automatic watering system (see Presentation of food and water).

Bedding should be provided that is comfortable for resting, that absorbs urine and is used by the animals for depositing odour patterns. There should be a balance in terms of cleaning, between increasing the anxiety of the animals by removing familiar odour patterns on the one hand, and minimising the build-up of harmful ammonia on the other (Eveleigh 1993). It has been shown that olfactory cues from nesting and bedding material affect aggression in a different way: transfer of nesting material reduces aggression, whereas sawdust containing urine/faeces intensifies

aggression (Hurst *et al.* 1993; van Loo *et al.* 2000). All laboratory rodents spend considerable time manipulating bedding, often creating tunnels (where the depth and consistency is sufficient) as well as building nests to provide shelter and warmth.

Sawdust is widely used as bedding material, but fine particles can cause preputial and respiratory problems. The type of wood can affect physiological parameters in the animal such as hepatic microsomal enzyme function (Vesell 1967; Haataja *et al.* 1989). Hygroscopic material like cat litter should be avoided as it may cause dehydration in the newborn. Nesting material, such as paper towels, tissues and wood wool, can provide shade from lighting, the opportunity to regulate their microclimate, such as temperature, and a shelter to hide from conspecifics and the ability to control the environment (van de Weerd & Baumans 1995) (Figure 21.5). Therefore, nesting material should be provided not only for breeding female mice, but for all laboratory mice.

**Figure 21.5** (a) Bowl-shaped nest of BALB/c mice. (b) Environmental enrichment for mice. (Photos: T.P. Rooymans.)

Bedding and nesting material should:

- be in accordance with the mouse's needs;
- not be toxic or harmful to the animal;
- be absorbent, but not dehydrating for neonates;
- not be excessively dusty;
- be economical to use and dispose of;
- be inedible, to avoid interference with experiments.

Housing and husbandry have a major impact on the laboratory animal throughout its life, not only during, but also before and after scientific procedures. It is important to consider the species-specific needs in relation to housing and feeding regimes; and also to take into account within-species variation associated with genetic background. While laboratory animals have partially adapted to captive life, they still show similarities to their wild counterparts. The environment of captive animals should cater for physiological and behavioural needs such as resting, nest building, hiding, exploring, foraging, gnawing and compatible social contacts (Olsson & Dahlborn 2002; Baumans 2004).

Many laboratory animal species such as rodents and rabbits are highly susceptible to predators, and are thus likely to show strong fear responses in unfamiliar situations if they cannot shelter. This is shown by attempts to flee, biting when handled, or sudden immobility to avoid being detected. For this reason, cages should be provided with shelter or hiding places. Careful handling from a young age, together with conditioning to experimental and husbandry procedures, will probably reduce these stress responses considerably (Hurst 1999). Ideally, the animal should feel secure in a complex, challenging environment that it can control (Poole 1998). A sense of security can be achieved by providing nestable and manipulable and effective nesting material, hiding places and compatible cage mates.

In practice, however, laboratory animals are usually housed throughout their lives in relatively barren cages and given unrestricted access to food. This frequently results in adverse effects on the behaviour and physiology of the animals, and in a shortened lifespan due to overfeeding and inactivity (van de Weerd *et al.* 1997b; Mattson *et al.* 2001).

Standardisation of environmental conditions has been designed to reduce individual differences within animal groups (intra-experimental variation), ultimately facilitating the detection of treatment effects, and to reduce differences between studies (inter-experiment variation), ultimately increasing the reproducibility of results across laboratories (Olsson *et al.* 2003; van Zutphen 2001). Nevertheless, despite rigorous attempts to equalise conditions among sites, tests with different inbred mouse strains, simultaneously carried out in three recommended laboratories, revealed significant effects from their respective sites for nearly all variables tested (Crabbe *et al.* 1999; Wahlsten *et al.* 2003). It seems that barren, restrictive and socially deprived housing conditions interfere with the development and function of brain and behaviour (Renner & Rosenzweig 1987; Würbel 2001; Benefiel *et al.* 2005), and restrictions such as those imposed by the standard rodent cage are potentially stressful (Mench 1998; Ladewig 2000). In other words, the barren environment that has been devised to minimise uncontrolled environmental effects on the animals may ironically be a primary source of pathological artefacts.

Current thinking (Council of Europe 2006) is that appropriate structuring of the cage/pen environment may be more beneficial than provision of a large floor area, although a certain area is necessary to provide a structured space. Except for locomotor activity (eg, playing), mice do not actually use open space as they are thigmotaxic, meaning that they use barriers and walls rather than the open space. Instead they use resources and structures within the area for specific behaviours.

### Environmental enrichment

One way of improving the living conditions of laboratory animals is to give animals opportunities to perform more species-specific behavioural repertoires through enrichment of their environment. Enrichment can be defined as any modification in the environment of captive animals that seeks to enhance their physical and psychological well-being by providing stimuli that meet their species-specific needs (Newberry 1995; Baumans 2005b). This approach has

been increasingly introduced into laboratory animal research facilities (Olsson & Dahlborn 2002). From a welfare point of view, it seems to be a good development, as there is general agreement that the well-being of the animals improves with the provision of environmental enrichment (see also Chapter 10). For example, beneficial effects of environmental enrichment have been described in animals with brain damage and disturbed motor function; an increased arborisation of dendrites has been found in the brains of these animals (Mohammed *et al.* 2002). The effects of environmental enrichment are dependent on the type of enrichment used. In the field of neuroscience, enrichment mainly refers to social housing in a large, complex cage containing different toys that are changed frequently in order to induce changes in the brain and behaviour (see Chapter 10). In animal welfare research, enrichment focuses on specific needs such as nest building, hiding and gnawing, in order to improve the well-being of the animals without major changes in physiology and behaviour (Zhu *et al.* 2006).

Enrichment of the animal's environment can be focused on both the social environment and the physical environment, consisting of sensory stimuli (auditory, visual, olfactory and tactile) and nutritional aspects (supply and type of food). The animal's psychological appraisal of its environment in terms of controllability and predictability can be improved by structuring the cage with nest boxes, tubes, partitions and nesting material (van de Weerd & Baumans 1995; Baumans *et al.* 2007). van de Weerd *et al.* (1997b) and van Loo *et al.* (2005) showed that paper tissue, for example, was strongly preferred by mice as a component of their cage (Figure 21.5). Enrichment items need to be designed and evaluated on the basis of knowledge gained in enrichment studies (van Loo *et al.* 2005) and knowledge of biology and behaviour of the animal. Furthermore it is important to know which type of housing and enrichment the animals were provided with at the breeder's facility, as differences may also have an impact on the animal and consequently on the scientific outcome. Besides meeting the needs of the animal, enrichment items should be practical and inexpensive, and pose no risk to humans, the animals used or the experiment. There is some concern, however, as to whether environmental enrichment conflicts with the standardisation of experiments. The question is: 'Do enriched animals show more variability in their response to experimental procedures because they show more diverse behaviours?' Some researchers think they do. In complex environments, for example, animals are not just responding to one stimulus but to many variable stimuli at once, and this can result in increased variation among subjects (Eskola *et al.* 1999; Tsai *et al.* 2003).

The counter-argument is that because an animal can perform more of its species-specific behaviour in enriched environments, it may be able to cope better with novel and unexpected changes and thus in fact show a more uniform response. If animals from enriched housing conditions are likely to be physiologically and psychologically more stable, it follows that they may be considered as more refined models that ensure better scientific results. In practice, however, results from different studies seem to indicate that the effects of enrichment on the variability in results depend on the parameter being measured, the strain of animal and the type of enrichment (van de Weerd *et al.* 2002; Wolfer *et al.* 2004).

It seems clear, therefore, that environmental enrichment should comprise a well designed and critically evaluated programme that benefits the animals as well as the experimental outcome; it should not be a process of randomly supplying objects that staff consider attractive for the animals. Enrichment needs to be regarded as an essential component of the overall animal care programme, and just as important as nutrition and veterinary care. The key component of the enrichment programme is the animal care staff, who must be motivated and educated (Stewart & Bayne 2004).

In summary, evaluating enrichment in terms of the animal (ie, by assessing the use of and preference for a certain enrichment, and the effect on behaviour, the performance of species-typical behaviour and physiological parameters) is essential. Equally important is evaluating the impact of enrichment on the scientific outcome (see Chapter 10) (van de Weerd *et al.* 2002; Baumans 2005b).

### Space recommendations

It is difficult scientifically to specify the minimum cage sizes for maintaining laboratory animals; much depends on the strain, group size and age of the animals, their familiarity with each other and their reproductive condition. Cage sizes recommended in current European guidelines on accommodation for laboratory animals are generally based on scientific evidence; where such evidence is lacking or insufficient, they are based on what is described as best practice (Council of Europe 2006), which has been agreed upon by researchers, veterinarians and animal staff.

Specifications for laboratory housing of mice are expressed in two documents issued in 1986. One is the Council of Europe's (1986) European Convention for the protection of vertebrate animals used for experimental and other scientific purposes (Convention ETS 123) with its Appendix A, Guidelines for the accommodation and care of animals, revised in 2006. The other is the very similar European Union's (1986) Council Directive on the approximation of laws, regulations and administrative provisions of the Member States regarding the protection of animals used for experimental and other scientific purposes (Directive 86/609/EEC) with its Annex II, Guidelines for accommodation and care of animals (revised in 2007). Article 5.1 of the Convention requires that '*Any restriction on the extent to which an animal can satisfy its physiological and ethological needs shall be limited as far as practicable*', while Article 5.b of the Directive requires them to '*be limited to the absolute minimum*'. In the USA, guidelines on accommodation and care of laboratory animals are included in the National Research Council's (1996) Guide for the Care and Use of Laboratory Animals of the National Research Council, although mice, rats and birds do not come under the official legislation in the USA. Space recommendations should allow housing of mice in harmonious groups. Increasing the complexity of the cage is more important than increasing floor area as such, as the inclusion of structures will provide more opportunities for activity and will increase the usable space. Furthermore, mice partition their space into sleeping, defecating, urinating and feeding areas, so the available space and structure in the cage should be sufficient and should also cater for play behaviour in young animals. Incentives for activity should be provided in the cage, such as nesting

material and climbing possibilities (Council of Europe 2006; European Commission 2007).

The use of environmental enrichment to improve the well-being of laboratory animals is widely promoted and is currently incorporated in European legislation (Kornerup Hansen & Baumans 2004; Council of Europe 2006; EU European Commission 2007). Many other countries have similar legislation and regulations on this matter, eg Australia (National Health and Medical Research Council (NHMRC) 2004; Animal Research Review Panel (ARRP) draft).

Other organisations besides governments are involved in developing guidelines and regulations on animal use. In Europe, the 2001 position paper of the European Science Foundation, an association of the major science-funding organisations, endorsed the principles of the Three Rs and the need for laboratory animal welfare research (European Science Foundation 2001).

### Environmental provisions

Although environmental measurements are taken at the room level (macro-environment), the conditions in the cage actually affect the animal's micro-environment. Mice 'engineer' their own micro-environments by huddling and building nests and in this way they are able to exert some control over temperature, humidity and light conditions. Furthermore, the micro-environment will vary, depending on the position of the cage on the rack, crowding of the rack, cage type, stocking density in the cage, type and amount of bedding and cleaning frequency. Also the use of filter caps and individually ventilated cages (IVCs) will affect the rate of air exchange, build up of ammonia, temperature and humidity (Serrano 1971; Baumans *et al.* 2002). IVC systems are designed to reduce infection risks, ammonia and carbon dioxide concentrations, cleaning frequency, workload and allergens. However, the high ventilation rate and reduced handling of animals in IVC systems are potential drawbacks. To protect the animals from draught due to the forced ventilation, nesting material or a hiding place should be provided (Baumans *et al.* 2002, 2007).

When the environmental temperature falls below the thermoneutral zone (where body temperature is regulated by conduction and convection of heat), body temperature is maintained by behavioural adaptation, such as nest building and/or increased metabolic rate. Environmental temperature has been shown to influence reproduction, organ weight, food and water intake and haematological parameters. These data indicate that the optimal temperature range for mouse rooms is 20–26°C (Yamauchi *et al.* 1983). According to the European Directive, the environmental temperature requirements range between 20 and 24°C. The upper end of this range (22–24°C) should be considered if the mice have to be housed in wire-bottom cages because of greater air exchange between the cage and the room, or if hairless or nude mice are being housed in cages with limited amounts of bedding (see also Chapter 10, which discusses evidence that the thermoneutral zone of mice is 26–34°C). Blom *et al.* (1993) studied preferences of mice for temperature and found that individual BALB/c mice preferred a cage temperature of 28°C, whereas C57BL/6 preferred 24°C and that preference depended upon the type of cage flooring.

Ventilation rates should be based on the heat production of the animals. Air changes are less important than creating an efficient flow in the room to keep ammonia levels within the animal's immediate environment at an acceptable level. The health of staff also needs consideration with respect to exposure to animal allergens, such as dander and urine. To reduce the possibility of airborne introduction of infectious diseases into an animal room, high-efficiency particulate air (HEPA) or similar filtration of incoming air should be considered and is mandatory for maintaining specified pathogen free or gnotobiotic mice.

It is important to avoid extremely high or low humidities and rapid changes in humidity. At low humidity levels, mice may suffer from respiratory problems due to excessive dustiness of bedding and feed, and drying of mucous membranes. At high humidity levels, bedding may become damp and fail to evaporate moisture leading to rapid soiling of cages and increased production of ammonia by urease-producing bacteria. Furthermore, infections of the upper airways may occur more easily.

Cage cleaning regimes should be a compromise between maintaining hygiene and keeping odour patterns left by the animals (van Loo *et al.* 2000). Normally, cages are cleaned once a week. Water bottles should also be changed at least once a week.

Lighting conditions for the essentially nocturnal mouse are very important. Lighting must be controlled to avoid external lighting fluctuations. Mice exposed to too high an intensity of light may show retinal atrophy in the long term (Clough 1984). Animals should be subjected to a regular light-dark cycle, generally 12h light: 12h dark, but there is some debate concerning the effect on animal behaviour of creating artificial 'dawn' and 'dusk' periods (Latham & Mason 2004). In some cases, a reversed lighting schedule, with lights on at night, can be useful for observing activity of rodents during the working day; red light can be used to facilitate daytime husbandry as most rodents are less sensitive to red light (Spalding *et al.* 1969). Mice show a preference for a low light intensity. Maximum light intensity in the room should not exceed 350 lux and the intensity levels within the cage should be lower, or the animal should be given the opportunity to withdraw to shaded areas, such as a shelter or nest (Council of Europe 2006; European Commission 2007).

Many noises audible to the human ear and ultrasound (frequencies higher than the human range, >20kHz) are important for rodents. Mice are more likely to be disturbed by high-pitched sounds and ultrasounds than they are by lower frequencies; care must be taken not to use equipment which emits these ultrasounds, such as electronic devices and computer screens (Clough 1984; Sales *et al.* 1999; Latham & Mason 2004; Voipio *et al.* 2006). It has been suggested that a constant background noise, such as radio music, has some benefits in facilitating breeding and making animals less excited, although it could also stress some animals. However it may benefit the staff more, which could have beneficial consequences for the animals in turn (Sherwin 2002); it certainly should not exceed 55 dB. Alarm systems, telephones and door bells within rodent facilities should sound outside the animals' hearing range where this does not conflict with their audibility to humans (Council of Europe 2006;

Federation of European Laboratory Animal Science Associations (FELASA) 2007).

### Social housing

As mice are gregarious animals, it is preferable to keep them in groups rather than in individual housing, but the groups must be stable and harmonious in order to avoid or minimise aggression within groups (Council of Europe 2006; European Commission 2007). Allocating animals to new, unfamiliar groups may be a source of intense, stressful conflicts (Brain 1990). The evidence suggesting that individual housing in mice can be deleterious is not convincing (Brain & Benton 1983; Krohn *et al.* 2006) but strain differences have been found (Haemisch & Gärtner 1994). Individually housed mice are still provided with olfactory, auditory and (probably less importantly) visual cues from conspecifics in the room, whereas isolated animals are also deprived of this input. However, 'living apart together' (two mice in a cage, separated by a grid partition), did not appear to be beneficial to mice submitted to abdominal surgery. Increased heart rate levels and differences in behaviour as compared with both socially housed and individually housed animals indicate that 'living apart together' may even be the most stressful of the three housing conditions, whereas social housing appeared to be the best (van Loo *et al.* 2007). It is natural for many rodents to live in mixed sex groups but breeding frequently increases agonistic behaviour and laboratory mice are usually kept in single sex groups, which is unnatural in itself. Excessive agonistic behaviour depends on the animal's familiarity with its cage-mates as well as its sex and age at the time of grouping (Council of Europe 2006; European Commission 2007; FELASA 2007).

Adult males from specific strains, eg BALB/*c*, may fight excessively when kept in single sex groups. Male mice of all ages tested so far have a preference for social contact during rest periods. During activity periods, the preference for social contact increases with age. Aggression can be reduced by: transferring used nesting material to the clean cage, at the time of cage cleaning (but not the soiled bedding mate-

rial as the urine pheromones increase fighting); keeping no more than three males per cage; and minimising disturbances such as removing a group member temporarily (van Loo *et al.* 2003; Baumans *et al.* 2007).

'Barbering' or 'trimming' (hair nibbling and whisker chewing) occur frequently in both sexes of some strains of mice (Figure 21.6). Usually one of the mice retains its whiskers and it is assumed that this is the dominant animal within the cage, but this is not conclusive (van de Weerd *et al.* 1992; Garner *et al.* 2004). Removal of the barber mouse may lead to another mouse taking over the barbering role. Barbering may not be restricted to whiskers: head and body fur may also be involved, as can occur in the C57BL6 strain. The aetiology of barbering is not clear. Genetic factors may play a role as well as boredom of the animals (van den Broek *et al.* 1993). In caged mice, barbering is another example of an abnormal behaviour that has become a normative behaviour pattern within the context of inadequate living conditions (Garner *et al.* 2004; Baumans *et al.* 2007). Interestingly, mice will allow themselves to be barbered, even if they are given the opportunity to withdraw from the barber (van den Broek *et al.* 1993). However, Garner *et al.* (2004) point to a number of welfare issues that arise from barbering, including referring to a reference on degenerative alterations in somatosensory cortical areas corresponding to the whiskers.

### Presentation of food and water

The mouse is an omnivorous animal. The incisors and molars grow continuously and are worn down by mastication. Attention should be paid to malocclusion leading to under-nutrition.

Feeding behaviour in rodents shows a diurnal pattern with the majority of food consumed during the dark period. Fasting overnight, sometimes part of an experiment, might lead to an increase of activity, resulting in unwanted variation in experimental results (Baumans 1999).

Food is usually presented *ad libitum* as pellets in the food hopper on the cage, which prevents soiling of food by the

**Figure 21.6** Whisker chewing ('barbering') in mice: barbering mouse (right); barbered mouse (left). (Photo: T.P. Rooymans.)

animals. The food rack should be kept sufficiently full, as it is difficult for the animals to gnaw the food when there are only a few pellets left. Restricted feeding has been shown to be beneficial in the long run in terms of reduced morbidity and mortality in the earlier stages of life (Mattson *et al.* 2001).

Enrichment related to food, such as grain scattered through the bedding, will meet the animal's need for foraging and will prevent boredom due to the gap in the animal's natural time budget usually filled with foraging (Baumans 2005b), although it might interfere with experiments, eg, certain nutritional research. BALB/c and C57BL/6 mice kept in enriched environments with nesting material have been found to weigh more than mice housed under standard conditions, although the latter consumed more food, probably due to the insulating effect of the nest or to reduced boredom (van de Weerd *et al.* 1997a).

Water can be provided in a bottle attached to each cage, and this should be changed at least once a week; an alternative is an automatic watering system, which supplies water through a valve connected to a piping system and serves a rack of cages from a central reservoir. The water valve can be located either outside or inside the cage. There is always some risk that the valve may become obstructed, resulting in dehydration of the animals or flooding in the cage. For this reason, automatic watering systems must be closely monitored to be certain that the water pressure is adequate and must be regularly cleaned and checked for contamination with bacteria and fungi.

### Identification and sexing

Many permanent or temporary methods of identifying individual mice have been developed. Permanent methods include tattooing (on the tail or toe), toe clipping and ear punching. However, toe clipping is not recommended for welfare reasons (Baumans 2005a), and ear punching may be obliterated and damaged by fighting. Subcutaneous implantation of a microchip is a safe and long lasting, but expensive way of identification and might not be suitable for newborn mice. Temporary methods of identification include pen marks on the tail (Figure 21.7), clipping or plucking unique

patterns in the fur, which may be visible for about 14 days, or dyeing the fur with a harmless dye, such as food dyes. Tail clipping is commonly used in genetically modified mice in order to take tissue samples from the offspring for identifying their genetic makeup. Concerns have, however, been raised about this procedure on the grounds that it may cause lasting harm in terms of pain, and disturbance of the thermoregulatory function of the tail.

The sex of the animal can be determined by comparing the anogenital distance, which is larger in males than in females. In females, a hairless strip is visible between anus and genital papilla (Figure 21.8). In males, testes can be present in the scrotum, but they can also be retracted through the inguinal canal into the abdomen, especially when the animal is scared or stressed.

### Health monitoring, quarantine and barrier systems

Scientific data obtained from animal experiments should be reproducible and reliable and therefore the health status of the animals should be defined. Microbiological quality control aims at control of the barrier system and the animal itself. Only careful monitoring of animal facilities will provide useful information about the microbiological quality of the animals. Most infections in rodents are subclinical and modifications of research results due to natural infections often occur in the absence of clinical disease. For instance, Sendai virus infection, which is associated with a decreased B-cell and T-cell response after antigenic stimulation, enhances the production of interferon and decreases the serum level of the 3rd complement factor (C3) (Boot *et al.* 2001; FELASA 2002).

Laboratory animals can be classified according to their microbiological status (conventional, specific pathogen free (SPF) or gnotobiotic). Conventional animals can harbour a whole range of infectious micro-organisms, since they are kept without the application of preventive hygienic measures. Conventional animals are still widely used in biomedical research. Mice should be considered as conventional animals if their microbiological status is unknown. As a rule,

**Figure 21.7** Identification by pen mark on the tail. (Photo: T.P. Rooymans.)

**Figure 21.8** Sex differences in the mouse: male (right) and female (left). (Photo: T.P. Rooymans.)

these animals are 'quarantined' for a period of time before use. The length of this period is based upon the longest incubation time required for excluding infections. This implies the expectation that the 'quarantine' period would reveal certain clinical symptoms in the animals. However, most infections in laboratory animals are latent and can only be detected with specific screening programmes, which may be too costly to use as a routine.

SPF animals are free from a number of potentially pathogenic micro-organisms. SPF only designates which micro-organisms are known not to be in the colony at the time of the last testing. There are various reasons why SPF animals are used; for example, testing the safety of products and the performance of animal experiments with no interference from infections. The duration of experiments partly determines the likelihood of contamination. Long-term experiments are at greater risk than short-term ones.

Gnotobiotic animals are animals with a defined microflora and can be divided into germ-free (GF) and colonisation-resistant flora (CRF) animals. GF animals can be obtained from conventional counterparts by performing a hysterectomy (rederivation) and are kept under sterile conditions within isolators. GF animals are very susceptible to infections by micro-organisms that only rarely cause disease in conventional animals. To provide GF animals with some resistance to opportunistic infections, they can be deliberately given flora, which provide the formerly GF animal with a general resistance to the growth of other bacteria (colonisation resistance). CRF animals are housed as GF animals within isolators. Frequently, CRF animals are used to start SPF breeding colonies (Boot *et al.* 2001). Gnotobiotic animals are used for various purposes, such as the production of viral vaccines.

The animals should be screened periodically. The screening programme may involve serological tests, bacterial cultures, parasitic examinations and regular histopathological examination of major organs. The frequency of screening should be every 3 months with a minimal sample size of eight individual sera from mice randomly sampled from each unit for the most frequently occurring micro-organisms (FELASA 2002). If a particular agent is present in about 25%

of the population, a sample size of 10 animals would be required in order for a 95% probability of detecting an infected animal. When an insufficient number of animals is present in an experiment to carry out the health-monitoring programme, sentinel animals can be used, which are obtained from a colony with a known microbiological status and introduced into the experiment animal unit.

### Barrier systems

To maintain the microbiological status of gnotobiotic animals, including CRF animals, these animals should be kept separated from the environment in isolators made of steel or plastic (Figure 21.9). All equipment, including food and bedding, is sterilised and introduced through a lock which can be sterilised by, for example, peracetic acid vapour.

For short-term experiments, animals can be housed in cages with a protective hood (filter top) (Figure 21.10), which are only opened within laminar air flow cabinets. IVC systems are now widely used in combination with laminar air flow cabinets as work stations in order to create a bio-containment zone at cage level. As the airflow within the cage may be quite high (up to 100 air changes per hour) the animals may suffer from the high ventilation rate inside the cage. This might be reduced by providing nesting material or a shelter where the animals can hide from draughts (Baumans *et al.* 2002).

Animal rooms are cleaned with hot water, preferably with high-pressure equipment. Cleaning of cages and drinking bottles makes disinfection and sterilisation more effective. Physical and chemical methods exist for disinfection and sterilisation and depend upon the material to be treated and the micro-organisms likely to be present.

The effect of cleaning and disinfection can be monitored using agar plates, on which the number of bacterial colonies is counted and strips, which show colour changes, may monitor the autoclaving process or formaldehyde treatment. Modern autoclaves have inbuilt registration and control systems.

## Transport

Transport of mice, even over short distances and/or under optimal conditions, is a stressful event for the animal. For example, immune functions are altered by shipment, and require at least 2–5 days to return to normal, and reproductive performance can be decreased (Cunliffe-Beamer & Les 1987). The extent to which the well-being of the animal is compromised depends upon its health status, age (old and very young animals are more susceptible), density of animals in the cage, conditions in transport vehicle and cage, such as temperature, ventilation, food and water supply, and the acclimatisation period (5–7 days) in the new environment.

Mice that are being moved over a short distance within the same facility can be transported in a clean cage or cardboard carton. For longer journeys, the cardboard container should be coated with moisture-impervious material. Ventilation openings should be present on at least the two opposite sides. The openings should be provided with steel wire mesh and filters to prevent escape or contamination en route (Figure 21.11). Bedding should always be supplied for

**Figure 21.11** Disposable transport cage of cardboard, the inside covered with plastic, provided with wire mesh and filters. (Photo: T.P. Rooymans.)

comfort and to absorb moisture. Food can be provided as pellets, and water as 'solid' water, eg, agar, apples or potatoes or commercially available gel in the cage (see also Chapter 13).

## Breeding

### Selection of breeding stock

The primary objective of a good breeding programme is to produce the maximum number of quality mice at the lowest cost. Selecting breeding stock is important for the consistent production of healthy and fertile animals. The criteria for the selection of breeding stock may include the following (Buckland *et al.* 1981):

- The female parent should have a good overall breeding record and should not be prone to killing her young.
- The animals should be in good health and show no deformities.
- If possible, animals should not be selected from the first or second litters as they are usually small and do not reflect the size and standard of future litters.
- Animals should be selected from litters showing an average litter size for the strain, average weaning weight for the strain and equal sex ratio within litters.
- The parent animals should not be aggressive when handled.

### Condition of adults

Ovarian follicle development begins at 3 weeks of age and matures by 30 days (see Reproduction section). Vaginal opening and the first oestrus may occur at 24 days of age, but complete sexual maturity is usually delayed until 7–9 weeks of age. For reproductive and developmental data see Table 21.1. The stages of the oestrous cycle can be identified by external appearance of the vaginal orifice or by examination of vaginal smears using a moistened cotton wool swab.

### Mating systems

#### *Monogamous pairs*

Male and female remain together throughout their breeding life. The advantage is that the post-partum oestrus (oestrus immediately after the birth of the young) can be used, but the system requires more space and labour (one cage per breeding pair). It is, however, the system of choice for inbreeding.

#### *Trios*

Three animals (one male and two females) are kept together throughout their breeding life. The advantage is that the system is suitable for inbreeding and outbreeding and more animals can be housed per cage (although there must be enough space to house three adults plus two litters). One potential disadvantage is that, when both females produce offspring simultaneously, it may be unclear which female produced which young.

#### *Harem*

Groups of animals are housed together usually one male and four females, which is space and labour saving. More males may cause increased fighting, resulting in poor welfare and reproduction. When the females are pregnant they can be moved to a littering cage or stay in the harem. The latter may be less successful due to more disturbance and less tolerance when more than two females are present and it may be unclear which mother is fostering which pups.

### Conception and pregnancy

When the cervix and vagina are stimulated physically during oestrus, prolactin is released from the anterior pituitary, which stimulates the corpus luteum to secrete progesterone, a process that continues for about 13 days. If fertilisation occurs, the placenta takes over progesterone production. If fertilisation does not take place, a pseudo-pregnant period starts, during which oestrus and ovulation do not occur for about 20 days. Fertilisation usually takes place in the ampulla or the upper portion of the oviduct and embryos are produced for 10–12h post-ovulation. Mating is normally detected by formation of a vaginal plug (see Reproduction).

Gestation is normally 19–21 days. As a consequence of post-partum oestrus, lactation and gestation may occur simultaneously. However, lactation can delay gestation through delayed implantation, and this may prolong gestation for up to 12–13 days in certain inbred strains (Fox *et al.* 2002).

### Nesting

As parturition approaches, female mice build a nest and spend time huddled in it. Thus, pregnant female mice should be provided with nesting material, such as soft paper (see housing section), which does not dehydrate the neonates.

### Parturition

During the last 2 days of gestation, the female's nipples become prominent, mammary glands become distended and a slight mucus discharge from the vagina may be observed. Foetal movement that is obvious through the abdominal wall of the dam and foetal descent into the pelvic inlet are usually indicative of parturition within 12h. The majority of births occur during the dark period.

Mice are born in either an anterior or posterior presentation. The female mouse normally walks around the cage during labour and delivery. After the pup is born, the female retrieves it, cleans it and places it in the nest. Pups and placentas are delivered simultaneously. Several minutes may elapse between the delivery of successive pups. Some females do not retrieve pups when they are born, but wait and retrieve them in groups. Primiparous females are more likely to reject litters than multiparous females.

Cannibalism of handled newborn mice can be minimised by ensuring that neonates are warm and free of blood and rubbed with bedding material from the home cage when

they are returned to the nest; sedation of the dam may also be considered.

### The young

The newborn mouse is relatively immature with closed eyes and ears and no fur (Figure 21.12). The development of external characteristics can be used to estimate the age of young mice (Table 21.2).

Maternal care can account for about 70% of the variation in body weight of neonatal mice. Milk production increases up to 12 days post-partum, and then declines until weaning at about 21 days. Transmission of passive immunity after birth by colostral antibodies has been demonstrated to a wide variety of antigens, including viruses, bacteria and parasites. Antibodies continue to be secreted in the milk throughout lactation (Fox *et al.* 2002). Milk uptake in newborn mice can be checked by looking at the 'milk spot', the milk-filled stomach of the young, showing through the furless skin of the belly.

Hand rearing of orphan or rejected newborn mice is not easy because of their small size, 4h feeding schedule and susceptibility to temperature fluctuation. If the dam dies or lactation fails when the litter is about 14 days of age, placing a moistened or soft diet and water in the cage may improve survival of the pups. A powdered diet can be made by grinding pelleted mouse food and a soft diet can be made by soaking the pelleted feed in water. Small petri dishes make good disposable food or water containers. By 18–19 days of age, small pieces of pelleted food should replace part of the powdered or soft diet. By 21–24 days of age, normal pelleted food can be provided if the mice are able to reach the feeder.

Fostering newborn mice to other lactating females may be used for hysterectomy-derived neonates, when the dam has died or in certain teratological studies. The foster mother should deliver her litter 1–4 days before the anticipated birth of the litter that will be fostered. The foster mother is removed from her nest and placed in a separate cage. Her litter and the litter to be fostered are mingled together. The litter to be fostered is placed in the nest after being rubbed

with soiled bedding material and the foster mother's litter removed. The foster mother is then returned to her cage but a few of the mother's pups may be left in the nest if the litter to be fostered contains only two or three pups and if each litter can be identified by, for example, coat colour. This procedure ensures that the litter size is adequate to maintain lactation. Research protocols may require partial exchange of litters between lactating female mice (cross-fostering). Age differences between litters to be cross-fostered should not exceed 4 days, and preferably should be only 1–2 days,

**Table 21.2** Characteristics of mice from birth to 4 weeks of age.

Age	Characteristics
Birth	Blood-red skin colour
1 day	Lighter red skin colour. Milk visible in stomach (Figure 21.13)
2 days	Lighter skin colour. Ears flat against head
3 days	Ear elevated about 45° away from head, ears open
4 days	Ears elevated 90° away from head
5 days	Skin thicker. Milk no longer visible in stomach
6 days	Fur starts as a fine stubble over back (Figure 21.14)
7 days	Complete coat of fine fuzzy fur is visible
8 days	Lower incisors visible, but not erupted
9 days	Inguinal nipples visible in female
10 days	Lower incisors erupted
11 days	Upper incisors erupted
11–12 days	First solid food intake
11–14 days	Eyelids open. Slit-like palpebral opening
3 weeks	Oval palpebral opening, fine soft fur
4 weeks	Round palpebral opening, smooth fur
4–5 weeks	Vagina opens

**Figure 21.12** Mother with newborn mice. (Photo: T.P. Rooymans.)

**Figure 21.13** Young mouse, age 5 days. Note the milk spot. (Photo: T.P. Rooymans.)

**Figure 21.14** Young mice, aged 14 days and 6 days. (Photo: T.P. Rooymans.)

because larger, older pups will crowd out smaller younger pups as they compete for milk.

Mice are normally weaned at 3 weeks, when they start to eat pelleted food.

## Feeding

### Laboratory diets

The health status, performance and metabolism of experimental animals are influenced by the composition of the diet and the feeding practice. Thus, nutrition not only affects the well-being of the animals but also the outcome of experiments (see Beynen *et al.* 2001 and Chapter 14).

Diets for laboratory animals are classified according to the degree of refinement of the ingredients and are known as natural ingredient, purified or chemically defined diets. The most commonly used diets for laboratory mice are natural ingredient diets. In these diets, a minimum of processing is performed on the ingredients. Natural ingredient laboratory diets for mice are usually based upon one or more cereals or cereal by-products to which fats, protein, vitamins and

minerals are added. The source of fat is usually vegetable oil, while protein sources include fish meal, milk solids and soybean meal. Nutrient concentration can vary considerably as a consequence of changes in the source of ingredients used in the manufacturing of the diet, as nutrient concentrations of natural ingredients are not fixed.

Chemically defined diets are often used in nutritional or toxicology studies. Chemically defined diets are formulated with pure chemicals, eg, individual amino acids replace whole proteins, which make the diets expensive. Purified diets are formulated with a combination of natural ingredients, pure chemicals and ingredients of varying degrees of refinement, for example, protein may be supplied as casein.

Mouse diets can be provided in pellet (compressed or expanded), meal and semi-moist or gel form. Pelleted diets are easy to feed and have minimal waste compared to the other forms of diets. Meal diets are used when test compounds must be added to the diet. The animals may waste large amounts and the diet has to be fed in the cage. Meal diets may be pelleted after the test compound is added if the compound is not heat- or moisture-sensitive. Gel-form diets are made by mixing equal parts agar and meal. These diets are often used in toxicological studies where it is important to incorporate dusty or highly toxic test compounds. Gel diets are easily contaminated by bacteria and should be stored under refrigeration.

Standard laboratory diets for mice are usually formulated either for maintenance of adult mice or for growth and reproduction. Maintenance diets are usually lower in fat (4–5%) compared to growth and reproduction diets (7–11%). Minimum protein levels range from 12–14% for maintenance and 17–19% for reproduction. Breeding female mice may be undernourished if fed on a maintenance diet, while adult mice that are not breeding may become overweight if maintained on growth and reproduction diets.

Different inbred strains of mice vary in their dietary requirements of protein, vitamins and minerals. Rapidly growing young mice and pregnant or lactating female mice have higher energy requirements than adult mice. Mice reared under germ-free or gnotobiotic conditions require higher dietary levels of B<sub>12</sub> and K vitamins in order to compensate for losses during sterilisation of the diet and for the absence of B and K vitamin synthesis by intestinal microflora. SPF mice have additional requirements for vitamin K. The efficiency of feed utilisation can be altered by the number of mice per cage. Mice caged in groups of six to eight use food more efficiently than mice caged in smaller groups or caged individually (Cunliffe-Beamer & Les 1987).

The diet is a potential source of micro-organisms that can be pathogenic to laboratory animals. Food for gnotobiotic animals must be sterilised by either autoclaving or by gamma-radiation; food for SPF animals is also usually sterilised. Autoclaving causes some destruction of most of the vitamins and may denature proteins and cause the pellets to stick together (this situation can be improved by treating the pellets with talc powder). Irradiation is less damaging, although it causes some loss of vitamins, particularly vitamin K. Losses on irradiation are much greater in the presence of water, therefore moist diets or aqueous solutions should not be sterilised by gamma-radiation (Beynen *et al.* 2001).

## Water

Drinking water is a potential source of pathogenic organisms, metals and organic chemicals. The type and amount of contamination will depend on the source of the drinking water. Tap water is not sterile and quickly becomes contaminated with even more bacteria after the bottle is placed on the cage. Water bottles may be contaminated if they are improperly washed or drinking tubes or bottles are in contact with saliva and faeces. Some mice push faeces and bedding into the drinking tube.

Water bottles and drinking tubes can be sources of *Pseudomonas aeruginosa* and other coliform bacteria. *P. aeruginosa* kills mice that have been immunosuppressed (by irradiation or other means) and has been associated with otitis media and encephalitis in recently shipped mice. Autoclaving filled water bottles and drinking tubes eliminates bacterial contamination arising from the source of the water or from ineffectively washed bottles or tubes; however, autoclaving does not prevent in-use contamination of the water. Bacterial contamination can be controlled by acidification (pH 2–3) or chlorination (15–20 parts per million active chloride).

The concentration of metals and organic chemicals in drinking water will vary with the source and type of pipe used to transport the water. Trace elements and heavy metals and organic chemicals can be sources of contamination or confounding variables in nutritional or toxicological experiments. Chemical contaminants can be removed by reverse osmosis, deionisation or microfiltration.

## Laboratory procedures

### Handling and restraint

Mice can be caught inside the cage by grasping the base of the tail with the thumb and index finger; they can be picked up by the tail and transferred to, for example, a clean cage (Figure 21.15). When holding a mouse by the tail, its weight should be supported on a surface such as the opposite arm or cage lid rather than allowing it to dangle. The tail must not be held by the tip as this may cause the skin to be sloughed

off. However, J.L. Hurst and colleagues (data in preparation) have recently reported that mice picked up and held by the tail (while supporting their weight on the arm or hand) subsequently attempt to avoid contact with the handler and show much stronger anxiety in standard tests than those picked up and held by one of three alternative methods for routine handling: cupped directly on the open hand, handled indirectly in a home cage tunnel or picked up in a tunnel and transferred to the open hand. They report that mice handled using these alternative methods rapidly become tame to human contact, spending much time voluntarily interacting with the handler after only a few handling experiences as well as showing low anxiety in standard tests. If the animal needs to be restrained, it should be placed on a rough surface, such as the cage lid. The loose skin of the neck between the ears can be held between thumb and index finger of the other hand (Figure 21.16). The mouse is lifted and the tail is secured between the fourth or fifth finger and the palm of the hand. This technique leaves one hand free for injections or other procedures (Figure 21.17).

One should be careful not to pull the skin too tightly, as the mouse may be choked. One should always watch the colour of the mucous membranes of the nose and mouth for that reason. Neonatal mice (less than 2 weeks of age) are picked up by grasping the loose skin over neck and shoulders with thumb and index finger.

Strains of mice differ in temperament. Some strains are very calm and rarely try to bite or escape, for example BALB/c, while others are 'nervous' and can jump 'like popcorn', such as C57BL. All mice go through a 'jumpy' stage at about 3 weeks of age. Working with mice should always be done quickly, quietly and gently.

Plastic or metal devices to restrain mice for procedures such as tail vein injections, blood pressure measurements or irradiation can be manufactured (Figure 21.18). Training mice to be handled might reduce stress, by using alternative handling techniques that avoid picking up mice by the tail and encourage voluntary interaction with the handler (see earlier in this section). However, restraint will always cause more or less stress (Meijer 2006).

Unnecessary disturbance or manipulation of a post-parturient female and her litter should be avoided for the

**Figure 21.15** Lifting a mouse from the cage. (Photo: T.P. Rooymans.)

**Figure 21.16** Restraint of a mouse. (Photo: T.P. Rooymans.)

**Figure 21.17** Restraint of a mouse. (Photo: T.P. Rooymans.)

first few days following birth. If handling of neonates cannot be avoided, the risk of cannibalism or rejection of the litter can be reduced by gentle handling of the dam and offspring, placing the dam in a separate cage while the litter is being handled, and wearing plastic gloves in order to prevent the neonates from acquiring human scent. Rubbing the pups with bedding material from the home cage when they are returned to the nest can also reduce the risk of cannibalism.

## Physiological monitoring

### Recording body temperature

The rectal temperatures of healthy mice vary in the range 36.5–38 °C and can be measured by inserting a thermocouple into the rectum. Rectal temperature is influenced by environmental temperature, age, strain and stress (eg, restraint).

**Figure 21.18** Plastic device for restraining mice. (Photo: T.P. Rooymans.)

Core temperature can also be measured by using telemetry. Although the transmitter, which has to be placed in the abdominal cavity, is still rather big for a mouse, it has been shown that behaviour and bodyweight return to normal within 10 days after implantation (Baumans *et al.* 2001a). This method has already been used to record mouse core temperature, heart rate and activity. Once the device has been implanted, measuring seems to be a stress-free method in the freely moving animal (Kramer *et al.* 1993; Meijer *et al.* 2006).

### Collection of specimens

#### Collection of blood

General advice on blood sampling can be found in JWGR (1993). The total volume of blood in a living mouse is rather constant and is about 8% of its body weight. If the volume of a sample withdrawn exceeds 10% of the total blood volume, hypovolaemia and cardiovascular failure ('shock') may occur. As a general rule, a maximum of approximately 8 ml/kg bodyweight of blood can be removed from a live mouse every 2 weeks (Baumans *et al.* 2001b; Pekow & Baumans 2002). Blood samples can be obtained from various sites of the body, using a variety of methods. The choice of the method will depend upon several factors, such as the

purpose of blood collection (arterial, venous or a mixture of the two), the duration and frequency of sampling and whether or not it concerns a terminal experiment. Samples obtained from various methods will not be identical with respect to cellular or other constituents. Anaesthesia may be required for some methods.

Blood samples can be collected from various sites:

- Small volumes of blood (for example for a smear) may be obtained by snipping off the very tip of the tail, which will result in a mixture of venous and arterial blood, together with tissue fluid. This method is suitable when small samples are required every few hours. The scab on the tail wound can easily be removed.
- The lateral tail vein can be punctured with a 0.6–1.0 mm needle after warming of the tail in warm water, under a heating lamp or in a climatic chamber (Figure 21.19). The mouse can be anaesthetised or placed in a restraining device. The ventral tail artery can be used in the same way. Using razor blades to cut the vein may prolong bleeding and create scar tissue, but the yield may be higher.
- The lateral saphenous vein can be punctured in the restrained mouse in the same way (Figure 21.20).
- Blood can be aspirated from the jugular vein, mostly by surgical exposure of the vein under anaesthesia, which provides a sterile blood sample.

Figure 21.19 Lateral tail vein. (Photo: T.P. Rooymans.)

Figure 21.20 Lateral saphenous vein. (Photo: T.P. Rooymans.)

- Arterial blood can be obtained from the abdominal aorta, brachial artery or carotid artery under anaesthesia.
- Puncture of the orbital blood vessels. For this procedure the anaesthetised animal is firmly held by the skin at the nape of the neck, which causes distension of the jugular vein. A fine glass tube or a Pasteur's pipette is then placed at the inner canthus of the eye and gently advanced alongside the globe into the vessels. The tube ruptures the vessels and blood can be withdrawn by capillary action. Contamination with tissue fluids and porphyrins from the Harderian gland can occur. It is not possible to take sterile blood samples using this method. Also complications, such as haemorrhage, inflammation and blindness, may occur, especially when the same eye is used repeatedly. Moreover, this technique may be aesthetically unpleasant for the operator to perform. For these reasons, this method is not considered acceptable in some countries (Baumans *et al.* 2001b) and is generally not recommended. However, the extent of trauma is proportional to the skill of the technician.
- Submandibular bleeding from the facial vein (Golde *et al.* 2005). This technique is now getting more popular; however, it should be performed under anaesthesia and haemorrhage or damage of the facial nerve and artery may occur.
- Cardiac puncture. In this method, blood is collected directly from the ventricle of the heart of the anaesthetised animal. Puncturing the atrium can be dangerous, due to the risk of leakage into the pericardium, resulting in cardiac arrest and death. When the animal has to survive the procedure, these risks must be taken into account.
- Implantation of indwelling cannulae can be used when repeated blood sampling is required. The indwelling catheter can be implanted via the jugular vein into the cranial vena cava and exteriorised at the top of the head, where it is secured with screws and acrylic glue or between the shoulders. The catheter's dead space is usually filled with a substance containing heparin.
- Exsanguination. To obtain the maximum amount of blood, decapitation can be performed using a guillotine or scissors, or by puncturing the aorta under anaesthesia. In this way about 30 ml/kg body weight or up to 50% of the total blood volume can be obtained. Exsanguination is also possible by removing the eyeball under anaesthesia and collecting blood from the eye artery.

#### Collection of faeces and urine

Mice often urinate and/or defecate purely as a result of being handled, which may provide the opportunity for collecting small samples of urine and faeces. Placing the animal in a plastic bucket will result in urination and urine can be collected with a syringe (van Loo *et al.* 2003; Meijer *et al.* 2006). Metabolic cages must be used for the quantitative collection of urine and faeces. The animals are housed on a grid above a funnel in which the urine and/or faeces are collected and separated (Figure 21.21).

**Figure 21.21** Metabolism cage with food hopper, water bottle and funnel. (Photo: T.P. Rooymans.)

#### *Collection of milk*

Mouse milk can be collected using milking 'machines' with single or multiple teat cups. Prior to milking, the lactating female is separated from her litter for 8–12h. Then, the mammary glands are washed with warm water and the mouse may be injected subcutaneously with oxytocin to stimulate milk flow.

#### *Collection of sperm*

Sperm for artificial insemination is usually obtained from the epididymides of a recently killed male mouse. However, electroejaculation of male mice has been described. A balanced salt solution with glucose should be used to dilute mouse semen (Cunliffe-Beamer & Les 1987; Hedrich & Bullock 2004).

### Administration of substances

#### **Dosing and injection procedures**

General advice on the administration of substances can be found in JWGR (2001). Three methods for the administration of substances can be distinguished: via skin, enteral and parenteral (Baumans *et al.* 2001b).

#### *Application to skin or mucous membranes*

The substance is applied in solution or as ointment on shaven skin or mucous membranes. This method is inaccurate and may cause discomfort to the mouse if the substance is irritating.

#### *Enteral administration*

Enteral administration means that the substance is brought into the gastrointestinal tract orally through food or drink-

**Figure 21.22** Administration of substances via stomach/oesophageal tube. (Photo: T.P. Rooymans.)

**Figure 21.23** Subcutaneous injection under the skin of the neck. (Photo: T.P. Rooymans.)

ing water, which is not very accurate and impossible when the substance is unpalatable, insoluble or chemically unstable. To stimulate the consumption of, for example, medicines or other substances, these can be administered in fat drippings, raspberry cream, yoghurt sweets or chocolate which are highly appreciated by mice.

Administration via a stomach/oesophageal tube is more accurate and can be performed by a curved needle with a blunt end (external diameter 0.8 mm), such as an infant lacrimal sac canula (Figure 21.22). The mouse is held firmly by the scruff whilst passing the needle along the palate into the oesophagus. The animal should be allowed to 'swallow' the needle. As the head is directed upwards, the risk of entering the trachea is minimal. The maximum volume to be administered should be 0.25–0.5 ml.

#### *Parenteral administration*

Parenteral administration refers mainly to injections. The most frequently used injection techniques in the mouse are:

- Subcutaneous (sc): usually under the skin of the neck using a 0.45 mm needle (26G). Resorption of the substance is slow. Maximum volume to be administered is 0.25–0.5 ml (Figure 21.23).

- Intramuscular (im) injections are usually avoided in the mouse because of its small muscle mass. If necessary, intramuscular injections of 0.05 ml or less may be made into the lateral thigh muscles using a 0.40 mm needle (27G). The tip of the needle should be directed away from the femur and sciatic nerve.
- Intraperitoneal (ip) injections may cause damage to the internal organs. To avoid the urinary bladder the injection should be given slightly off the midline. The needle should neither be inserted horizontally (between the skin and the abdominal wall) nor vertically (risking damage to the kidney). The injection should be given in the lower left or right quadrant of the abdomen. There is a slight risk of causing damage to the intestines (mainly due to their mobility) (Figure 21.24). To be sure the procedure has been carried out properly, the plunger must be retracted to determine whether any urine, intestinal contents or blood have been aspirated. The maximum volume to administer is 0.5–1.0 ml with a 0.45 mm needle (26G) (Baumans *et al.* 2001b; Pekow & Baumans 2002).
- Intravenous (iv) injection into the tail vein is usually the fastest and most accurate method, but requires more technical skill. The maximum volume to administer as bolus is 0.125 ml with a 0.45 mm (26G) or 0.50 mm (25G) needle. For preparation of the vein see section Collection of blood.
- Avoid air bubbles in the injection fluid (which can cause embolism).
- The injection fluid must be brought to room or body temperature prior to use.
- Some injection fluids can cause tissue irritation, for example, high or low pH, and should therefore be administered after having been diluted with saline. These substances should, preferably, be given intravenously, as they quickly become diluted in the blood. When using the ip route, dilution also occurs, but there is a risk of peritonitis (Baumans *et al.* 2001b).

### Anaesthesia and analgesia

The principles of anaesthesia/analgesia and an overview of substances and dosages are described by Flecknell (1996, 2009). Pain occurring during surgical procedures can be prevented by the use of appropriate anaesthetic techniques. Most anaesthetics affect many body systems, and so may interact with experiments. To minimise such interactions, anaesthetic regimens should be selected with care, by considering the pharmacology of the drugs involved. Uncontrolled pain may interact with the experimental procedures.

A variety of anaesthetics can be used, depending on the type, duration and purpose of the experiment, strain and age of the mouse and the skill of the personnel. An ideal anaesthetic should induce a stable anaesthesia, be easy to administer, not influence physiology, be reversible and be safe for the animal and personnel.

General anaesthesia can be produced by inhalational agents such as halothane, isoflurane and ether. (The latter is generally not recommended and banned in some countries for the irritant properties to mucous membranes and the induced excitation which is unpleasant for the animal. Its explosive properties also make it a safety hazard.) Anaesthesia can also be produced by injectable agents such as pentobarbitone, ketamine and fentanyl/fluanisone plus midazolam.

Personnel anaesthetising mice with volatile anaesthetics should be aware of the hazards associated with prolonged exposure to these agents. The facemasks that are used to

Points of special attention when carrying out these procedures are:

- Use clean, sharp, short and sterile needles.
- Use an appropriate needle size. A thin needle causes less pain and prevents the fluid from flowing back. The required thickness of the needle (gauge) will depend upon the viscosity of the fluid. When using very thin needles, there is a risk of cracking. On the other hand larger needle sizes for viscous injections require shorter injection time and because of shorter restraint time appear to be less distressing to the animal (Barclay *et al.* 1988).
- Never inject more fluid than the recommended maximum volume.

Figure 21.24 Intraperitoneal injection. (Photo: T.P. Rooymans.)

administer inhalant anaesthetics to mice usually leak the anaesthetic agent into the surrounding environment. The exposure to personnel can be reduced by placing the anaesthetic apparatus inside a fume hood or preferably by ducting the vapours to the outside using a suitable scavenging system.

The following are recommended for anaesthetising mice (see also Flecknell (2009)):

- Fentanyl/fluanisone (Hypnorm, Janssen) (0.4 ml/kg ip) with midazolam or diazepam (5 mg/kg ip). When using midazolam the components are mixed with water for injection. This anaesthetic mixture provides anaesthesia for 30–40 minutes and can be reversed partially by nalbuphine (4 mg/kg ip or sc).
- Ketamine (75 mg/kg ip) can also be used in a mixture with medetomidine (1.0 mg/kg ip), mixed in one syringe. This combination can be partially reversed by atipamezole (1 mg/kg sc). Another combination is ketamine (80–100 mg/kg ip) and xylazine (10 mg/kg ip) administered together as a single ip injection and reversed by atipamezole (1 mg/kg sc). Both of these mixtures provide moderate anaesthesia for 20–30 minutes, but are often insufficient for major surgery (Flecknell 1996).
- Pentobarbital is not a drug of choice in major surgery on account of its inadequate analgesic properties. When it is used, it should be administered at a dosage of 40–50 mg/kg ip. Overdosage or underdosage occur frequently (Flecknell 1996) and dilution may be useful to prevent peritoneal irritation.
- Inhalation anaesthesia can be achieved with halothane, isoflurane or enflurane using an anaesthetic chamber. Atropine (0.04 mg/kg sc, ip) can be administered to reduce salivation.

Local anaesthetics are used for anaesthesia of specific parts of the body, while the animal remains conscious. Local anaesthesia in the mouse is usually restricted to:

- surface anaesthesia, where the local anaesthetic is applied to the skin or mucous membranes as a gel, spray or cream;
- local infiltration of a local anaesthetic into the deeper layers of tissue, which can be used for procedures such as skin biopsies.

The most frequently used local anaesthetic agents are procaine, lidocaine and bupivacaine.

Before inducing anaesthesia, the animal should be in good health and sufficiently acclimatised to an experimental environment. Pre-anaesthetic fasting is unnecessary and undesirable in mice (Hellebrekers *et al.* 2001) as they show no vomit response. Anaesthetised mice should be placed in their cages in a lateral or ventral recumbent position with the head slightly extended. This position minimises aspiration of salivary secretions and reduces the intrathoracic pressure caused by abdominal viscera pressing against the diaphragm. If prolonged surgical procedures or recovery periods are anticipated, sterile physiological saline or balanced salt solutions should be administered sc or ip (0.5–1 ml per 15–25 g body weight).

The depth of anaesthesia can be estimated by:

- the righting reflex: the animal turns over to a position on its feet after being placed on its back;
- the pedal withdrawal reflex, when a digit or interdigital skin is pinched;
- movement of whiskers and ears in response to a puff of air.

Ophthalmic ointment or artificial tears should be used to prevent drying of the cornea during anaesthesia.

Post-operative pain, and pain occurring as a result of non-surgical experimental procedures, can be alleviated by the administration of analgesics. In order to control pain effectively, it is essential to be able to assess the degree of pain that is being experienced by the animal. Post-operative care should be provided. This is likely to include: analgesics and fluids; a quiet, warm place, such as an incubator, intensive care unit or a cage provided with a heating pad or lamp to maintain body temperature; and observation and attention by skilled personnel. Monitoring of urine output and defecation gives an indication of the hydration status and condition of the gastrointestinal tract, respectively. Behavioural scoring systems and food and water intake can be used in the assessment of pain in the animal post-operatively. Twitching, flinching, stretching, reduced climbing and locomotion can be seen (Baumans *et al.* 1994; Baumans & Brain 2001; Roughan & Flecknell 2003; van Loo *et al.* 2007; National Research Council 2008) and reduced nest building can be observed (Arras *et al.* 2007; van Loo *et al.* 2007). It has been demonstrated in humans that effective analgesia reduces the time needed for post-operative recovery (Flecknell 1996; Hellebrekers *et al.* 2001, see also Flecknell 2009)).

The following analgesics can be used in the mouse (Flecknell 1996; Hellebrekers *et al.* 2001):

- non-steroidal anti-inflammatory drugs (NSAIDs), such as carprofen (5 mg/kg sc, 12 hourly), aspirin (120 mg/kg per os 4 hourly) and flunixin (2.5 mg/kg sc, im, 12 hourly);
- opioid analgesics, such as buprenorphine (0.05–0.1 mg/kg sc, 12 hourly).

Surgical procedures in mice require aseptic conditions (sterile instruments, cap, mask, gown and gloves). The mouse's hair can be removed by shaving and the skin decontaminated with 70% alcohol or povidone-iodine. Tissues should be handled using a 'no touch' technique. This means that only the tips of the surgical instruments touch the mouse and surgical instruments are returned to a sterile surface between successive procedures.

## Endpoints

It is important to determine humane endpoints (the humane killing of animals at a stage that the first signs of approaching death are recognised). The animal would benefit, as unnecessary suffering is avoided or reduced, and also researchers would benefit as the scientific results would be more valid, data being less variable and timely collection of samples being scheduled. Clinical signs that can help to determine humane endpoints are rapid weight loss (15–20%), prolonged diarrhoea, nasal discharge, coughing, neoplasia accounting for 10–20% bodyweight, self-mutilation,

central nervous system signs, severe ulceration or bleeding, drop in body temperature  $>4^{\circ}\text{C}$ , inability to ambulate, laboured breathing and cyanosis. A pilot study may help specify humane endpoints in particular experiments (Baumans *et al.* 1994; Hendriksen & Morton 1999; Morton & Hau 2003).

## Euthanasia

Mice are killed in the laboratory at the end of an experiment, to provide blood and other tissues, to counter suffering when it exceeds an acceptable level, when they are no longer suitable for breeding or when there is surplus stock.

The 1986 Council Directive of the EEC on the protection of animals used for experimental and other scientific purposes (86/609/EEC) requires humane killing of experimental animals, with a minimum of physical and mental suffering. Methods of euthanasia should be painless, achieve rapid unconsciousness and death, require minimum restraint, avoid excitement, be appropriate for the age, species and health of the animal, must minimise fear and psychological stress in the animal, be reliable, reproducible, irreversible, simple to administer and safe for the personnel and (if possible) aesthetically acceptable. It is important that personnel are trained and experienced in recognising and confirming death in the animals (EC Working Party reports on euthanasia of experimental animals 1996, 1997).

Acceptable methods of euthanasia in mice are:

- Stunning by a blow on the head, followed by exsanguination.
- Cervical dislocation, in which the cervical vertebrae are separated from the skull using a pencil or similar placed in the neck and followed by a pull on the tail base.
- Decapitation, by guillotine or scissors although this method is still under discussion with regard to the onset of unconsciousness.
- Inhalational anaesthetics such as halothane, enflurane and isoflurane in overdose.
- Carbon dioxide  $>70\%$ , which may cause excitation and stress, due to irritation of the mucous membranes and the induced hypoxia. The animal is placed in a chamber either prefilled with the gas, which will cause a short-lasting distress, but seems to result in a rapid loss of consciousness, or exposed to rising concentrations which seem to cause less distress but prolong consciousness. The optimal filling rate is still uncertain and prefill and rising concentrations both can cause welfare problems. However, rats exposed to carbon dioxide in their home cage instead of in a gas chamber did not show signs of distress (Hackbarth *et al.* 2000). There is still some discussion as to whether the addition of oxygen to high carbon dioxide concentrations contributes to the animal's welfare; it may reduce but not overcome welfare problems. It is also possible that high oxygen would prolong consciousness. It is clear that further studies are needed in this respect (Newcastle Consensus meeting on Carbon Dioxide Euthanasia of Laboratory Animals 2006).

- Sodium pentobarbital, iv or ip. The agent should be diluted for ip injection to prevent irritation and pain to the peritoneum.

Killing methods acceptable for use in unconscious mice include rapid freezing, exsanguination or potassium chloride injection.

If a foetus is removed from the anaesthetised mother, it may be killed by decapitation. Foetuses not anaesthetised prior to removal from the mother may be killed by rapid cooling in liquid nitrogen. Newborn mice can be killed by stunning or decapitation (EC Working Party reports on euthanasia of experimental animals 1996, 1997).

## Common welfare problems

### Disease

#### Signs of disease

Signs associated with disease include withdrawal from the group, hunched-up position, ruffled fur, sunken eyes, reduced growth rate, emaciation, diarrhoea, 'chattering' (a clicking sound associated with severe respiratory infections), laboured breathing, cyanotic or pale extremities, reduction in the number of offspring born or weaned, reduction in the number of breeding pairs producing offspring or increased mortality (Figure 21.25). However, many infectious diseases of mice cause few, if any, obvious signs of disease. These latent infections can have a significant impact on experiment results, as they do not cause clinical signs in infected mice, but they can alter histology or immune responses. *Pseudomonas aeruginosa* can be present in the intestine of mice without any apparent ill effects. However, if these same mice are irradiated or subjected to other immunosuppressive procedures, *P. aeruginosa* can cause a fatal septicaemia.

The signs associated with an infection, especially viral infections, vary depending upon strain, age and microflora of the mouse, previous exposure of the mouse to the infectious agent and the strain of the infectious agent.

To make a correct diagnosis of a disease, specific skills and experience in pathology and related disciplines including microbiology are needed. A complete diagnostic examination should include the history of the disease (sex, age, strain, microbiological status, source, use, performed procedures), environment, clinical signs, such as general condition, respiratory system, circulatory system and locomotion; also additional information from blood samples, urine, skin scrapings etc, *post-mortem* and microbiological examination (eg, histology, detection of antibodies) (van Dijk *et al.* 2001).

#### Common diseases

Tables 21.3, 21.4 and 21.5 contain lists of the major viral, bacterial and parasitic infections of mice. Specialists in laboratory animal medicine should be consulted to develop a disease-control programme.

**Figure 21.25** A sick mouse with sunken eyes, ruffled fur and a hunched up position. (Photo: T.P. Rooymans.)

### Prophylaxis

Genetic and environmental factors play an important role in the causation of disease. Genetic factors are involved in disease susceptibility, eg, differences between mouse strains in tumour incidence (BALB/c, CBA, DBA/2) and myocardial calcification (C57BL/6). Environmental factors, eg, nutrition, husbandry, infections and other noxious agents can contribute to the causes of disease. Hygiene and improvement of the microbiological status will reduce the incidence of infections dramatically. Good management with health-monitoring programmes, knowledge of the biology of animals and epidemiology of diseases is a prerequisite (see Health monitoring, quarantine and barrier systems).

Key elements in an effective disease-control programme for mouse colonies are:

- microbiological assessment of breeding colonies;
- microbiological assessment of cell lines, transplantable tumours or other biological materials;
- development of standardised husbandry procedures that minimise transmission of infections between cages and between rooms;
- microbiological and mechanical monitoring of cage washing equipment, autoclaves and environmental conditions;
- understanding and controlling personnel (see Health monitoring, quarantine and barrier systems).

### Abnormal behaviour

An important concept in the well-being of animals is homeostasis, which implies that the animal is in harmony with its internal and external environment and is able to keep that environment controllable and predictable. When homeostasis cannot be maintained, discomfort or stress may occur, which can become manifest as a disease or abnormal behaviour, such as the development of stereotypies.

Stereotypies can be defined as repeated, simple behavioural patterns, which seem to be meaningless and are typical of the individual animal, such as circling movements or constant jumping in the cage (Baumans 2005a). Whether stereotypy is a sign of abnormal brain function, or whether it is 'merely' a sign of chronic frustration, which is still a serious welfare problem, stereotypy is likely to be associated with differing stress responses between individuals (Garner & Mason 2002). Minimal responses or lack of reaction to stimuli (apathy) can also be considered as abnormal behaviour. Together with clinical and physiological parameters, abnormal behaviour may indicate that the well-being of the animal is compromised.

### Reproductive problems

Reproductive problems may be caused by internal factors, such as: diseases and infections, eg pyometra in female mice or inflammation of the seminal vesicles in the male; chemicals, oestrogenic stimulation by oestrogen-like substances in the diet; immaturity or senescence; nutritional restriction; disturbances of maternal care, such as cannibalism, neglect of the young, insufficient milk production; or environmental factors, such as high (>28°C) or low (<10°C) temperatures in the cage, bedding containing fine particles (which may cause preputial inflammation in the male, preventing mating), deprivation of nesting material, noise and disturbance in the animal room (which may prevent mating or cause cannibalism or neglect of the newborn young) and overcrowding (Harkness & Wagner 1995). During the process of inbreeding a decline in reproductive performance may occur.

**Table 21.3** Viral diseases of mice (Cunliffe-Beamer & Les 1987; O'Brien & Holmer 1993; Boot et al. 2001; FELASA 2002; Fox et al. 2002) (ELISA, enzyme-linked immunosorbent assay; HAR, haemagglutination reaction; IB, immunoblot; IFA, indirect immunofluorescence assay; LDH, lactate dehydrogenase; PCR, polymerase chain reaction; VN, virus neutralisation).

Name (synonyms: virus family)	Incidence	Clinical signs	Pathological lesions	Diagnosis (suitable tests methods)*	Control	Transmission of infection	Comments
Mouse coronavirus Mouse hepatitis virus (MHV)	Frequent	Acute, inapparent infection, wasting disease in nude or thymectomised mice, diarrhoea (often fatal) in suckling mice or immunodeficient mice, ruffled fur, inactivity, dehydration, immunomodulatory effects	1. Respiratory pattern: replication in upper respiratory mucosa with dissemination to multiple organs in susceptible hosts including liver leading to multifocal necrotising hepatitis 2. Enteric pattern: bowel infection with the formation of multinucleate syncytial giant cells pathognomonic	ELISA, IFA	Self-limiting in immune competent mice; hysterectomy derivation; cessation of breeding	Air-borne, direct contact. Biological products	Chronic intestinal carriers, neurotrophic, hepatotropic and enterotrophic strains of virus, alters immune responses
Parvovirus Minute virus of mice (MVM)	Frequent	Inapparent infection, infection of neonates retards growth, diarrhoea. Neuropathogenic in suckling mice	None, mild hypoplasia of external germinal layer of cerebellum, renal infarcts. Foetal resorption Lymphocytotropism	ELISA, IFA, IB, VN	Hysterectomy derivation	Chronic carriers. Contact with infected mouse, urine, faeces	Chronic renal carriers, alters immunological responses and tumour development
Mouse parvovirus (MPV)	Frequent	Inapparent infection	Lymphocytotropism	ELISA, IFA, IB, VN	Hysterectomy derivation	Chronic carriers. Contact with infected mouse, urine, faeces	Chronic renal carriers, alters immunological responses and tumour development
Paramyxovirus Sendai (SV)	Frequent	No pathology in natural infections. Inapparent infection, ruffled fur, sometimes catarrhal bronchitis, dyspnoea, death in young mice. 129/J and DBA/2 strain more sensitive. Often complicated by secondary infections ( <i>Pasteurella</i> )	Interstitial pneumonia with necrosis followed by marked squamous metaplasia of bronchial epithelium	ELISA, IFA	Vaccination for small numbers of animals, select breeders with antibody, hysterectomy derivation	Extremely contagious. Direct contact, aerosols biological products. Cessation of breeding and no introduction of new stock may be effective in elimination	Acute self-limiting infection in immunocompetent mice, post-infection alteration of immune responses. Influence on foetal development
Pneumonia virus of mice (PVM)	Moderate	Inapparent infection	Interstitial pneumonia, mild bronchial reactions compared to Sendai virus infection	ELISA, IFA, PCR	Select breeders with antibody, improve ventilation, hysterectomy derivation	Aerosols, direct contact	Acute self-limiting infection (pneumonia) in immunocompetent mice

**Table 21.3** Continued

Name (synonyms: virus family)	Incidence	Clinical signs	Pathological lesions	Diagnosis (suitable tests methods)*	Control	Transmission of infection	Comments
Rotavirus Epizootic diarrhoea of infant mice (EDIM); mouse rotavirus enteritis	Moderate	Acute, mild to severe watery yellow diarrhoea with constipation in 7–16-day-old mice, no signs in adult mice	Colon and caecum distended, mucoid yellow or grey-green content, vacuolated epithelium, no inflammation	ELISA, IFA	Hysterectomy derivation, filter covers on cages combined with culling of infected litters	Air-borne. Cessation of breeding and no introduction of new stock may be effective in elimination	Self-limiting infection
Arenavirus Lymphocytic choriomeningitis virus* (LCMV)	Moderate	Congenital or neonatal infection: inapparent infection with late onset immune complex disease, runtng, some mortality. Infection in adult: clonic convulsion, tremors, die or recover within 3–6 days	Lymphoid infiltrate in choroid plexus, proliferation of lymphoid cells and lymphocytolysis, in spleen and lymph nodes, vacuolar degeneration of neurones. Necrosis of lymphoid and hepatic tissue	ELISA, IFA	Prevent wild mice from entering premises, select non-viraemic breeders, destroy carriers	Vertical transmission. Zoonosis	Clinical signs vary with age, genotype, viral strain and route of inoculation, lifelong viraemia in persistently infected mice, alters immunological responses. Infects endocrine glands
Herpesvirus Mouse cytomegalovirus (MCMV)	Moderate	Inapparent infection, suppression of immune system	Intranuclear inclusion in salivary gland duct epithelium and spleen, experimental disease produces a variety of lesions	ELISA, IFA	Filter covers on cages, prevent wild mice from entering premises	Close contact; may be vertical	Natural infection of laboratory mice is infrequent, virus excreted in saliva
Mouse thymic virus (MTV)	Rare	None in natural or experimental infection	Thymic necrosis if inoculated into mice less than 10 days old	ELISA, IFA	Prevent wild mice from entering premises	Chronic infection	Virus can be isolated from salivary glands and saliva of adult mice, susceptibility of inbred strains varies
Picornavirus Theiler's mouse encephalomyelitis virus (TMEV), mouse polio	Moderate	Inapparent infection, flaccid paralysis of hindlegs may occur	No macroscopic lesions, acute necrosis of ganglion cells in anterior horn	ELISA, IFA	Foster nursing, hysterectomy derivation	Faecal–oral route	Virus shed in faeces, experimental infections result in encephalitis or demyelination
Orthopox virus Ectromelia, mouse pox	Rare	Acute, inapparent infection; skin lesions on feet, tail, nose; found dead	Hepatic, splenic, lymph node, thymic necrosis, intestine engorged, dermal oedema and lymphocytic infiltrate, epidermal necrosis	ELISA, IFA	Culling and disinfection	Through skin abrasions. Biological products. Vertical transmission	Clinical signs influenced by genotype, virus resistant to many disinfectants

Hantaviruses*	Rare	Subclinical infection	Virus detectable in lung tissue	ELISA, IFA	Prevent wild mice from entering premises culling of infected animals. Hysterectomy derivation	Excreta/secretora, air-borne, biological products, zoonosis	Lifelong excretion in urine and faeces
Papovavirus K papova virus, (KPV), mouse pneumonitis virus	Rare	Inapparent infection unless inoculated into neonates, then laboured respiration and death	Consolidated lungs, thickened alveoli, endothelial cells swollen, hepatocyte vacuolation	ELISA, IFA, PCR	Hysterectomy derivation		Low incidence and low antibody titres
Polyoma virus (MPV)	Rare	Inapparent infection, experimental infection of neonates produces tumours in a variety of organs	Tumours rare in natural infection, demyelination reported in nude mice	ELISA, HAR, IFA	Hysterectomy derivation, prevent wild mice from entering premises	Urine, faeces, saliva	Virus shed in urine, saliva, faeces
Lactate dehydrogenase elevating virus (LDV)	Rare	Inapparent infection, paralysis of immunosuppressed C58 or AKR mice	Elevation of serum LDH, neuronal degeneration with mononuclear infiltrate in AKR, C58 mice	LDH plasma test, PCR	Eliminate infected animals. Pass tumours in another rodent species	Mouse biological products most likely source	Lifetime high-titre viraemia, not readily transmitted by natural means, alters immunological responses of infected mice, associated with transplantable tumours and mixed cell lines
Adenovirus Mouse adenovirus, (MadV): MAAd-1, MAAd-2	Rare	Inapparent infection. In infant and athymic mice fatal wasting disease	MAAd-1: necrosis brown fat, myocarditis, adrenocortical changes, intranuclear inclusions in kidney tubulus MAAd-2: enterotropic infection with inclusion bodies in enterocytes	ELISA, IFA	Hysterectomy derivation, improve sanitation procedures	MAAd-1: urine MAAd-2: faecal-oral route	Antibody present in 15–45% of older mice in an infected colony, transmits readily between cage mates (via urine?), less transmission between cages
Reovirus Reovirus 3 (Reo 3)	Rare	Often subclinical. Experimental infection leads to encephalitis, pulmonary oedema, emaciation, oil-matted hair, steatorrhoea, runting in suckling mice, jaundice	Necrosis in liver, exocrine pancreas, salivary gland, heart and brain, pancreas	ELISA, IFA, HAR, VN	Hysterectomy derivation	Faecal-oral route	Influences DNA replication, monoclonal antibody production. Clinical signs rarely reported

\*also zoonotic disease

**Table 21.4** Bacterial and other diseases of laboratory mice (Cunliffe-Beamer & Les 1987; O'Brien & Holmer 1993; Boot et al. 2001; FELASA 2002; Fox et al. 2002) (ELISA, enzyme-linked immunosorbent assay; IFA, indirect immunofluorescence assay; MA, microagglutination; PCR, polymerase chain reaction).

Genus and species	Incidence	Clinical signs	Pathological lesions	Diagnosis	Control	Comments
<b>BACTERIA</b> <i>Pasteurella pneumotropica</i>	Frequent	Inapparent infection, abscesses, pyometra, pneumonia, conjunctivitis	Abscesses	ELISA, IFA, MA. Isolate organism from upper respiratory tract, vagina or lesions	Culling of animals. Hysterectomy derivation	Viable foetuses may be derived from infected uteri
<i>Staphylococcus aureus</i>	Frequent	Inapparent infection, dermatitis, abscesses head/neck, conjunctivitis	Acute ulcerative dermatitis	Isolate organism from lesions	Eliminate affected mice, improve sanitation, monitor personnel. Hysterectomy derivation	Athymic mice especially susceptible
<i>Citrobacter rodentium</i> (freundii 4280)	Moderate	Transmissible colon hyperplasia. Soft faeces, ruffled fur, occasional rectal prolapse	Mucosal hyperplasia in descending colon ('pipe-like colon')	PCR. Isolate organism from faeces, pathognomonic lesion	Eliminate sick animals. Filter-top cages. Neomycin sulphate (2 mg/ml) or tetracycline (0.5–1 mg/ml). Temporary cessation of breeding	Not all <i>C. freundii</i> isolates are pathogenic
<i>Clostridium piliforme</i> (Tyzzer's disease)	Moderate	Inapparent infection, sudden death	Focal necrosis of liver, hyperaemic large intestine	ELISA, IFA. Identify organisms in liver or intestinal mucosa (special stains required), serological tests	Hysterectomy derivation. Sterilisation of rooms, materials	Activated by immunosuppression. Resistant to desinfectants
<i>Mycoplasma pulmonis</i>	Moderate	Inapparent infection, chattering, dyspnoea, ruffled coat, rhinitis, bronchopneumonia, otitis, reproductive failure	Suppurative rhinitis, chronic bronchopneumonia with syncytial giant cells	ELISA, PCR. Isolate organism from upper respiratory or genital tracts, serological tests	Hysterectomy derivation, tetracycline suppresses clinical signs	Can be isolated from uterus with viable foetuses. Synergistic effect with other infections
<i>Pseudomonas aeruginosa</i>	Moderate	Inapparent infection, mice found dead, occasional otitis media	Multiple areas of necrosis and haemorrhage	Isolate organism from intestinal tract or lesions	Acidification or chlorination of water	Activated by stress or immunosuppression
<i>Corynebacterium kutscheri</i>	Rare	Murine pseudotuberculosis. Inapparent infection, abscesses in liver, lung, kidney	Septic emboli and abscesses in many organ, pneumonia	Isolate organism from lung, liver or spleen	Hysterectomy derivation	Activated by stress or immunosuppression
<i>Corynebacterium bovis</i>	Rare	Scaly skin disease in nude mice, mortality in newborns	Skin lesions	Isolate organism from skin and mouth of nudes	Hysterectomy derivation	Activated by stress or immunosuppression
<i>Klebsiella pneumoniae</i>	Rare	Rough fur, hunched posture, anorexia, dyspnoea. Opportunistic pathogen	Pneumonia, empyema, abscesses	ELISA, IFA. Isolate organism from lung or abscesses	Hysterectomy derivation. Antibiotics only in single cases	Can be part of normal intestinal flora
<i>Salmonella enteritidis</i> *	Rare	Inapparent infection, septicaemia, anorexia, lethargy, weight loss, soft faeces	Acute: hyperaemic viscera, catarrhal enteritis. Subacute: hyperaemic intestinal mucosa, necrotic foci in liver and spleen, lymph nodes enlarged	Isolate organism from intestinal tract, liver, spleen, lymph nodes	Hysterectomy derivation, repeated faecal cultures and elimination of state carriers, such as wild rodents	Antibiotics do not eliminate carrier

<i>Salmonella typhimurium</i> *	Rare	Septicaemia with focal necrosis in spleen, liver and lymph nodes, chronic infection causes arthritis	ELISA, IFA, PCR. Isolate organism from joint fluid	Exclusion of wild rodents or carrier animals	Spontaneous disease rare in mice, inapparent infection in rat. Disabling – lethal infection
<i>Streptobacillus moniliformis</i> *	Rare	Sudden death, acute sepsis, polyarthritis, paralysis, stillbirth, abortion, abscess, keratoconjunctivitis, chronic skin ulceration	ELISA, IFA, PCR	Quarantine diseased animals	Insufficient information on importance of infection
CAR bacillus (cilia-associated respiratory bacillus)	Rare	Chronic respiratory disease, loss of body weight	PCR. Isolate organism from bile canaliculi	Hysterectomy derivation, antibiotics intensively (Fox et al. 2002)	Chronic inflammation liver and/or gastrointestinal tract. Elevated liver enzymes
<i>Helicobacter</i> sp.		Chronic hepatitis, gastritis	Isolate organism from lesions	Kill infected mice. Hysterectomy derivation	Transmission of infection via faeces
<i>Streptococcus</i> sp. α-haemolytic β-haemolytic		Respiratory infection, haemorrhagic discharge from body orifices, especially in immunodeficient mice			
CHLAMYDIA <i>Chlamydia trachomatis</i>		Rough fur, dyspnoea, cyanosis, chattering	Elementary bodies in macrophages or bronchial epithelium (special stains required)	Hysterectomy derivation	Not reported since 1950s
MYCOTIC DISEASES <i>Pneumocystis carinii</i>		Pneumonia in immunodeficient mice	ELISA, PCR, silver staining lung	Hysterectomy derivation	Mainly in immunodeficient mice
DERMATOPHYTES <i>Microsporium gypseum</i> *		Inapparent infection	Isolate fungi from hair and skin cultures, microscopic examination of hairs for hyphae and spores	Difficult, kill infected mice	Rare in mice
<i>Trichophyton</i> spp.*		Inapparent infection, sparse hair coat	Isolate fungi from hair and skin cultures, microscopic examination of hairs for hyphae and spores	Difficult, kill infected mice	Rare in mice
RICKETTSIA <i>Eperythrozoon coccoides</i>		Inapparent infection, anaemia	Ring-shaped organisms attached to red blood cells	Eliminate lice, hysterectomy derivation, tetracycline	Splenectomy activates inapparent infections, potentiates certain viral infections, antagonises experimental plasmodium infections

\* also zoonotic disease

**Table 21.5** Parasitic infections of mice (Cunliffe-Beamer & Les 1987; O'Brien & Holmer 1993; Boot *et al.* 2001; FELASA; 2002; Fox *et al.* 2002).

Common name	Genus and species	Incidence	Clinical signs	Diagnosis and control	Potential effects on research results
Lice	<i>Polyplax serrata</i>	Rare	Pruritis, anaemia	Identify the parasite in hair samples	Transmits <i>Eperythrozoon coccoides</i>
Mites	<i>Myobia musculi</i>	Frequent	Inapparent infection; pruritis; alopecia; dermatitis	The most efficient treatment is ivermectin spray solution (ivermectin 1% diluted 1:100 with a mixture of propylene glycol and water 1:1)	Serum protein alterations, elevated serum IgE
	<i>Myocoptes musculus</i>	Frequent	Inapparent infection; pruritis; alopecia; dermatitis		
	<i>Radfordia affinis</i>	Rare	Inapparent infection; pruritis; alopecia; dermatitis		
	<i>Ornithonyssus bacoti</i> *		Anaemia		
Nematodes (pinworm)	<i>Aspicularis tetraoptera</i>	Frequent	Inapparent infection (reduced growth rate?)	Seen with naked eye in gut, particularly caecum	Perturbation of host immune system
	<i>Syphacia obvelata</i>	Moderate	Inapparent infection (reduced growth rate)	Sticky tape test on perineum to see banana-shaped eggs of <i>Syphacia</i> sp. Fenbendazole 50ppm in feed to control	Perturbation of host immune system. May influence intestinal physiology
	<i>Syphacia muris</i>	Moderate	Sometimes enteritis	Ivermectin treatment, 2 mg/kg per os twice at 10-day intervals	Perturbation of host immune system
Protozoa	<i>Giardia muris</i>	Moderate	Inapparent infection → enteritis, weight loss, abdominal distention may occur	See organism on wet mount of faecal material or H&E section; Trophozoites in intestinal tract. 0.1% dimetridazole in drinking water for 14 days may control clinical disease; sanitation, disinfection	
	<i>Spiroucleus muris</i>	Moderate	Inapparent infection. Diarrhoea; weight loss; occasional mortality seen in young post-weanling mice		Alter macrophage and other immunological responses
	<i>Tritrichomonas</i> spp.	Frequent	Inapparent infection; no known pathological significance	Commensal organism, no treatment warranted	None known
Cestodes (tapeworms)	<i>Hymenolepis nana</i> *	Moderate	Inapparent infection → local enteritis	Diagnosis by observation of parasite in gut. Praziquantel (0.05% in diet for 5 days)	
	<i>Taenia taeniaeformis</i> ( <i>Cysticercus fasciolaris</i> )	Rare	Asymptomatic (rodents are intermediate host)	Observation of cysts in liver on <i>post-mortem</i>	

\* zoonotic disease

## The laboratory rat

Jaap M. Koolhaas

### Biological overview

#### General biology

The laboratory rat is the domesticated form of the species *Rattus norvegicus* or brown Norway rat. Although the genus *Rattus* contains 66 species, the most commonly known other rattus species is *Rattus rattus* or black rat. The genus belongs to the family of the Muridea and the order of Rodentia. The two species differ considerably in their habitats, behaviour and ecology. The wild *Rattus norvegicus* has agouti-coloured fur, meaning that it has the agouti gene which produces hairs with colour bands varying between brown-black and red-yellow. *Rattus rattus* may have a more variable coat colour, but is mainly dark brown or black. The most conspicuous difference between the two species concerns the relatively large, mouse-like ears of *R. rattus*. The two species share more or less the same habitat, but *R. norvegicus* lives mainly in burrow systems at ground level, whereas *R. rattus* tend to occupy higher areas in trees and roofs.

Whereas most species of *Rattus* are indigenous in subtropical and tropical areas, both *R. norvegicus* and *R. rattus* are cosmopolitan and can be found on all continents. The Norway rat has a rather interesting recent evolutionary history. The species seems to have originated in central Asia, and has spread over almost all of the world during the last two or three centuries (Hedrich 2000). This spread was strongly facilitated by the increase in long-distance trading in the early eighteenth century. Early *R. norvegicus* colonies were established by Russian ships and wrecks in the Baltic region; meanwhile, they dispersed overland, reaching Paris by about 1750 and Switzerland by 1809. *R. norvegicus* reached Greenland about 1780, the eastern part of the United States in 1775 and the Pacific coast in 1851. In all of these areas they rapidly displaced *R. rattus*, and often became a major pest.

The Norway rat is a generalist which is able to survive in a wide variety of habitats and climatic conditions. The species greatly benefits from the presence of human beings and may live in buildings, harvest stores, sewer systems and on rubbish dumps. In nature, however, it prefers to live in burrow systems usually located near water. The burrow system occupies 2–4 m<sup>2</sup> and consists of tunnels 5–7 cm in diameter and 0.25–1.5 m long (Pisano & Storer 1948). The tunnels usually end in small chambers used for nesting and

storage of food. The area around the burrow system can be considered as the territory and will be defended against unfamiliar conspecifics. However, the home range of the animals (ie, the range in which they search for food) may be about 100 m<sup>2</sup>. The rat is a nocturnal animal and generally has three activity periods, one at the beginning, one in the middle and one at the end of the night. It feeds during these activity periods taking three to five separate meals. The worldwide success of the Norway rat is partially due to the fact that the species is omnivorous, having a remarkable capacity to balance its nutrient intake in a broad range of dietary conditions.

The senses of smell, hearing and touch are highly developed. Behaviour is strongly determined by olfactory signals. In a social setting, male rats are able to recognise social status of other males, reproductive status of females and kinship solely on the basis of olfactory cues (Beynon & Hurst 2004). Moreover, rats are very sensitive to olfactory signals from predators such as cats and alarm pheromones from other rats (Dielenberg & McGregor 2001). Rats emit a large repertoire of ultrasonic vocalisations: 22 kHz sounds occur in aversive stressful situations; pups emit 40 kHz sounds when left alone by the nursing mother and have a clear function in eliciting pup retrieval by the mother. Recent evidence suggests that the 50 kHz sound, in particular the frequency modulated form, reflects a state of positive affect (a positive emotional state), since it is emitted by adults during sexual and aggressive behaviour and in response to rewarding conditions (Panksepp 2007; Portfors 2007), although see also Chapter 6, Vocalisations. Although the function of these vocalisations is still not fully clear, the rat can hear frequencies up to 80 kHz. Tactile receptors are particularly well developed on the head, around the whiskers, on the paws and on the tail. Studies indicate that the rat whisker system has a sensitivity of less than 90 µm, which is comparable to that of primate fingertips (Carvell & Simons 1990).

Rats have dichromatic colour vision. One type of cone in the retina has a photo pigment with a maximal sensitivity at a wavelength of 510 nm (green) (Neitz & Jacobs 1986), which declines rapidly at wavelengths above 560 nm (red-infrared). A second type of cone has its maximal sensitivity in the near ultraviolet range (360 nm) (Jacobs *et al.* 1991). Visual acuity is generally low, albino strains being more variable and often lower in visual acuity than pigmented strains (Prusky *et al.* 2002).

## Size range and lifespan

The size of a rat is usually expressed in terms of body weight. Growth rate depends not only on strain, but also on quality and availability of food, as well as environmental factors such as temperature and social situation. Male laboratory rats are particularly prone to develop obesity and may reach a weight of about 800 g.

Size can also be determined using morphological parameters such as body and tail length. Body length is measured from the tip of the nose to the middle of the anus and tail length from the middle of the anus to the tip of the tail. Although the body length to tail length ratio is rather constant in adult rats, the absolute values, particularly the length of the tail, may be influenced by the environmental temperature during rearing.

The maximum lifespan of wild rats kept in a semi-natural enclosure is about 600 days for males and 700 days for females, whereas the median lifespan (50% survival) is 300 days for males and 550 days for females (Calhoun 1962). Notice that the maximum and median lifespan are different measures of longevity, which cannot be compared directly. In laboratory strains longevity may vary considerably depending on the strain and diet. The maximum lifespan of the Wistar strain, for example, is about 1200 days (3.2 years) for males and 1400 days (3.8 years) for females. Median lifespan for the Wistar rat is 850 days for males and 900 days for females (Ghirardi *et al.* 1995).

## Social organisation

The fact that the Norway rat is a social species by nature has often been under-emphasised, if not ignored, in the design and interpretation of laboratory experiments. Although much remains unknown about the rat's social system, it is clear that the species is gregarious and that social hierarchies easily develop in groups of rats. Generally, in groups of wild rats, one dominant male can be distinguished which lives together with a number of females and often younger males. In this latter group of males, two social layers may be distinguished: a group of socially active subdominant males and subordinate males. Dominant males that are replaced by a former subdominant male tend to be relegated to the position of a social outcast, being chased by most of the other colony members and having a peripheral existence at the outskirts of the colony. The group size of populations of feral rats may vary considerably, depending on environmental conditions such as food availability and nesting conditions. However, in larger colonies, smaller subgroups will emerge, which usually consist of family members (Calhoun 1962).

## Reproduction

The rat has an exceptionally high reproductive capacity. Both males and females are, on average, sexually mature at the age of 2–3 months. The oestrous cycle is 4–5 days. At the time of oestrus, receptivity occurs in the second half of the dark period (Barbacka-Surowiak *et al.* 2003). In the wild, a

receptive female will be followed and mounted by the dominant male and often by a number of other male colony members as well (McClintock & Adler 1978). After several successful copulations, the female's willingness starts to decline; this is indicated by aggressive actions and escape behaviour by the female. Gestation is 20–21 days, and during the few days prior to delivery of the pups, the pregnant female starts to build a nest and will defend her nest against both male and female colony members. This maternal aggression will continue throughout the first week of nursing, after which it gradually declines and another reproductive cycle may start (Rosenblatt *et al.* 1994). In temperate regions, wild rats have a clear seasonal variation in reproduction governed by day length and food availability. Some studies of laboratory rats indicate the presence of an intrinsic annual cycle (Claassen 1994; De Boer *et al.* 2003). The average litter size is approximately 10 and in the wild, sex ratio depends on season, population density and food availability (Bacon & McClintock 1994; Parshad 1997).

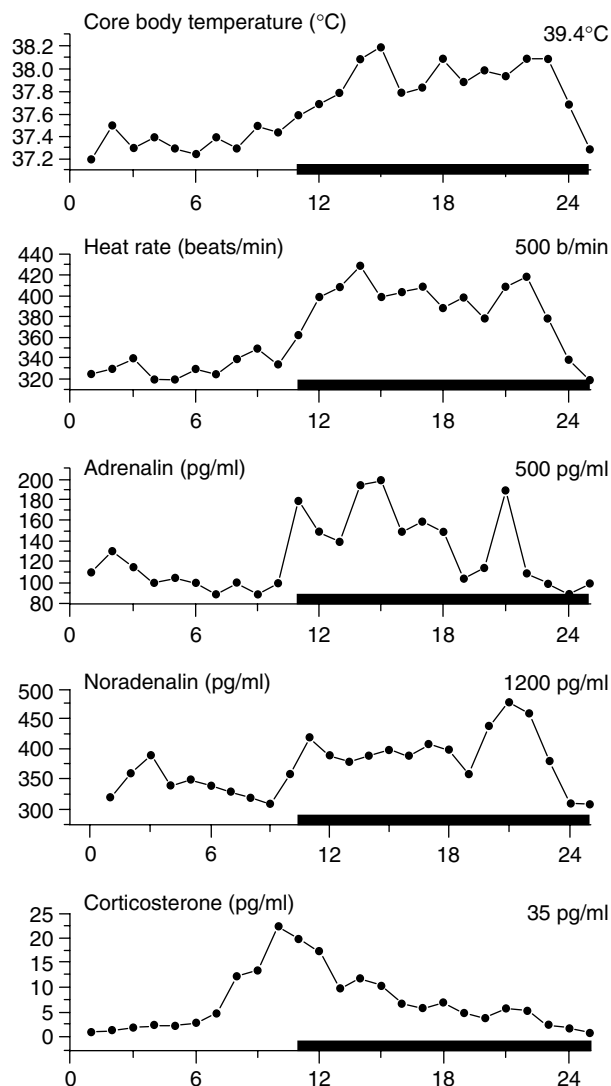

## Standard biological data

Some of the basic physiological and morphological data of the Wistar rat are presented in Table 22.1, but see Krinke *et al.* (2000) for more extensive information. These data should, however, be used with some caution, as many of the parameters are not static but highly dynamic in time, varying both diurnally and throughout life. Moreover, there are significant strain differences, and within strains there may be differences between suppliers, in particular where outbred or random-bred strains are concerned.

Most physiological parameters show a strong circadian variation and are highly responsive to environmental stressors. Figure 22.1 shows the circadian variation in some neuroendocrine and physiological parameters measured in 4-month-old male Wistar rats, measured using stress-free

**Table 22.1** Basic biological data of Wistar rats.

Parameter	Normal value
Chromosome number	42
Lifespan (years)	2–4
Body weight at birth (g)	4.5–6
Daily food intake (g/100 g BW)	10
Daily water intake (ml/100 g BW)	10–15
Defecation (g/24 h)	9–13
Urine production (ml/24 h)	10–15
Weight of organs (in % BW)	
Adrenal (single)	0.02
Blood	5–7
Brain	1
Heart	0.5
Kidney (single)	0.5
Liver	3
Lung	1
Ovary (single)	0.05
Spleen	0.2
Testis (single)	0.5
Thymus	0.07
Thyroid	0.005

**Figure 22.1** Circadian variation in plasma corticosterone, noradrenalin and adrenalin levels, heart rate and core body temperature in adult male Wistar rats. The black bar indicates the dark period of the light-dark cycle. The data on the right-hand side of each graph indicate the maximum response levels obtained during 15 minutes restraint stress (unpublished data from the author).

methods (permanent jugular vein cannulation, radiotelemetry). The figure in the right-hand part of each graph shows the maximum value of these parameters obtained during 15 minutes' restraint (data collected by the author).

### Breeds, strains and genetics

Most of the laboratory rat strains are albino or derived from an albino form. Although the precise origin of the albino rat is unknown, it is very likely that the first laboratory albinos came from collections kept for breeding and show purposes. The use of rats for research in the laboratory started at the end of the nineteenth century, by a number of French and English scientists. More systematic breeding started in the early twentieth century in the United States by King and

**Figure 22.2** Frequency distribution of the individual levels of aggressive behaviour in the Wistar rat (Harlan) and the wild-type Groningen rat.

Donaldson at the Wistar Institute. They extensively compared up to 25 generations of laboratory-bred wild rats with the same generations of albino rats. The initial differences were considerable. More recent studies confirm the general idea that laboratory strains of rats must be considered as a very special selection from the original wild species *Rattus norvegicus* (De Boer *et al.* 2003). Figure 22.2 shows the frequency distribution of the individual level of aggressive behaviour in a population of Wistar rats and a population of a laboratory-bred wild-type rats (De Boer *et al.* 2003). Compared to this semi-wild population, even the use of the outbred Wistar strain shows a strong selection bias. Currently, more than 400 inbred strains are available and about 50 outbred or random-bred strains. A list of available inbred strains is presented in the International Index of Laboratory Animals (Festing 1993), and a more recent overview can be found at the MGI website<sup>1</sup>. A more extensive description of the origin and stockholders of these strains is given by Hedrich (1990). Provided a constant monitoring of the genetic stability of an inbred strain is carried out, they have the advantage that they remain genetically stable over a long period of time. However, it is important to be aware that the use of inbred strains depends on the nature of the experiments. The main disadvantage of inbred strains is that each of them represents a very narrow selection of the wide and functional genetic variation observed in a wild population. Consequently, one may question the general validity

<sup>1</sup><http://www.informatics.jax.org/external/festing/rat/STRAINS.shtml>

of the results. Therefore, if the results of the experiments are to be extrapolated to the human population, as for example in toxicity testing, the use of at least two inbred strains is often preferable (see Chapters 3 and 4). An analysis, using DNA markers, of the genetic relationships or genetic distance between 60 inbred rat strains has been published by Otsen *et al.* (1995).

The disadvantage of outbred strains is that each breeding colony may be different due to genetic drift. Hence, a Wistar or Sprague-Dawley rat from one breeder may be genotypically and phenotypically different from those obtained from a different source. Considerable differences in neuroanatomy, behaviour and pharmacology have been reported, for example, in Sprague-Dawley rats obtained from different commercial breeders (Rex *et al.* 2007).

Examples of frequently used strains:

- Wistar albino. This strain was developed at the Wistar Institute in 1906. The animals are easy to handle and male aggressive behaviour develops relatively late. It is an outbred or random-bred strain and a large number of varieties exist worldwide.
- Sprague-Dawley albino. This strain originates from R.W. Dawley from Wisconsin in 1925. Originally female Wistar rats were crossed with males from an unknown origin. The animals are gentle and may grow to a large size. This random- or outbred strain may vary considerably across breeders.
- Long-Evans hooded. This strain was originally developed at Berkeley, California in 1910 by crossing Wistar females with wild male rats. The head and extremities are black, and the rest of the body is white. It has pigmented eyes, and, although this strain can be easily handled, the level of aggressive behaviour is generally high.

Apart from the traditional inbred and outbred strains, a wide variety of genetic selection lines are available. These lines are genetically selected for the presence or absence of certain behavioural or physiological characteristics. For example, the Roman High Avoidance (RHA) and the Roman Low Avoidance (RLA) lines are selected for their behavioural performance in an active shock avoidance paradigm, using the Roman Wistar as the parental population. The Kyoto Wistar was used to select the Spontaneous Hypertensive Rat (SHR) line, using high sympathetic reactivity as a selection criterion. Most of these genetic selection lines are not commercially available, and can only be obtained via the specific research institutes that breed and select these lines.

## Genomics

The analysis of the full rat genome is an important recent development. This project was a joint effort by 13 research institutes, coordinated by the American National Institute of Health to produce the Rat Genome Database<sup>2</sup>. Recently, a genome wide analysis of single nucleotide polymorphisms

(SNPs) has also become available for 35 different rat strains including wild rats (Nijman *et al.* 2008).

## Laboratory management and breeding.

### General husbandry

#### Housing

In the past, laboratory rats have been housed under a wide variety of conditions and in cages of all sorts of materials. Most countries have formal rules and guidelines for accommodation and care of laboratory animals, for example: the European *Directive for the Protection of Animals used for Experimental and Scientific Purposes 1986*, for which the guidelines were recently updated (European Commission 2007), or the American *Guide for the Care and Use of Laboratory Animals* (National Research Council 1996). These guidelines specify floor area required per animal in relation to weight and number of cage mates, and the minimum cage height. Although these guidelines may differ between countries, they have led to a considerable degree of standardisation of housing conditions and improvement of welfare. However, it is difficult to scientifically specify the minimum sizes of pens and cages for maintaining laboratory rats as much depends on the strain, group size and age of the animals, their familiarity with each other and their reproductive status. For example, increasing the available floor area per animal does not necessarily improve housing conditions, because in some more socially active strains, well defined dominance relationships may develop. This in turn may lead to a larger variation between individuals and even the development of stress pathologies (Tamashiro *et al.* 2005).

In view of the importance of play in the development of adult social behaviour and adaptive capacity it is recommended that animals are provided with sufficient space during the first 3–4 weeks after weaning, with a maximum of seven or eight animals on a floor space of about 0.2m<sup>2</sup> (Yildiz *et al.* 2007). For most strains, this density will be adequate until the animals reach a body weight of around 300g. As the animals grow older and become larger, the number of animals may be reduced to three per 0.2m<sup>2</sup> cage. There is general agreement on stocking densities in the various European, American and Australian regulations and codes of practice. When changing to a different housing system or different rat strains, it is generally recommended that all animals are carefully monitored in terms of their behaviour, breeding performance and general condition.

Most modern cages have their walls and floor made from solid macrolon with a stainless steel mesh lid. These cages are available in different sizes and are relatively cheap and easy to clean. Although stainless steel cages with a wire mesh floor may be easier to clean, the rats have no opportunity for behavioural thermoregulation; consequently, they should only be used when temperature, humidity and ventilation (draught) are well controlled. Indeed, when given a choice, rats prefer solid floors for resting (Manser *et al.* 1995). Within the ambient temperature range of 20–28°C no thermoregulatory differences have been observed between animals housed on acrylic floors or metal floors. Below this range, however, animals housed on metal floors show a

<sup>2</sup><http://www.nih.gov/science/models/rat/>

significant increase in metabolism, whereas above 28°C animals housed on acrylic floors have problems controlling their body temperature (Gordon & Fogelson 1994).

### Environmental provisions

In general, cages should be provided with adequate bedding material. The main function of bedding is to absorb urine and faeces. However, bedding material seems to be essential for certain biological needs as well. It provides insulation and with some materials the opportunity for nest building. Therefore, using appropriate bedding material may be an easy way to improve the well-being of laboratory rats. A variety of bedding materials is commercially available, ranging from wood chips, wood shavings and sawdust to absorbent paper. Experiments using preference tests have shown that male rats generally prefer bedding which consists of large fibrous particles (Blom *et al.* 1996). This preference may be due to several factors. Experimental evidence suggests that rats prefer bedding material which they can manipulate. Certain types of bedding material should be avoided if they contain irritating dust, or produce high levels of ultrasound in a frequency range for which rats are extremely sensitive when the animal moves (Blom *et al.* 1996).

Certain experimental conditions preclude the use of bedding material, for example in experiments where diet is critical and where the ingestion of bedding could affect the experimental results. In these conditions, it may be necessary to use a wire mesh floor and carefully controlled environmental conditions.

Several studies show that environmental enrichment may be another important provision for the animals. Animals raised from weaning in an environment enriched with objects such as ladders, balls, tubes and boxes are better in several learning tasks, are less defensive, show more exploration, and have a thicker cerebral cortex and a higher synaptic density than rats raised under standard conditions (Smith & Corrow 2005). Although environmental enrichment is generally considered to improve animal welfare and is advised in most of the codes of practice, the scientific evidence in support of this conclusion is still rather limited, and the value very much depends on the enrichment used (see reviews by Benefiel *et al.* (2005), Gonder and Laber (2007) and Chapter 10 this volume). Moreover, it may have unexpected and unintended consequences as well. Minor changes in the cage may alter the animal's behaviour and physiology considerably and often in an unexpected direction. In view of the wide range of supplies available for enrichment, and hence the lack of standardisation, this will reduce the reproducibility of experimental data (Bayne 2005; Benefiel *et al.* 2005). The bottom line is that environmental conditions and provisions are reflected in the physiology, neurobiology and behaviour of the animal. More fundamental research is required to determine whether, and in which direction, this altered state affects the capacity of the animal to cope with the laboratory environment and the conditions of animal experimentation.

### Social grouping

Rats are social animals by nature, and an extensive literature shows that they are very sensitive to social isolation (Hall

1998). Although isolation at any age can have permanent effects on behaviour and physiology, some periods seem to exist throughout which rats are particularly vulnerable to social isolation. In particular, pre-weaning maternal separation and handling affects a wide variety of adult behavioural and neurobiological processes. Another sensitive period is the one when juveniles spend much time playing, particularly post-natal weeks 5 and 6. Even brief social isolation during these 2 weeks has a significant effect on subsequent adult social behaviour and stress reactivity (Gutman & Nemeroff 2002). In adulthood, long-term social isolation is well known to induce a number of behavioural disturbances such as increased locomotor activity, learning deficits, anxiety and aggression (Arakawa 2005; Malkesman *et al.* 2006). Some experiments have indicated that isolation at adulthood may induce a state of anxiety or depression which is presumably due to changes in central serotonergic neurotransmission, and which are difficult to restore with resocialisation (Maisonnette *et al.* 1993; Silva *et al.* 2003). Although these data indicate that the social environment has a strong and often lasting impact on behaviour and physiology, the consequences for animal welfare are not always clear and have not been studied very well (Krohn *et al.* 2006). Great care should be taken in standardising the social environment and, wherever possible, rats should be housed in a social group to ensure that they are normal both behaviourally and physiologically. In the author's experience, a reliable standardised method of avoiding the effects of social isolation, without encountering problems with dominance relationships, is to house individual male rats with a female sterilised by ligation of her fallopian ducts.

In the breeding colony, rats are usually housed in all male and all female groups. These groups should be of a standard size and composed of littermates. Mixing litters may affect the social relations between group members and may induce social stress. Mixing groups of adult male rats should be avoided, as it can result in serious dominance fights, and consequently in injury and social stress. In some experiments, regular mixing of social groups has been used as a procedure to study the adverse effects of social stress (Mormede 1997).

### Presentation of food and water

Food is generally presented in food trays forming part of the lid of the cage and standard procedure is to provide food *ad libitum*. However, a large number of experiments show that longevity is increased when food availability and/or caloric intake is restricted (for a recent review see Goto *et al.* 2007). In a well controlled study, Roe *et al.* (1995) found that a restriction of food intake to 80% of the *ad libitum* intake increased the 30 months survival from 42% to 68%. Moreover, under such food restriction regimes, the incidence of neoplasms is significantly reduced, in particular in the aging animal. This suggests that welfare may be improved with a restricted diet if the animal is to be kept into its old age.

Water should always be given *ad libitum*. However, in a recent review, Rowland (2007) argued that 12–24 h of water deprivation falls well within the regulatory range of physiological and behavioural adaptive mechanisms of the rat. The behavioural and physiological adjustments to these

periods of water deprivation seem to minimise the additional physiological and psychological stress of deprivation. Water is usually given in containers with a stainless steel nipple. This allows the water intake in individual cages to be monitored and controlled. Several sizes of water bottles for rats are available commercially. In large animal facilities, automatic watering systems may be used. However, these systems must be checked regularly to ensure that the water valves are functioning properly to avoid the possibility of the animals becoming dehydrated or the cage flooding.

### Identification and sexing

Many experimental procedures require individual marking of animals for which several methods can be used. Due consideration should be given to using the least invasive method that is compatible with the study. The easiest way is to write a number at the base of the tail with a permanent marker. However, as a result of tail skin growth and renewal, these marks have to be renewed every 2 weeks. This is also the case with coloured dyes applied to the fur. Tattooing numbers or codes on the tail ears or toes is a more permanent way of marking. Another method of individual marking is to use an ear notch or ear-punch code, or to use numbered metal ear tags. However, because of the important role of auditory information in the social communication of rats, and because ears can be damaged by fighting, and the markings obliterated, these methods are often unsuitable. Rats can also be identified by means of injectable microchips or transponders. These chips are commercially available and sufficiently miniaturised. Each chip is provided with a unique code, and in some systems an additional code for the experiment can be added. The chip can be read without handling the animal using a portable reader provided with a display. Data from the reader can also be downloaded on to a computer. These electronic identification systems are reliable, and further developments are to be expected. For example some systems include the facility to measure body temperature or heart rate in association with the individual code of the animal.

The sexes can readily be distinguished on the basis of the anogenital distance (Figure 22.3). In males, the distance

between the urethra and the anus is greater than in females. Moreover, males can be distinguished by the wrinkled, sparsely haired scrotum at the root of the tail. In a cool environment, the testes may be retracted. The vagina of the female is an orifice at some distance caudal to the urethra.

### Physical environment and hygiene

Rats are normally housed in well ventilated rooms in which temperature, light and humidity are controlled. They can be bred and maintained in a wide range of environmental temperatures, provided that a sufficient degree of behavioural thermoregulation such as nest building is possible (Gordon 1990). Most codes of practice specify a room temperature of 20–22°C mainly for the purpose of standardising laboratory experiments. Temperature should be measured in the cage because this may deviate strongly from room temperature, depending on the ventilation, the density of animals per cage and the location of the cage with respect to the heating system of the room. When rats are kept in wire mesh cages, the environmental temperature should not drop below 22°C, and there should be no draughts.

The animal room should be well ventilated without creating draughts. It is difficult to give a standard recommendation on the number of air changes per hour, as it depends on: the number of animals kept in the room, their size, the humidity of the air and the cage cleaning routine. However, a few general guidelines can be provided. The main purpose of ventilation is to provide the animals with air of good quality. Apart from the obvious requirements of sufficient oxygen and low levels of carbon dioxide, the concentration of ammonia should be kept as low as possible. Ammonia is a breakdown product of urea and is harmful to the animals because it may facilitate bacterial infections of *Mycoplasma pulmonis* in the mucous membranes of the eyes, nose and the respiratory tract (Schoeb *et al.* 1982). As long as the bedding remains dry, ammonia will not be formed. This, in turn, depends on the number of animals per cage, the humidity, the ventilation and the frequency of cleaning. A smell of ammonia in the animal room, however, is a good indication that the animals are overcrowded or the cages need clean-

**Figure 22.3** Sexing newborn rats (male on left, female on right). Note the greater distance between urethra (1) and anus (2) in the male.

ing. Humidity should be around 50%. When it drops below 30%, young animals tend to develop ring tail (Njaa *et al.* 1957). Cages should not be cleaned more often than once a week, because cleaning in itself is a considerable stressor and may disrupt the social structure in the cage. However, any increase in ventilation should not result in draught. On average 8–20 air changes per hour should suffice for a normally populated animal room (Clough 1984).

The use of individually ventilated cages (IVC) is increasingly common. A wide variety of systems is commercially available. Ventilated caging strongly improves the working conditions of animal care staff in terms of exposure to allergens. However, few studies have addressed the question of rat welfare in these housing systems. Depending on the system, ventilation rate may range between 40 and 50 air changes per hour, but 120 air changes per hour can also be found. In a study on the impact of cage ventilation on rats, Krohn *et al.* (2003) concluded that the number of air changes should be kept below 80 changes per hour according to preference tests and telemetric measurements of heart rate and blood pressure. It is not clear why the ventilation rate of IVC systems differ so strongly from the recommended ventilation rate of animal rooms. Most likely, this discrepancy is due to the fact that the ventilation rate of small cages is technically easier to increase than that of a whole animal room. Nevertheless, from a biological point of view, the currently used ventilation rates of individual ventilated cages might be considered as a rather artificial laboratory condition, since feral rats live in burrow systems with hardly any ventilation in the nesting chambers.

Rats are generally kept in light-controlled rooms with a photoperiod of 12h light and 12h dark. Different photoperiods such as 16h light and 8h dark are sometimes to improve for example breeding results. However, it is important to realise that the photoperiod may strongly affect experimental results (Prendergast *et al.* 2007; Prendergast & Kay 2008).

Rats are extremely sensitive to light, in particular albino strains. Retinal damage in albino rats due to light exposure is frequently reported (Perez & Perentes 1994). On the basis of the analysis of retinal damage it is recommended that the light intensity as measured at the level of the bedding of the cage should not exceed 50lux (Perez & Perentes 1994; Semple-Rowland & Dawson 1987). However, when behavioural measures are also considered, such as activity and light avoidance, welfare of the animal seems to be optimised at levels below 25lux. As a result of their sensitivity to light, rats may differ in the degree of retinal damage depending on the distance between the cage and the light source. A more uniform light intensity may be obtained by putting shelves at some distance above the cages.

### Health monitoring, quarantine and barrier systems

Infections of laboratory animals can severely influence the outcome of experiments. Therefore, a health monitoring programme is essential to ensure reliability and reproducibility of research data. The Federation of European Laboratory Animal Science Associations (FELASA) advises that breed-

ing units of laboratory rats should be screened every 3 months with respect to serology, bacteriology, parasitology and pathology with a sample size of at least four animals (FELASA 1994). Table 22.2 summarises the recommended viral, bacterial and parasitic infections to be monitored. It is recommended that positive serological results should be confirmed using another method or a repeated investigation. Bacterial and fungal infections should be investigated in samples from nasal turbinates/nasopharynx, trachea, prepuce/vagina and caecum. In addition, serum samples should be tested for mycoplasmas and *Leptospira* spp. Parasitology should be based on a microscopic examination of the skin, and of fresh wet samples of the caecal contents, the inner lining of the ileum and of faecal flotation.

Depending on the requirements of the experiments, rats can be housed under different regimes with respect to microbiological control. In many experiments, it is sufficient to keep the animals under conventional clean conditions. This means that there are no special barrier systems and that the microbiological status of the animals is not guaranteed. However, with regular health monitoring and some precautions with respect to cleaning regime, quarantine, and traffic of animal care staff, healthy and highly standardised animals can usually be obtained.

Other experiments require a more strict microbial status. To guarantee the microbiological status of the animals, a strict barrier system is required. These systems usually

**Table 22.2** Recommended list of viral and bacterial infections to be monitored every 3 months in rat breeding colonies (FELASA 2002).

<i>Viral infections</i>	<i>Test frequency</i>
Kilham rats virus	3 months

Ecotoparasites	3 months
Endoparasites	3 months

consist of physical barriers, combined with strict rules regarding disinfection of cages, utensils and personnel. A microbiologically defined breeding colony is started with animals obtained by caesarean section and fostered with microbiologically defined or germ-free mothers kept in isolators, according to standard procedures.

In some highly controlled experiments, it is necessary to keep rats in germ-free conditions. Special isolators are required to prevent contamination. These animals are, however, highly abnormal, because they lack the natural micro-organisms involved in essential processes such as digestion and heat production.

## Transport

Long-distance transportation of rats should be avoided wherever possible because of the long-lasting effects of stress on behaviour and physiology (Koolhaas *et al.* 1997). When rats are obtained from a commercial breeder, they should be allowed a recovery period of at least 1 week, but preferably 2–3 weeks. Although the animals can be transported in cages used for standard laboratory housing, special disposable transport cages are available as well. When the rats are shipped by air, the transport cage should meet the criteria of the International Air Transport Association *Dangerous Goods Regulations Manual* (IATA 2010). Although it is unlikely that animals will drink or eat, owing to the stress involved in transportation, if the journey is expected to last longer than 24h, they must be provided with food and water. For a general discussion of transport issues see Chapter 13.

## Breeding

### The adults

Rats are sexually mature at around 2 months of age. The fertile state of the female is most easily recognised by her behaviour in the presence of a male rat. Females in oestrus perform a highly characteristic soliciting behaviour, consisting of hopping and ear-wiggling and presenting the anogenital region to the male (Erskine 1989). When the male attempts to mount her, a receptive female adopts the lordosis position. Experienced animal care staff can induce lordosis in the female rat by gently palpating her flanks. A more elaborate way of determining the fertility state of the female is by monitoring the oestrous cycle by means of daily vaginal smears. These smears are taken by flushing the vagina with a drop of saline using a small drip pipette, or by taking a sample with a small flexible spatula. The sample is subsequently put on a glass slide, dried and stained with cresyl violet. The phase of the oestrous cycle can be determined under the microscope on the basis of the presence and quantity of cornified epithelial cells and leucocytes. Table 22.3 summarises some of the basic data on reproduction in the rat.

The male will frequently mount an oestrous female and, after several intromissions, an ejaculation occurs. This sequence of events may be repeated two or three times with

**Table 22.3** Reproductive parameters.

Female	Normal value
Mammary glands	6 pairs
Vaginal opening (day)	28–60
First oestrus (day)	40–65
Oestrous cycle	Polyoestrus
Length of oestrous cycle (days)	4–6
Stage 1 dioestrus	6h
Stage 2 pro-oestrus (early)	60h
Stage 3 pro-oestrus (late)	12h
Stage 4 oestrus	10–20h
Stage 5 metoestrus	8h
Age at first mating (day)	50–100
Gestation period	21–23
Size of litter	3–18
Male	Normal value
Descent of testes (day)	15–50
Age at sexual maturity (day)	40–50
Age at aggressive maturity (day)	90–120
Age at end of mating (months)	9–24
Minimum number of intromissions	3–10
Length of ejaculation (s)	10–20

a post-ejaculatory interval of 5–10 minutes. After a while, the female ceases courtship behaviour and defends herself from the male. Simultaneously, the vaginal fluid and the ejaculate coagulate and form a plug. The presence of such a plug is often used as evidence of mating. When the time of conception has to be determined accurately, either the behaviour of the male and female can be observed directly, or a series of vaginal smears can be taken and monitored for the presence of sperm.

Sperm cells can be detected microscopically in the vaginal smear up to 12h after conception. It is difficult to detect pregnancy before the 15th day post conception. After day 15, fetuses can be detected by palpation, body weight rapidly increases, the female starts to perform nest-building behaviour and maternal aggression towards males gradually develops.

On the day of delivery, the pregnant rat becomes restless, and nest-building behaviour reaches its maximum. Pups are delivered at intervals of 5–10 minutes, usually during the last hours of the dark period and the beginning of the light phase. After delivery of a pup, the mother bites the umbilical cord, eats the placenta and cleans the neonate. A weak or stillborn neonate will usually be eaten immediately.

### The young

A healthy rat neonate is pink coloured and begins to suckle within the first few hours after birth. Disturbance of the delivery process should be avoided, because this may lead to infanticide by the mother. From the second day onwards, a beige spot shining through the abdominal wall of the pup indicates the amount of milk it has consumed. Normally, mothers nurse their pups for about 1h, after which she leaves the nest for several hours to rest and eat. The mother keeps the pups together in the nest, and when one escapes from the nest, she rapidly retrieves it. Pup retrieval is facili-

tated by ultrasonic vocalisations emitted by pups which have become separated from their mother and littermates (see Stern and Lonstein (2001) for a review on maternal behaviour). A healthy neonate has a pink colour and a well filled abdomen. Pups with a dark pink, violet or cyanotic, often wrinkled skin are indicative of a mother with insufficient milk supply. A somewhat disturbed nest and the absence of pup retrieval is indicative of a mother who is not nursing her pups properly.

Pups are extremely sensitive to rearing conditions. A large amount of literature shows that the adult behavioural, neurobiological, immunological and neuroendocrine reactivity (Tang *et al.* 2006) is affected by quality of nursing, neonatal handling, maternal separation, environmental enrichment and social isolation. Increasing evidence shows that these effects are mediated by the epigenetic process of DNA methylation resulting in permanent blockade of the expression of specific genes (Meaney & Szyf 2005; Szyf *et al.* 2008). Some of these influences seem to become more prominent in the aging rat, indicating that neonatal environmental factors affect the speed of aging (Meaney *et al.* 1991). In view of these influences of rearing conditions, it is recommended that neonates are raised with as little disturbance as possible, and that the cleaning regime, number of pups and sex ratio per nest are standardised. Any manipulation of the litter, such as reducing size or mixing with others, should be done on the first day after birth.

At birth, the pups are hairless, toothless and blind. The newborn is essentially poikilothermic and must rely upon the maternally maintained microenvironment and huddling of the litter to achieve thermal homeostasis. Within 2 weeks, thermoregulation matures, the coat develops and the eyes open. By day 9 the incisor teeth are sufficiently developed to gnaw and by day 11 the first solid food is usually taken.

The young are generally weaned at the age of 21 days, and subsequently housed in groups of the same gender. The period immediately after weaning till the age of about 60 days is characterised by intense play fighting. This is essential for the development of normal adult social behaviour (Pellis & Pellis 1998).

### Breeding systems

Several systems can be used for breeding rats depending on whether inbred or outbred strains are used. The main purpose of any breeding system is to maintain a standard genetic quality of animals over generations. Inbreeding requires the crossing of closely related animals, usually brother  $\times$  sister mating. To maintain adequate control over the genetic quality of the foundation stock, monogamous mating is recommended. In random-bred colonies, inbreeding is inevitable, but the degree of inbreeding depends on the breeding system used. When a monogamous mating system is used, the inbreeding coefficient, which represents the loss of genetic variation in the colony ( $\Delta F$ ) will be  $1/(2N)$ , where  $N$  is the total number of breeding animals. This means that the smaller the breeding colony, the greater will be the degree of inbreeding. Polygamous mating can be used for the expansion or production stock. However, using one male with several females for foundation stock, increases not only the risk of inbreeding, but also the likelihood of

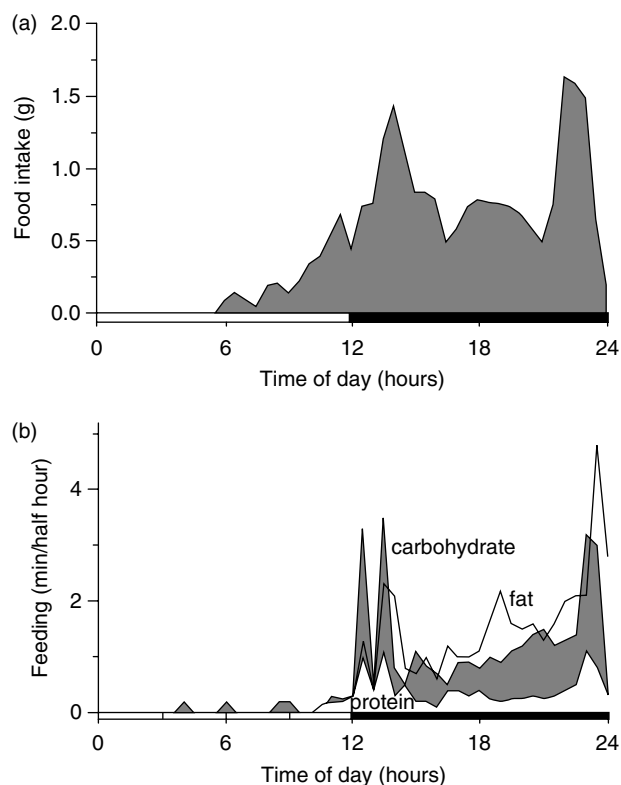

uncontrolled selection, and selection based on breeding performance. It is therefore better to use a monogamous rotation mating scheme. Rotation schemes are designed to reduce the degree of inbreeding by 50%. If a random-bred colony is maintained as a closed colony for at least four generations, and the number of breeding animals is sufficiently large for a  $\Delta F < 1\%$ , the colony may be designated as an outbred stock (Willis & Dalton 1998; Zimmermann *et al.* 2000).

Random-bred and outbred strains have a certain degree of genetic heterogeneity. In some experiments, this heterogeneity may be desirable, for example when results should have some degree of general validity in a population. It has the advantage that the results are based upon a broad spectrum of genotypes. In other experiments, genetically homogeneous inbred strains are required. This has the advantage that the individual variation is reduced and hence the number of animals required per experiment. However, it is important to realise that the results may only be valid for the particular genotype in question. To minimise this problem, F1 hybrids of two inbred strains can be used; they are still genetically homogeneous, but share the genetic characteristics of two different genotypes.

### Feeding

The Norway rat is omnivorous by nature, and has a remarkable capacity to adjust its diet and food intake for specific dietary deficiencies (Markison 2001). The rat is widely used to study the mechanisms of food intake and body weight regulation (Schwartz *et al.* 2000). Feeding occurs in a specific daily pattern (Figure 22.4). Most of the food intake takes place during the dark period with a higher incidence of feeding in the first and last 2h of the dark period (Strubbe & Woods 2004). Rats exhibit a clear preference for certain diets and, in the laboratory, they show preferences for specific nutrients, which vary across the light-dark cycle (Tempel *et al.* 1989; Shor-Posner *et al.* 1994). Figure 22.4 also shows the daily variation in preference for carbohydrate, fat and protein-enriched lab chow. Nutrient balance and in particular amino acid intake is also maintained by coprophagia. Depending on the nutritional balance of their food, rats may eat 10–50% of their own faeces (Fajardo & Hornicke 1989). Moreover, recent studies show a strong influence of the social environment on food preference, ie, individual rats rapidly adopt the food preference of their cage-mates (Galef 2003). Finally, the rat is well known for its conditioned taste aversion, namely its capacity to associate a certain type of food or taste with sickness (Mediavilla *et al.* 2005).

Food is generally supplied *ad libitum*. However, it is now well established that food restriction will increase life expectancy and reduce tumour development in aging rats (Roe *et al.* 1995; Goto *et al.* 2007). Despite these studies, rats are still bred with *ad libitum* food availability. Commercially available diets are generally made from natural ingredients. Although most manufacturers specify the formula of their diets, the exact concentration of dietary components, nutrients and contaminants may vary considerably. This variation may either be due to different brands or to the use of different natural ingredients within the same brand. If such

**Figure 22.4** Circadian variation in food intake (a) and nutrient preference (b) in male Wistar rats. The black bar indicates the dark period of the light–dark cycle.

variations are likely to have an adverse or unpredictable effect on the experimental results it may be necessary to use a chemically defined or purified diet.

## Laboratory procedures

### Handling and training

Rats can usually be handled easily without the use of gloves or forceps. Before handling a rat, it is important to ensure that the animal is awake and alert. Rats which are not used to handling should be picked up by the base of the tail and immediately put on the arm of the handler (Figure 22.5). To comfort the animal, one may gently stroke the back of the animal and the neck region. They like being petted and tickled, during which they emit ultrasonic vocalisations as a sign of positive affect (Panksepp 2007). After a few minutes, the animal is usually willing to be picked up with the hand around its body (Figure 22.6). Rats recognise humans as individuals, so that it is always best if they are handled by a familiar person, usually the animal care staff. If rats are routinely gently handled and petted they are much less likely to be stressed by routine experimental procedures such as injections. A good relationship with a handler makes an important contribution to the welfare of these animals. Force should not be necessary and avoided as much as possible, because it will result in stress to the rat and elicit defensive responses. However, some strains of rats may be aggressive or nervous and difficult to handle. In this situation, it will be

**Figure 22.5** Method of holding a rat which has not been handled previously.

**Figure 22.6** Holding a friendly rat or one used to handling.

necessary to handle the rat more firmly to avoid biting and escape. The best way of holding a defensive rat is presented in Figure 22.7. The animal should be approached from the back, with one hand grasping the base of the tail and the other hand should be laid on the back of the animal. The thumb and forefinger should form a circle around the neck of the animal, with one forepaw included in the ring. The other forepaw can be fixed between the forefinger and the middle finger. In general, rats are very easily trained to cooperate. It is recommended, therefore, to adapt the animals to the handling procedure several days before the animal will be used for experimentation. See also Chapter 16.

### Physiological monitoring

A wide variety of techniques is available to monitor physiological processes in rats. A summary of the most common experimental and surgical techniques is presented by Waynforth and Flecknell (1992), whereas a more advanced manual of microsurgical techniques is presented by Dongen *et al.* (1990). However, many of these techniques are too

**Figure 22.7** Restraining a rat.

complex to be suitable as a standard daily laboratory procedure. Because stress from handling significantly affects their physiology, data should be obtained from undisturbed animals. Body temperature, for example, is often recorded using a thermistor inserted into the rectum to a depth of 3–5 cm. However, handling is unavoidable for this procedure; so in fact it measures stress-induced hyperthermia. Recent developments in chip technology using implanted transponders combine the identification of the individual with a body temperature measurement in the freely moving animal. More detailed and permanent recordings of body temperature can be obtained using permanently implanted transmitters. Transmitter systems are also suitable for monitoring heart rate, blood pressure, electroencephalograms (EEG) and electrocardiograms (ECG) in freely moving animals.

Blood samples can be collected in several ways. A decision tree for the choice of the best method can be found on the website of the National Centre for the Replacement, Refinement and Reduction of Animals in Research<sup>3</sup>. Generally, for the assay of stress-sensitive and rapidly changing substances in the blood, a permanently implanted jugular vein canula is recommended (Waynforth & Flecknell 1992). This technique allows repeated sampling over a period of several weeks. Another method of sampling to obtain reliable baseline values of stress-sensitive substances is to collect trunk blood from decapitated animals. This method, of course, has the disadvantages that it is fatal for the animal and does not allow repeated measures from the same individual. Moreover, great care should be taken that the whole procedure from catching, handling and decapitation of one animal does not affect stress levels in the subsequently sampled animals (Zethof *et al.* 1995). For the assay of less reactive substances, blood may be collected with a syringe from the tail vein. When a large volume of blood is required, a cardiac puncture can be used with the animal under deep anaesthesia (Joint Working Group on Refinement (JWGR) 1993).

Urine and faeces can be collected by housing the animals in commercially available metabolism cages. Faeces can be

<sup>3</sup><http://www.nc3rs.org.uk/bloodsamplingmicrosite/>

**Figure 22.8** Giving an intraperitoneal injection to a well handled rat.

used to measure baseline concentrations of steroid hormones (Lepschy *et al.* 2007).

### Administration of medicines

Most of the commonly used techniques to administer substances to rats are extensively described in Waynforth and Flecknell (1992) and by the JWGR (2001). As some of these procedures can be rather stressful to the animal and may, therefore, interfere with the experiment, alternative stress-free methods will be indicated here.

Intravenous (iv) injections can be given via the sublingual vein or the lateral vein at the root of the tail in an anaesthetised rat (needle size: 0.5–0.6 mm). When frequent iv injections are required or the injection is to be combined with subsequent blood sampling, the implantation of a permanent jugular vein catheter is recommended. This method allows a stress-free iv injection to be given in freely moving animals.

Intraperitoneal (ip) injections are given in the lower left quadrant of the abdomen, to avoid damage to vital organs such as liver, stomach and spleen (needle size: maximum 0.9 mm). It is not usually necessary to restrain the animal so that an animal which is used to handling can be given an ip injection as depicted in Figure 22.8. More nervous, defensive animals will need to be held more firmly, including their hindquarters, and a second person may be needed to give the injection.

Subcutaneous (sc) injections can be given by placing the animal on top of the cage or on a table and raising a fold of the skin of the neck (needle size: 0.5–0.6 mm). The needle should be slid into the fold with its tip parallel to the body surface. When a more chronic administration of substances is required, it may be better to use osmotic mini pumps, the implantation of pellets or silicon capsules, in preference to a frequent injection schedule. Osmotic mini pumps are commercially available in a range of infusion rates and durations.

Intragastric administration of fluids can be performed by gavage of the oesophagus using a curved needle with a small bulb at the tip. Different sized rats need different sizes

of gavage needle (Waynforth & Flecknell 1992). For per oral administration the rat is held firmly by the skin of the neck and the back so that the head is kept immobile and in line with the back. Great care should be taken that the injection fluid does not enter the trachea. When frequent intragastric administrations are required, a permanent intragastric catheter may be implanted.

### Anaesthesia and analgesia

General anaesthesia can be induced either by inhalation or by injection of anaesthetics by intraperitoneal, intramuscular or intravenous route. There are excellent standard works available with all the detailed information on anaesthesia and pain management (Flecknell & Waterman-Pearson 2000; Flecknell 2009). Reference to these books is strongly recommended. Table 22.4 summarises the inhalation and injection anaesthetics recommended for use in rats.

Inhalational anaesthetics are generally preferable because they have the advantage of easy adjustment of the depth of anaesthesia and rapid recovery. Induction of anaesthesia with volatile anaesthetics can be achieved using an induction chamber connected to a vaporiser. After induction of anaesthesia, gas can be delivered through a face mask or via an endotracheal tube; a calibrated vaporiser should be used. The volatile anaesthetic is mixed with air or a mixture of N<sub>2</sub>O and O<sub>2</sub> (1:1).

Several types of injectable anaesthetics are suitable for rats. The selection of these anaesthetics depends on a variety of factors such as: the duration of the surgery; the preferred degree of muscle relaxation; and the appropriate level of analgesia. In rats, the anaesthetic is generally given as a single intraperitoneal injection. However, it is important to appreciate that the response to these injectable anaesthetics may vary strongly between individual animals and between sexes and strains. Therefore, when using a new anaesthesia regimen for the first time, the dosage required should be carefully assessed.

It is sometimes useful to reduce possible side effects of the anaesthetic compound by administering certain drugs as premedication. Sedatives or tranquillisers can be used to reduce the stress associated with the induction of anaesthesia and to promote a smooth recovery. However, most of these compounds have little or no analgesic properties and cannot be used to reduce post-operative pain. Anticholinergic agents may be used to reduce the production of saliva and to reduce undesirable autonomic responses.

During surgery, the depth of the anaesthesia should be monitored frequently. This can be assessed easily by checking some reflexes of the animal. A correctly anaesthetised rat shows a regular deep respiration and an absence of the righting reflex when being placed on its back. Pinching the tail with the finger nails does not induce a flick of the tail or vocalisations and a puff of air on the eyes does not induce an eye blink reflex. In view of the sensitivity of the rat's eyes for bright light, they should be protected from the surgical light, and a drop of saline in the eye will prevent the eye from dehydration during long surgical procedures.

**Table 22.4** Inhalation and injection anaesthetics recommended for use in rats.

<i>Drug and indication</i>	<i>Dose and route of administration</i>	
<b>Premedication (anticholinergics)</b>		
Atropine	0.05 mg/kg sc	
<b>Premedication (sedatives)</b>		
Diazepam	2.5 mg/kg ip	
Acepromazine	2.5 mg/kg sc	
Hypnorm (fentanyl/ fluanisone)	0.4 ml/kg ip	
Xylazine	10 mg/kg sc	
Medetomidine	0.5 mg/kg sc	
<b>Anaesthesia (short duration, 5–10 minutes)</b>		
Alphaxalone	10–12 mg/kg iv	
Propofol	10 mg/kg iv	
Methohexitone	7–10 mg/kg iv	
<b>Anaesthesia (medium duration, 20–60 minutes)</b>		
Hypnorm/ midazolam	2 ml/kg ip (1 part Hypnorm, 1 part midazolam and 2 parts water for injection)	
Ketamine/ xylazine	90 mg/kg ip 10 mg/kg ip	
Ketamine/ medetomidine	75 mg/kg ip 0.5 mg/kg ip	
Pentobarbital	40–55 mg/kg ip	
<b>Anaesthesia (long duration, non-recovery)</b>		
Chloralose	130 mg/kg ip	
Urethane	1–2 g/kg ip	
<b>Anaesthesia (inhalation agents, short/medium/long duration)</b>		
Halothane	Induction	Maintenance
	concentration 4–5%	concentration 1–2%
Isoflurane	Induction	Maintenance
	concentration 4%	concentration 1.5–3%
Methoxyflurane	Induction	Maintenance
	concentration 4%	concentration 0.5–1%

Many anaesthetics interfere with the thermoregulation of the animal. Therefore, body temperature should be carefully monitored during anaesthesia. An electric blanket controlled by a thermostat and integrated with a rectal temperature probe should be used.

Generally, rats recover rapidly from major surgery. However, a post-operative recovery period of at least 1 week is recommended. Moreover, pain should be relieved using analgesic treatment. The most common analgesics for rats are summarised in Table 22.5 (Bertens *et al.* 1993; Flecknell & Waterman-Pearson 2000; Flecknell 2009).

Analgesics administered systemically may have side effects which interfere with the experiment. In these situations, the use of local analgesic ointment to treat surgical

**Table 22.5** Alphabetical list of analgesics for postoperative pain relief.

Drug	Dose
Aspirin	100 mg/kg per os, 4 hourly
Buprenorphine	0.01–0.05 mg/kg sc, iv 8–12 hourly
Butophanol	2 mg/kg sc, 4 hourly
Codeine	60 mg/kg sc, 4 hourly
Flunixin	2.5 mg/kg sc, im, 12 hourly
Morphine	2.5 mg/kg sc, 2–4 hourly
Nalbuphine	1–2 mg/kg im, 3 hourly
Paracetamol	100–300 mg/kg per os, 4 hourly
Pentazocine	10 mg/kg sc, 4 hourly
Phenacitin	100 mg/kg per os, 4 hourly
Pethidine	10–20 mg/kg sc or im, 2–3 hourly

wounds should be considered. This will also prevent the animal from biting surgical wounds and stitches. Recovery is improved after a few days when group housing can be re-established.

## Euthanasia

The most appropriate way of killing rats is, to some degree, determined by the type of experiment involved. When the body will not be used for further experimental purposes, the best way of killing the animal is using a rising concentration of carbon dioxide and oxygen (6:4). After the animal has lost consciousness, the concentration of carbon dioxide is raised to 100% and kept at this level for at least 10 minutes. Although this method is widely used throughout the world, there is a significant debate on the stressful nature of this technique (Conlee *et al.* 2005). The immediate use of 100% carbon dioxide should be avoided, because it induces severe dyspnoea and signs of stress. Alternative methods include pre-euthanasia anaesthesia and the use of argon rather than carbon dioxide. Carbon dioxide should not be used to kill neonatal rats because they are relatively resistant to it. When specimens have to be obtained, administering a lethal dose of anaesthetic is usually an appropriate method. However, if the anaesthetic agents could interfere with the experimental results, physical methods of euthanasia are inevitable. Methods include concussion of the brain, cervical dislocation and decapitation (using a special guillotine or sharp scissors). The choice of method will depend on the size of the animal and local regulations. See also Chapter 17.

## Common welfare problems

### Disease

Rats can be kept free of disease relatively easily under conventional husbandry conditions, provided that these conditions meet certain criteria. For example, it is essential to avoid overcrowding not only in the breeding cages, but also in the whole animal room. Moreover, proper ventilation, humidity control, a cleaning regime using dust-free bedding

material, and the use of filter caps are the best prophylactic precautions that can be taken. Reports in the literature suggest that a restricted feeding regime may be the best way to reduce the incidence of neoplasm in aging rats (Roe *et al.* 1995).

The most important indicators of disease and/or lack of well-being in rats are summarised below.

- **Appearance.** Piloerection and a rough greasy or matted pelage, sometimes with loss of hair, a loose skin, signs of muscle wastage on the back, dehydration and reduced body weight may all be observed. Eyelids are half or fully closed and the eyes have the appearance of being sunken. Red secretion from the lacrimal glands accumulates around the eyes (chromodacryorrhoea).
- **Faeces.** Soft faeces, or diarrhoea, a dirty tail and an unpleasant smell are indicative of an intestinal infection.
- **Behaviour.** Initially, animals may be more alert and aggressive, but will become progressively more passive; they stop eating and drinking and reduce exploratory behaviour (Roughan & Flecknell 2003). Sometimes rats gnaw affected parts of the body.
- **Posture.** The animal frequently lies down, initially curled up with the head touching the abdomen, later stretched with the tail extended. A hard belly indicates abdominal pain. A tilted head is indicative of an infected middle ear.
- **Locomotion.** A diseased rat moves slowly with a stiff-legged gait and arched back.
- **Vocalisation.** Squeaking when handled.
- **Physiology.** Sneezing may be the first sign of a respiratory infection. When the condition of the animal worsens, breathing is audible and laboured and the respiratory frequency increases. Hypothermia indicates a serious condition and a pale appearance is indicative of anaemia or loss of blood.

Sick animals must always be examined by a veterinarian for a complete clinical and *post-mortem* diagnosis. However, many diseases may take a subclinical course with no apparent signs of illness. It is important to be aware of such subclinical diseases, such as latent viral infections, because they may interfere with the standardisation of the experiments. Regular microbiological monitoring of the rat population is therefore essential.

The most common infectious diseases of rats involve infections of the respiratory tract by *Mycoplasma pulmonalis*, *Pasteurella* spp. and *Pneumococcus* spp. Under proper husbandry conditions, the disease will only be apparent in some animals. However, the disease may become a serious problem under less optimal husbandry conditions, or when experimental procedures compromise the physical condition of the animals. If the disease cannot be controlled by chemotherapy or by antibiotics, sick animals must be removed from the colony as soon as possible. Respiratory diseases are transmitted by air or by contact between the animals. Reducing the pH of drinking water is sometimes used to reduce the spread of the infection in a colony through contaminated drinking spouts. See Fox *et al.* (2002) for more extensive information on diseases and their treatment and control.

## Abnormal behaviour

Rats rarely show obvious signs of abnormal behaviour. The incidence of stereotypies is very low under standard housing conditions. Abnormal behaviour is usually expressed as an increase in reactivity to environmental stimuli leading to panic reactions, or as increased passivity or state of depression. Occasionally, abnormal aggressive behaviour may occur in group-housed males. One male may continuously attack one of his cage mates, leading to serious wounding or death of the victim, and sometimes to cannibalism. There are no known solutions to this problem, other than killing the particular group of animals.

Another type of abnormal behaviour is chewing the fur of cage mates. The cause of this problem and its solution are unknown.

## Reproductive problems

Rats, in particular the outbred strains, generally reproduce without any problems. After giving birth, the mothers of some strains may be infanticidal. This usually results from disturbance to the nest and the nursing mother caused by cage cleaning or other activities in the animal unit. Sensitive strains should be bred in separate, quiet breeding facilities, and pregnant females should be provided with nest boxes and nesting material.

# 23 The laboratory gerbil

Eva Waiblinger

## Biological overview

### Taxonomy

The Mongolian gerbil (*Meriones unguiculatus*) is the most widely used species of gerbil, and gerbil-like rodents, in the laboratory. There are several other species in the genera *Gerbillus* (gerbils, between 54 and 62 species) and *Meriones* (sand rats, 14 species). Gerbil taxonomy and phylogeny have recently been discussed by various authors (Michaux *et al.* 2001; Palinov 2001; Jansa & Weksler 2003; Steppan *et al.* 2004; Chevret & Dobigny 2005). This chapter will be limited to the Mongolian gerbil, or jird. The gerbil's scientific name *Meriones unguiculatus* means 'little clawed warrior' after Meriones, a marshal and relative of the Cretan king Idomeneus in the Trojan War. Meriones is said to have been one of the warriors in the Trojan Horse.

### Standard biological data

Basic biological data on the gerbil have been described by McManus (1972b), Thiessen and Yahr (1977), Tumblebrook Farm (1979), and by Field and Sibold (1999). Gerbils have 44 chromosomes, four pairs of mammary glands, and have a typically rodent dental formula (one incisivus, a diastema and three molars in each half mandible). The body temperature is 38.1–38.4°C (measured by rectal probe), heart rate is 360bpm (range 260–600bpm) and the respiration rate is 90 per min with a range of 70–160 per min. Gerbils drink 9.63 ± 1.95% of body weight per day, which corresponds to 4–7 ml per day per 100 g body weight. Caloric uptake is 40.32 ± 4.92 kcal per day per 100 g body weight, corresponding to 5–8 g per day per 100 g body weight. Urine volume is 3–4 ml per day and the urine is highly concentrated.

### Size range and lifespan

Gerbils are of intermediate size between a rat and a mouse (body length 11–13.5 cm). The fur-covered tail is slightly shorter than the body (9.5–12 cm), with a small tuft of black hair at the tip. An erect adult gerbil is about 15 cm high. At birth pups weigh about 3–4 g, at 20 days around 16 g, at 30 days 25 g, at 40 days 40 g, at 3 months 65 g, at 6 months 70–90 g; adult males weigh between 80 and 130 g, and

females between 60 and 100 g. Gerbils can live up to 6 years, however, 3–4 years is more usual (Thiessen & Yahr 1977).

### External features

The external features of a typical laboratory gerbil are shown in Figure 23.1. The wild type has an agouti-brown coat and a cream-coloured belly. Males are generally heavier than females (Agren *et al.* 1989a, 1989b). The hindlegs are relatively long compared to the forelegs. The animals often sit on their haunches to look around, feed or groom themselves, and the long hindpaws are used extensively during digging behaviour to vigorously kick out and remove loose substrate from under the belly. Hopping locomotion can only be observed if the gerbils have a large area of several square metres with rough flooring available, but their locomotion is never comparable to kangaroo-type hopping which can be seen in *Jaculus jaculus*, the giant jumping rat. Gerbils perform rapid foot-thumping with the hindfeet during alarming situations, and the males foot-thump after copulation (Roper & Polioudakis 1977; Holman & Seale 1991). In erect, attentive posture, gerbils stand up on the toes, and the tail acts as extra support. In the laboratory, gerbils do not readily climb, at least not upside down at the cage top as mice do (Lerwill 1974; Roper & Polioudakis 1977). This is due to their fur-covered soles of the hindpaws, and lack of friction pads and opposable toes. If startled, however, gerbils can readily jump over a 30 cm high barrier (wild gerbils can jump up to 60 cm; I.W. Stuermer, personal communication). Adult animals can comfortably crawl through tubes or tunnels of a diameter of 5 cm.

### Senses and communication

#### Sound production

Gerbils are able to produce sounds of between 20 and 150 kHz with peak intensities up to 106 dB (Thiessen *et al.* 1978). Ultrasonic calling rate in gerbil pups increases from birth until day 4, then decreases, and from day 20 onwards, no vocalisations were detected by De Gheff (1974). Broom *et al.* (1977) and Lerwill (1978) have also described the ontogeny of sound production in gerbils. Male gerbils' pre-, within- and post-copulatory vocalisations differ, with

**Figure 23.1** A typical inquisitive laboratory gerbil.

upsweep (28–35 kHz), unmodulated (26 kHz) and modulated (28–38 kHz) calls; females vocalise much less during copulation (Holman 1980; Holman & Seale 1991).

#### Hearing capacities

Gerbil ears are not mature at birth. The sound-conducting apparatus and inner-ear structures develop between day 16 and 20 (Finck *et al.* 1969). Woolf and Ryan (1984) however found the first cochlear microphonic potentials at day 12, with a very high 103 dB threshold. Juvenile gerbils first approach an auditory stimulus (low-intensity tape-recorded gerbil social call compared to broad-band white noise or lacking stimulus) at 16 days of age (Kelly & Potash 1986). Hearing sensitivity increases up to the age of 9 months. Adult gerbils respond to frequencies from 100 Hz to 60 kHz (Ryan 1976), with maximum sensitivity (<10 dB) between 4 and 44 kHz. In older gerbils (between 12 and 28 months), sensitivity is reduced at the range of 8–24 kHz, however this is only the case in domesticated, not wild gerbils (Stuermer & Wetzel 2006; Eckrich *et al.* 2008). Minimum resolvable angles (MRAs) for sound localisation in azimuth for broad-band noise is 23° (if the animal is stimulated from the front) and 45° (stimulated from the back) (Maier & Klump 2006). Gerbils use both phase and intensity differences to localise sounds (Heffner & Heffner 1988).

#### Vision

Jacobs and Deegan II (1994) described gerbils as 'visually alert rodents'. Visual performance in gerbils (spatial and temporal resolution, size constancy, pattern discrimination) was analysed by Ingle (1981), using gerbils trained in behav-

ioural tasks. The retinas have rods (peak sensitivity at 499–501 nm (Jacobs & Nietz 1989), about 87% of receptor population) and cones (12–14% of total receptor population). There seem to be two types of cones: 95–97.5% of the cone population is green sensitive (peak sensitivity at 493 nm, very close to the rod sensitivity, but at high illumination levels), only 2.5–5% of the cones are blue sensitive (sensitivity possibly between 420 and 430 nm). Therefore gerbils can be said to have dichromatic, blue–green colour discrimination abilities (Jacobs & Nietz 1989; Govardovskii *et al.* 1992; Bytyqi & Layer 2005). Gerbils are also sensitive to ultraviolet (UV) light. Jacobs and Deegan II (1994) found indications for another UV sensitive pigment having a peak sensitivity at 360 nm. Receptor density was found to be 314 000–332 000/mm<sup>2</sup> for rods and 45 000–50 000/mm<sup>2</sup> for cones (Govardovskii *et al.* 1992). Visual acuity was found to be 1.8–2 cycles/degree at 70 cd/m<sup>2</sup> (Baker & Emerson 1983; Wilkinson 1983), the acuity for horizontal gratings being better than for vertical gratings. Gerbils have a good stereopsis, depth perception and cliff response (Collins *et al.* 1969). The gerbil visual system seems to be well adapted to diurnal life. It is not known whether albino-eyed gerbils have reduced acuity and are more susceptible to bright light than dark-eyed ones, as is the case in rats (Birch & Jacobs 1980).

#### Olfaction and scent marking

Gerbils are macrosmates with high densities of olfactory receptors and a well developed bulbus olfactorius (Loskota *et al.* 1974b; Thiessen & Yahr 1977). Gerbil pups show responses to odours from as early as day 4, and strongly prefer home cage odour between day 8 and 14 (Cornwell-Jones & Azar 1982). Gerbils also show pronounced scent-marking behaviour, smearing sebum of their ventral gland, which is present in both sexes, on objects in their territory and also on group members (for a detailed description of scent gland functions, see Thiessen and Yahr (1977)). Marking behaviour is characterised by the animal stretching out, lowering the abdomen and then crawling forward, dragging the gland over the substrate (Roper & Polioudakis 1977). In the wild, gerbils predominantly mark along the border of their territory, with the dominant breeding male marking most, followed by the breeding female and adult male offspring (Agren *et al.* 1989a, 1989b). Since scent-marking is controlled by androgens, males scent-mark more frequently than females (Thiessen & Yahr 1977). Gerbils of black coat colour mark more frequently than agouti animals (Dizinno & Clancy 1978). In isosexual groups of males, scent-mark frequency can be used as an indicator of rank (Shimozuru *et al.* 2006a), whereas body weight is usually taken as correlate of rank in mixed-sex groups (Weinandy 1995). Females scent-mark their pups, which might help the mother to recognise her own offspring (Wallace *et al.* 1973), and the pups recognise maternal nest odours and are attracted to them (Yahr & Anderson-Mitchell 1983). According to Roper and Polioudakis (1977), scent-marking is used to mark and identify group and family members. Gerbils can discriminate between odours of familiar and unfamiliar conspecifics (Tang Halpin 1975; Yahr 1977). Age, social stress and social defeat decrease scent-marking behav-

ior in male gerbils (Yamaguchi *et al.* 2005; Shimozuru *et al.* 2006b).

### Activity patterns

Gerbils are polyphasic, diurnal and crepuscular. They exhibit two major peaks of activity after dawn and around dusk, but are also active during the day (Susic & Masirevic 1986; Weinandy 1995; Weinert *et al.* 2007). Daily activity patterns are temperature dependent in the wild (Leont'ev 1954) and in seminatural conditions (Randall & Thiessen 1980). When activity is measured using a running wheel, activity shifts mostly to the night; however, this seems to be an artefact induced by the running wheel (Refinetti 2006).

### Social organisation

#### Extended family groups and sexual suppression

In the wild, gerbils live in extended families with one breeding pair and its offspring of several generations, in group sizes of 2–17 animals (Agren *et al.* 1989a, 1989b). Leont'ev (1954) even captured up to 26 animals in one burrow. As a rule, only the dominant pair reproduces, whilst adult offspring of both sexes remain with the parents and usually do not reproduce (Roper & Polioudakis 1977; Swanson & Lockley 1977; Agren *et al.* 1989a, 1989b; Solomon & Getz 1996). It is unclear whether gerbils really are monogamous. Agren *et al.* (1989a) found that females in oestrus actively solicit copulations of neighbouring males. So far, no paternity analyses have been performed in wild gerbil groups or in naturally grown families in semi-natural housing, therefore information on extra-pair reproduction is lacking. Adult sons often exhibit well developed ventral glands and testes; adult daughters' ventral glands, uteri and ovaries are undeveloped. Payman and Swanson (1980) and Swanson and Lockley (1977) suggested that suppression of sexual maturation in daughters is caused by the presence of the mother and her next litter. Clark and Galef found that sisters, but also other familiar animals, inhibit each other's reproductive development, with this inhibition being even more pronounced in the presence of the mother. In contrast, exposing suppressed females to unfamiliar males speeds up their maturation (Clark & Galef 2001a, 2002; Clark *et al.* 2002). Sexually suppressed adult group members participate in digging the communal burrow, hoarding food, territorial defence and co-operative breeding (Agren *et al.* 1989a, 1989b). Animals of a group also coordinate their actions according to the behaviour of group members, especially in predator avoidance (Ellard & Byers 2005).

#### Reasons for philopatry

In wild gerbils, adult offspring remain with the family and parents (ie, 'philopatry') long after weaning. Apparently, the presence of older offspring was not found to enhance reproductive success of the parents in the laboratory (Ostermeyer & Elwood 1984). French (1994) suggested that

remaining with the parents offers opportunities for reproduction during prolonged interbirth intervals of the dominant female. According to French (1994), seven of 49 (14.3%) female offspring managed to produce offspring in the presence of the mother, albeit with lower pup weight and higher mortality; Scheibler *et al.* (2004) observed only two of 56 (3.8%) daughters giving birth while still with the family. Salo and French (1989) consecutively showed that adult offspring remaining with the family and helping at the nest can acquire essential parental skills which later improve their own reproductive performance, irrespective of sex. Since extended residence in the parental group by non-breeders can enhance their reproductive performance, it is advisable to leave future breeding animals longer with their parents.

#### Sudden intra-group aggression and expulsion of group members

One problem often encountered is a sudden outbreak of aggression in hitherto peaceful groups of animals, followed by expulsion of group members. If these animals are not removed, they will be killed. The problem is quite severe in pet gerbils, but its frequency in the laboratory is unknown. The author's experience is that such periods of aggression can also occur in same-sex groups, without increasing animal numbers, even in groups of only two same-sex animals. Researchers at the University of Halle have analysed this problem in naturally grown family groups of laboratory gerbils in semi-natural enclosures (Scheibler *et al.* 2004). Aggression originated from the founder female in 60% of the cases, who was either pregnant or lactating, or the founder male (13%). Pup mortality was very high during these periods of aggression (70%). Increased reproductive competition, especially for the female breeding position, seems to trigger such periods of aggression in reproducing families (Scheibler *et al.* 2005a, 2005b, 2006a). However, there is no explanation so far for such periods of sudden aggression occurring in hitherto stable same-sex groups.

### Reproduction

Under laboratory conditions gerbils reproduce all year round, whereas in the wild, the main reproductive season is from late winter to summer, with only two to three litters per year (Naumov & Lobachev 1975). During a lifetime, females produce eight litters, on average, but there have been females with 17 and more. The young are altricial (naked, blind and highly dependent on the parents) and are kept in the nest or nest chamber and retrieved by the parents if they crawl out of the nest.

#### Lack of inbreeding avoidance

Gerbils are able to recognise kin independent of familiarity (Valsecchi *et al.* 2002). Valsecchi's findings did not undermine Agren's suggestion (Agren 1984a) that there is a particular period of time (60–70 days of age) during which prolonged social contacts between males or females result

in the establishment of a sibling bond between these animals, inhibiting reproduction. Despite female gerbils' ability to recognise kin, they do not avoid reproduction with close relatives such as siblings.

### Role of the male in rearing young

In gerbils, the male actively participates in raising the pups. They collect nesting material, help build the nest, warm and clean the pups, and might occasionally also retrieve a pup back to the nest (Clark *et al.* 2001; Clark & Galef 2001b; Weinandy *et al.* 2001). Males and females coordinate their activities at the nest in a manner that ensures constant supervision and care of the pups, so that if the female leaves the nest, the male guards the pups and *vice versa* (Waring & Perper 1980). The presence of the father increases pup activity and physical contact between pups and parents. Pups with the father present open their eyes earlier (Salo & French 1989; French 1994; Piovanotti Arua & Vieira 2004).

### Bruce effect

There are contradictory results on the Bruce effect in gerbils (disruption of pregnancy or failure of implantation following exposure of the female to a strange male). Norris and Adams (1979a) failed to find evidence of the Bruce effect in gerbils, except when newly mated pairs were separated (Norris 1985). However, Rohrbach (1982) found that both the presence of a strange male or female, as well as changes in the housing conditions (cold, change to smaller or new cage) can block implantation in mated female gerbils. The presence of strange males reduces maternal care in lactating females, resulting in high pup losses.

### 'Stud' males and 'dud' males

Mertice Clark and Bennett Galef have demonstrated in a series of experiments that gerbil males differ strongly in their reproductive performance depending on their position in their mothers' wombs (Clark *et al.* 1992, 1998; Clark & Galef 1994, 1999, 2000). Males ('dud' males) situated between two sisters in the uterus will have much lower adult circulating testosterone levels, low territorial and sexual activity levels, but very high nest-bound activity levels (nest building and caring for pups), whereas males gestated between two brothers ('stud' males) will develop into sexually and territorially very active adults, but with less interest in pup care. According to these authors, this phenomenon leads to a testosterone-mediated trade-off between parental and sexual efforts, but its function and adaptive quality is yet unclear (Vandenberg 1993). Some males gestated between sisters have testosterone levels as low as those of females and are unable to mate and impregnate females. Generally, the serum level of testosterone in male gerbils determines whether these animals exhibit sexual or pup care behaviour. 'Dud' males have about half the testosterone levels of their 'stud' conspecifics, and wild gerbil males have much lower testosterone levels than laboratory gerbils (Blottner & Stuermer 2006; Stuermer *et al.* 2006). Circulating levels of testosterone in male laboratory gerbils ranges from 0.35–

3.72 ng/ml, with temporal variation. At the age of around 10 weeks (70–80 days), testosterone levels are highest (up to and even over 4 ng/ml), then again drop to 1–2 ng/ml thereafter (Clark & Galef 2001b; Clark *et al.* 2004).

### Uses in the laboratory

To assess the most common uses of gerbils in the laboratory, a quick search on ISI Web of Science yielded at least 711 published English papers on *Meriones unguiculatus* between January 2000 and October 2007. Most papers dealt with ischaemia (ie, stroke research) (336 papers, 47.2%). Due to the lack of carotid arterial anastomoses (incomplete circle of Willis) in the majority of gerbils the effect of vascular clamping of the carotids is more reproducible from animal to animal than in other species (Tumblebrook Farm 1980, 1985; and personal communication, C. Nitsch, Functional Neuroanatomy, University of Basel). However, Laidley *et al.* (2005) demonstrated that 23–39% of laboratory gerbils had a complete or unilateral complete circle of Willis, therefore the role of gerbils in stroke research is questionable. A large part of the references dealt with research into parasitic and other infectious diseases (110 papers). Gerbils are used in filariasis research as hosts for *Brugia pahangi* and *B. malayi*, as and are used also in echinococcosis, amoebiasis, babesiosis, giardiasis, trypanosomiasis, and schistosomiasis research. They are also occasionally used as hosts for ascarids, *Taenia* sp., *Trichostrongylus* sp. and *Neospora caninum*, and have been used as 'feeding stations' for ticks (*Ixodes ricinus*), and are also used in research into *Helicobacter pylori* infection.

Gerbils are frequently used in neurology research (98 references in total), which centres on the auditory system (53 out of 98 references). Gerbil behaviour and behaviour associated with reproduction were the subject of 61 references, followed by epilepsy and seizure research (49 references). Gerbils seem to be especially seizure-prone, seizures occur in response to sensory stimulation or forced exploratory behaviour and it seems the propensity for seizures is partly hereditary. In the 1970s, Loskota first established non-inbred seizure-prone and seizure-resistant strains of gerbils by selective breeding. As a result, gerbils became a model for spontaneous or conditioned seizures (Loskota *et al.* 1972; Loskota & Lomax 1974, 1975). Today there are several seizure-prone inbred strains of gerbils available. However, the propensity for seizures might present a problem in the general husbandry of these animals, wherever epilepsy is not the subject of research.

Questions on nutrition, in particular bioavailability of beta-carotene, were addressed in 17 studies. Five addressed new methods for biomedical procedures (blood collection, intravenous (iv) injections, anaesthesia and total body electrical conductivity (TOBEC) measurements), and some tentatively suggested gerbils as models for schizophrenia (Bagorda *et al.* 2006), psychosis (Brummelte *et al.* 2007) and depression (Hendrie & Pickles 2000; Starkey & Hendrie 1997; Jaworska *et al.* 2008). The remaining 26 references covered a variety of subjects including cancer, genetics, general anatomy, toxicology, circadian rhythms and thermoregulation. Only six studies dealt with behaviour or

reproduction of gerbils in the wild or the behaviour of recently caught wild gerbils in the laboratory.

## Breeds, strains and genetics

### Provenance and breeding history

Wild Mongolian gerbils originate from the central Asian semi-deserts and steppes and can be found in Mongolia, Inner Mongolia (China) and southern Siberia. In the wild, they live in extended, territorial family groups (Agren *et al.* 1989a, 1989b), which inhabit self-dug burrows, that are widely branched and up to 60–80 cm deep (Bannikov 1954; Naumov & Lobachev 1975; Scheibler *et al.* 2006b). Gerbils prefer habitats with short, sparse vegetation and dry, loose and sandy soil (Bannikov 1954; Liu *et al.* 2007).

The Mongolian gerbil was discovered in 1866 by the French missionary Abbé Armand David. Travelling from Beijing to north-west China he found three 'yellow rats with long, hair-covered tails'. He sent these animals to the director of the Paris Natural History Museum, Monsieur Milne-Edwards, who named the species *Meriones unguiculatus* (Milne-Edwards 1867). In 1935, 20 pairs of gerbils were caught by C. Kasuga in the Amur river valley in Manchuria and exported to Japan, where the Kitasato Institute established a closed breeding colony (Rich 1968). In 1949 another breeding colony was established at the Central Laboratories for Experimental Animals, Tokyo, by M. Nomura. From this breeding stock, in 1954, 11 pairs were sent to V. Schwentker who had founded the West Foundation/Tumblebrook Farm in 1940 at Brant Lake (USA) to introduce new laboratory animal species to the USA. Only four males and five females bred, so all animals of the Tumblebrook Farm colony descended from these animals. From Tumblebrook Farm, gerbils reached various laboratories and research groups at universities and pharmaceutical companies, for example the Worcester Foundation for Experimental Biology, Shrewsbury, Massachusetts, where a sub-colony was established in 1962.

In the 1960s, the gerbil was established as a laboratory animal in Europe (Rich 1968). In 1964 J.H. Marston imported 12 pairs from Massachusetts to Birmingham (Norris 1987). With the exception of 12 pairs imported by the Laboratory Animal Centre, Carshalton, in 1966 direct from Schwentker's foundation colony, this random-bred colony at Birmingham has been used to generate the breeding stock for laboratories throughout the UK and Europe, and has also established the gerbil as a pet animal. In 1995, Ingo W. Stuermer's German-Mongolian expedition caught wild Mongolian gerbils in Mongolia, and 60 of these animals were used for breeding in Germany (Strain Ugoe:MU95) to analyse domestication-induced changes in gerbil morphology, behaviour, reproduction, endocrinology and neurobiology (Stuermer 1998; Stuermer *et al.* 1998, 2003; Blottner *et al.* 2000; Neumann *et al.* 2001). Most animals used today are descendants of the colonies mentioned above. Currently, only a few studies are conducted with wild gerbils in their natural habitat (Wang & Zhong 2006; Liu *et al.* 2007; Zhang & Wang 2007). In the wild, *Meriones unguiculatus* is not endangered and is often viewed as an agricultural pest (Prof. R.Samjia, personal

communication), and also as a reservoir for bubonic plague-carrying fleas (Jun *et al.* 1993; Davis *et al.* 2004).

### Domestication

Nowadays, more than 50 generations and several bottlenecks separate laboratory gerbils from their wild ancestors caught in 1935 (Rich 1968). There are pronounced differences between wild and laboratory gerbils. In 1995, a German-Mongolian research team caught about 170 wild gerbils in Mongolia, then housed and bred them in the lab and compared these F0, F1 and F2 animals with laboratory gerbils (Stuermer 1998; Blottner *et al.* 2000; Neumann *et al.* 2001; Stuermer *et al.* 2003, 2006). The latter show typical signs of domestication: higher body weight with higher variability, higher testes, liver and total fat weight, lower brain weight (17.7% lower), lower heart, lung, kidney and stomach weights, shorter intestinal tract length, higher testicular activity, greater litter size (mean 5.6 pups in laboratory gerbils compared with 4 in first generation wild gerbils bred in the laboratory), but also faster auditory discrimination learning in laboratory gerbils compared to wild gerbils. Microsatellite variability, and probably also genetic variability in general, is reduced in laboratory gerbils. Wild gerbils develop less stereotypic digging, but since this abnormal behaviour develops during ontogeny, and is caused by housing conditions in the laboratory, it is not surprising that adult wild gerbils did not develop this behaviour. Epileptic seizures do not occur in wild gerbils, but started to appear in their offspring. Stuermer observed rapid changes towards domestication characteristics with only a few generations of breeding wild gerbils in the laboratory. Despite these obvious changes, basic behavioural needs are still the same in all gerbils, as is demonstrated by their intensive digging behaviour, need for a burrow, social contact, gnawing and hoarding activities.

### Colour mutations

Since the occurrence of the first coat colour mutations, black and spotted, a wide variety of coat colours has emerged (Waring *et al.* 1978; Swanson 1980; Waring & Poole 1980; Henley & Robinson 1981; Leiper & Robinson 1984, 1985, 1986; Matsuzaki *et al.* 1989). To date, there are at least seven loci coding for gerbil coat colour known, some of them with up to four alleles. However, agouti, black and spotted are still the most frequent colours in laboratory gerbils; other colours are rarely used. Colour varieties and breeding for colour is more common in pet gerbils. There are differences in behaviour and physiology between the agouti and black (Dizinno & Clancy 1978), and females seem to prefer males of their own fur colour (Wong *et al.* 1990). Also, there seems to be a connection between coat colour and seizure propensity in gerbils (Gray-Allan & Wong 1990; Fujisawa *et al.* 2003). When breeding the gerbil in the laboratory it is important to note that 'spotted' is a homozygously lethal, dominant gene (Waring *et al.* 1978). Therefore, if two spotted gerbils are mated, about a quarter of their offspring will die *in utero*. To improve reproductive output, spotted gerbils should always be mated to non-spotted ones.

## Strains and supplies

A number of strains are available from the major breeders. Most of these gerbils are inbred due to several bottlenecks and founder effects in the history of laboratory gerbil breeding. Several authors have described and bred seizure-prone animals (Gray-Allan & Wong 1990; Buckmaster & Wong 2002; Fujisawa *et al.* 2003). However, these animals are not currently available from the major laboratory animal breeding companies. The original authors would have to be contacted for these strains.

## Laboratory management and breeding

### General housing and husbandry

#### Temperature and humidity range

Originating from arid steppes with continental climate (a dry climate with temperature extremes), gerbils can tolerate a wide range of temperatures. In the wild, they would escape these extremes by going underground into their burrows. Without a burrow, but with the opportunity to build an isolating nest and with deep substrate, they can tolerate between 0 and 35°C provided that that humidity is low and food is available *ad libitum*. Juvenile gerbils are unable to thermoregulate before the age of 12 days. Endothermic capacity then increases until the age of 21 days (McManus 1972b). Adults are more temperature tolerant (18–29°C) than juveniles (19–24°C) in the laboratory, therefore gerbils should be kept at temperatures between 20 and 24°C and humidities between 35 and 55% (ie, at lower humidities than suggested for other laboratory rodents) (Council of Europe 2006). At higher humidities, gerbils develop a matted, ruffled fur due to activation of the hard-erian gland. The secreted substances of this gland are distributed all over the fur by the animals grooming themselves, then evaporate and help cool the body. If humidity is too high, no evaporation occurs and hard-erian secretions remain in the fur, rendering it matted (Thiessen & Yahr 1977; Grant & Thiessen 1989).

#### Burrow/shelter

In the wild, gerbils dig their own extended burrow systems. Bannikov (1954) recorded 14–504 burrows per hectare; the author observed regions in Mongolia with gerbil burrows every 10–15 m. Gerbil burrows contain several of metres of tunnels, food and nest chambers (Naumov & Lobachev 1975; Thiessen & Maxwell 1979; Brunner 1993; Scheibler *et al.* 2006b). The burrow is one of the most important resources for gerbils in the wild: it offers protection from climatic extremes and from predators, allows for raising pups in relative safety and for storage of food (Naumov & Lobachev 1975; Thiessen & Yahr 1977, p. 64). Captive and domesticated gerbils show pronounced burrow digging behaviour. Raising gerbils without a burrow or burrow-like structure in the laboratory has a profound effect on their behaviour. Wiedenmayer found that lack of an adequate burrow structure consisting of at least a nest chamber and access tunnel leads to stereotypic digging in the corner of

the cage, an abnormal behaviour exhibited for up to 21% of active time, with bout lengths from 12 s up to several minutes at a time (Wiedenmayer 1995, 1996, 1997a, 1997b). Gerbils reared in a burrow structure (Figure 23.2), however, do not develop stereotypic digging. Laboratory gerbils should, whenever possible, be provided with an artificial burrow system that consists of a dark nest chamber of at least 13 cm × 13 cm × 13 cm, accessible via a dark tunnel (length about 15–20 cm, diameter about 5 cm). Wiedenmayer's findings were independently confirmed by Schmook (2004) and the author of this chapter (Waiblinger & König 2004). Schmook even found that established stereotypic digging in adult gerbils can be reduced if an artificial burrow is added. In Switzerland, these findings led to an adjustment of the minimum housing requirements of gerbils in the laboratory. According to the revised Swiss Animal Protection Ordinance, laboratory gerbils need to be provided with an artificial burrow structure or the opportunity to dig in deep substrate. Also, The Council of Europe ETS No. 123 recommends either a thick layer of substrate for digging or a burrow substitute for gerbils. Unfortunately, no such artificial burrow system is commercially available to date. One prototype example can be seen in Figure 23.3.

The presence or absence of a shelter also affects other behaviour. Upon presentation of a startling visual stimulus, shelter-reared gerbils respond by fleeing, foot-thumping and concealment, whereas open-reared gerbils approach the stimulus. After 24 h of access to a shelter, open-reared gerbils also start to flee into the shelter (Clark & Galef 1977, 1979; Cheal & Foley 1985; Cheal *et al.* 1986). In the author's experience, gerbils reared with a burrow are shyer and more difficult to handle. Offering gerbils an artificial burrow increases costs and animal care workload. Depending on the research project for which the animals are intended, rearing with shelter may or may not be advisable. See also Chapter 10 regarding enrichment.

#### Minimum cage requirements

Gerbils should be kept in solid-bottomed cages with a thick layer of substrate (at least 5 cm) to allow for digging. It must be gnaw-resistant, for example made from polycarbonate. Cage height should be at least 15 cm but 18 cm is better to allow the animals to rear on their hindlegs. The EU Council's Group of Experts on Rodents and Rabbits suggested a minimum cage floor area of 1200 cm<sup>2</sup> and a height of 18 cm for gerbils, with 150 cm<sup>2</sup> per animal weighing less than 40 g, and 250 cm<sup>2</sup> per animal weighing more than 40 g, either for same-sex groups or breeding pairs and their offspring (Council of Europe 2006). If an artificial burrow (nest box and 20 cm access tube) has to be fitted in a cage, the minimum floor area for breeding pairs should be 1500–1800 cm<sup>2</sup>, otherwise these structures are difficult to fit in conveniently (author's own experience).

#### Environmental provisions

##### *Digging and chewing opportunities*

Since gerbils are proficient diggers and gnawers, they should be provided with digging and gnawing opportunities: digging substrate such as wood chip bedding, and chewable

**Figure 23.2** Laboratory gerbils in a self-dug burrow in moist sand (a) and layout of such a burrow (b), dug in terrarium measuring  $0.5\text{ m} \times 1.5\text{ m} \times 0.6\text{ m}$ , side views. The big terrarium contained a smaller one, placed upside down into the bigger one, inaccessible to the animals. The gerbils were only able to dig tunnels in a 10 cm thick layer of moist sand between the two terrarium walls, therefore practically all tunnel and nest structures were visible from the outside (system described by Hauzenberger *et al.* 2006). 1: litter nest, 2: sleeping nest (Waiblinger, Ramer & Riva, unpublished).

materials such as hay, straw, tissues, paper, cardboard, branches and wood sticks. All this material is autoclaveable, and if the gerbils are not used for nutritional studies, there is no reason for not providing them with gnawing material. As substrate, wood chips and wood shavings are generally used, for example aspen shavings.

#### *Sand bath*

In pet gerbil housing, offering a sand bath (bird or chinchilla sand) has proved very successful for fur cleanness and fur shine, and Pendergrass and Thiessen (1983) have shown that sandbathing helps thermoregulation in gerbils. In the author's experience gerbils regularly use the sand bath, first to wallow and roll in it, then as a latrine.

#### *Running wheels*

Running wheels are not a necessary provision; Sherwin (1998) either found no or negative effects on gerbils. At the University of Halle, it was found that wheel running and bar gnawing are mutually replaceable abnormal behaviours (Master thesis B. Hünemörder, personal communication), and that activity patterns of gerbils differ significantly

between those with running wheels and those without. The latter exhibit the typical biphasic crepuscular activity pattern, the former only one activity peak during night-time (Refinetti 2006; Weinert *et al.* 2007). If running wheels are used, they should be 30 cm in diameter, and not have rails or spokes, but a solid running surface.

#### **Social grouping**

Gerbils should not be housed alone whenever possible. Neonatal maternal separation leads to behavioural and neurochemical depression-like changes that differ in males and females, with more pronounced effects in males (Jaworska *et al.* 2008). If adult pair-bonded gerbils are separated, fatness and transient depression- and anxiety-like symptoms can be observed (Starkey & Hendrie 1997, 1998a, 1998b; Hendrie & Pickles 2000; Starkey *et al.* 2007), as well as pregnancy failure (Norris 1985). Singly housed gerbils show pathological changes in the dopamine innervation of their prefrontal cortex that impair learning and working memory (Winterfeld *et al.* 1998), and increased activity and heart rate (Weinandy 1995). If separated for too long, they may react with aggres-

(a)

(b)

**Figure 23.3** (a) Artificial burrow system which can be inserted into a laboratory cage type IV. (b) It consists of a dark nest box, access tube and an additional transparent box.

sion upon regrouping with their old group-mates. The author observed aggression occurring after just 2 days of separation.

Gerbils can be kept in breeding pairs of one female and male with their offspring. The offspring can remain for some time after the birth of the next litter (see sections on extended family groups and sexual suppression, and on abnormal behaviour). Some authors also suggested polygynous breeding pairs with one male and two females (Marston & Chang 1965). On the other hand, gerbils can be satisfactorily kept in same-sex groups of two or more animals. It is the experience of the author, and of thousands of pet gerbil owners, that in contrast to male mice and to recommendations made by the Council of Europe (2006 p. 19), male gerbils can easily be kept in same-sex groups. Same-sex male groups are usually more harmonious than same-sex female groups.

The following suggestions reflect the author's experience in grouping gerbils since there are no systematic studies on the success of the various grouping methods. Creating new adult gerbil groups is difficult because of aggression exhib-

ited towards strange animals and should be avoided, except when forming opposite-sex breeding pairs (Clark *et al.* 1986). In this case, grouping during oestrus is advisable. Preferably, same-sex groups should be formed before the age of 7–8 weeks. Unfamiliar animals should always be brought together in an unfamiliar enclosure, such as a freshly prepared cage, and be observed for at least 2 h. The animals can alternatively be separated by a screen or wire mesh partition for 5–7 days before allowing direct contact (Clark *et al.* 2002). Intensive ano-genital sniffing, chasing, slashing tail and grinding teeth are signs of high arousal and gerbils displaying such behaviours should be distracted by food, sound or short blasts of air. If fighting starts, the animals should immediately be separated (wearing thick gloves is advisable) and they should not be reintroduced to each other. On the other hand, the author's experience is that, if a gerbil pokes its head under the snout of another, performs high, but audible cheeps, and is groomed on the back or belly, grouping was successful. Animals sleeping huddled together can be left alone.

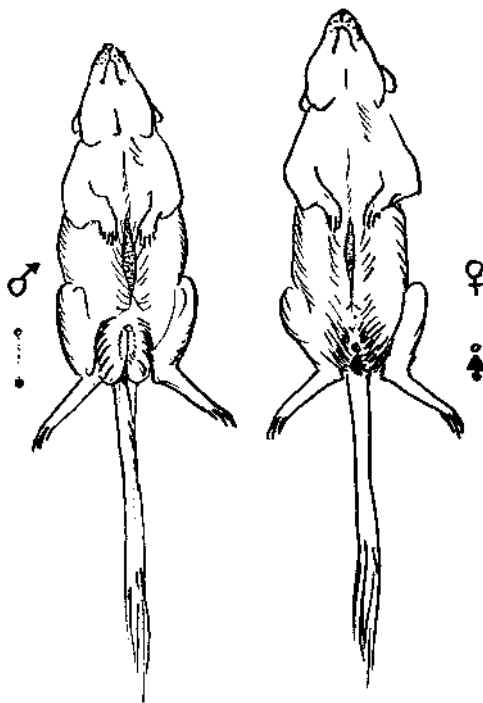

### Identification and sexing

Gerbils can easily be marked by clipping their fur in defined patterns. If only the upper parts of the hairs are shaved, the darker underfur will show. Colour dyes can also be used, however clipping fur is much easier and will last for 5–6 weeks in adults. Placing subcutaneous transponders for identification between the shoulder blades needs a short anaesthesia, but will mark the animals permanently. The newest transponders are only 4 mm long and less than 1 mm in diameter. Toe-clipping should not be used, except as a last resort for neonates where the other marking methods are not applicable. However, Leclercq and Rozenfeld (2001) have suggested plantar tattooing of neonates as an alternative to toe-clipping.

For sexing, the animals should be placed on a smooth surface and lifted at their tail-base since they should not be placed on their back. Sexing is easy in adult gerbils: the distance between genital papilla and anus is double in males, the connecting line is thin and covered with fur. Scrotal sacs are darkly coloured in agouti males. In females, the anogenital distance is much shorter, and there is a triangular naked area between genital papilla and anus (Figure 23.4). In juvenile animals, anogenital distance is the only distinguishable feature. In female neonates, the teats are visible, in males, the genital papilla is more prominent and has a roundish opening.

### Physical environment and hygiene

Because of low urine quantities, gerbil cages do not have to be cleaned as often as mouse cages. Depending on stocking

**Figure 23.4** Sexing adult gerbils. In males (left), the distance between genital papilla and anus is much greater than in females (right). The latter exhibit a triangular naked area between papilla and anus.

density and cage size, they might only be cleaned every 1–2 weeks. Cleaning is stressful to these animals, since they leave scent marks all over their territory. Weinandy measured stress responses in gerbils subjected to different stressors, using implanted heart-rate transmitters and found that cage change is less stressful than group recomposition, but more so than handling, confrontation with an intruder or confrontation with a resident animal, and that gerbils needed about 30 minutes for their heart rate to return to baseline after cage cleaning if this was done in their active time, and 120 minutes if cages were cleaned during their inactive time (Weinandy 1995; Weinandy & Gattermann 1997). Cages can also be partially cleaned, for example to avoid disturbing lactating or pregnant females.

### Health monitoring and quarantine

Health monitoring involves close observation of appearance (eg shiny, smooth fur vs. matted, ruffled fur), body weight (ie, weight loss as an indicator of poor health) and behaviour on a regular basis. Gerbils should be inquisitive and active, and should eat and drink normally. Implanted heart rate transmitters or temperature-sensitive transponders can give additional information, but since these methods are, to some degree invasive, they are not suitable for all cases. Gerbils purchased from outside should be quarantined and screened for infectious agents as appropriate.

### Transport

Only healthy animals should be transported. Special care has to be taken if pregnant or lactating females are transported. Only animals compatible with each other should be transported together; groups should not be mixed for transport. Transport boxes should allow sufficient air circulation, but also protect the animals from adverse environmental influences. Gnaw-proof boxes of non-toxic material must be used to prevent animals from escaping. Transport time must be minimised. Food and water should be provided on both short and long transports, since delays can always occur. Water can be offered in the form of gel packs ('solid drink'), moistened food and/or vegetables of high water content such as cucumbers, apple or lettuce. See also Chapter 13 and Laboratory Animal Science Association (LASA) (2005).

### Breeding

#### Condition of adults

Gerbils are less prolific breeders than mice or rats, due to longer interbirth intervals, smaller litter sizes and higher pre- and post-natal pup mortality. Future breeding animals should remain with their parents as long as possible. This is advantageous for future breeding performance since the animals thus gain experience in pup care, resulting in measurable benefits of their own future reproductive performance (Salo & French 1989; French 1994). Norris and Adams (1972) found that the shortest interval (40 days) from pairing

to parturition was achieved if mature, sexually experienced males were paired with inexperienced or experienced females, and longest (up to 90 days) if inexperienced males of 60 days were used. Clark *et al.* (2002) introduced females of various ages (35, 70, 90, 100 days) to experienced males and found latency to parturition being 34, 36, 45, and 78 days, respectively. The probability of younger females getting impregnated by the first male they were paired with was much higher. Older females tended to have smaller litters than younger females, and longer interbirth intervals, but they were more likely to retrieve removed pups to the nest, spent more time in contact with and nursing the pups, and their pups also grew more rapidly. Older mothers gave birth to more male-biased litters, as predicted by parental investment theory. It is therefore difficult to suggest an optimal age for pairing female gerbils. Future breeding animals should be introduced to each other between the ages of 60 and 90 days. Gerbils should not be paired too early, since familiarity resulting from growing up together can inhibit or delay reproduction in females (Clark & Galef 2001a, 2002; Clark *et al.* 2002).

#### Identifying fertile state

In laboratory males, testes descend at 30–45 days of age. Roughly 40 days later, active spermatogenesis and mating behaviour begin (70–84 days). Suggested breeding age for males is 75–85 days (Field & Sibold 1999). Without serum testosterone analyses, it is impossible to distinguish so-called 'stud' or 'dud' males (ie, those that will be able to father many offspring or not, see Reproduction section). However, since males with low circulating testosterone levels and lower litter sizes care better for their young, the effect of a low testosterone level is somewhat compensated.

Vaginal opening is at 40–76 days of age, depending on the animal's social surroundings (Norris & Adams 1979b). Sexual maturity is reached at 63–84 days of age if the female is separated from her mother and sisters after weaning. Females are able to breed from 3 months to about 3 years and longer (Field & Sibold 1999; I.W. Stuermer, personal communication). The mean age of wild gerbil females first giving birth was 199 days (F0, wild-caught); for the offspring (F1) of wild-caught gerbils this figure was 71 days (Blottner & Stuermer 2006; Stuermer *et al.* 2006). If paired at 60 days, earliest age at first conception lies around day 75, but Clark and colleagues (2002) observed the first litter being born to a female aged 69.7 days, if paired at the age of 35 days.

#### Breeding systems

The social system of gerbils indicates monogamous pairing as the optimal breeding system (Agren 1984b; Clark *et al.* 1986; Solomon & Getz 1996; Saltzman *et al.* 2006). Polygynous systems can result in aggression between the females, but some authors prefer this mating system (Marston & Chang 1965; Scheibler *et al.* 2005a, 2005b).

Fostering is possible in gerbils and is most successful within 24h after parturition. For artificial insemination the same techniques are used as in rats and mice. After PMSG and hCG treatment, sperm is injected into both uterine horns. Artificial insemination has a success rate of about

50%. Reasons for infertility in females are often neoplasia of the ovaries and uterus, or ovarian cysts. Ovarian cysts have a prevalence of 4.3–50% in gerbils.

#### Conception and pregnancy

Basic reproductive data are taken from Burley (1979), Marston and Chang (1965), Norris (1987), Norris and Adams (1972, 1974, 1981a, 1981b, 1982) and Tumblebrook Farm (1979).

Mating occurs when females are in oestrus during normal oestrous cycles, during post-partum oestrus (13h after parturition, 80% fertility) and after weaning, if the female was not impregnated during post-partum oestrus. The cycle length is 4–6 days. Peak activity of mating is 2–3h before the onset of the dark phase in the late afternoon, duration of oestrus is between 12 and 18h. The onset of post-partum oestrus is about 13.5h after parturition, ie, the delivery of the last pup. This duration of this oestrus is somewhat shorter: 7–9h (Prates & Guerra 2005). Mean ovulation range is 6.6 ova (range 4–9). During post-partum oestrus, females spend more time in pup-related behaviours, such as crouching over the pups, licking them, staying in the nest with them or nest building, than males. Males exhibited more female-directed behaviour such as allogrooming and sniffing, and engaged in intense copulatory behaviour (593 mounts or one mount every 47s). Even during delivery, males attempted to mount, but were rejected at all times by the female. Gerbil males do not help females during parturition as occurs with dwarf hamsters. Paternal behaviour is suppressed by sexual motivation on the day of their mate's parturition and post-partum oestrus. Parental behaviour by males is pronounced before and after this day (Clark *et al.* 2004).

Oestrus can either be identified by female behaviour (Weinandy *et al.* 2002), or determined using vaginal smears (Marston & Chang 1965), which, however, is not very reliable, and further confused by the vaginal plug after mating. Leucocytes, epithelial cells with nucleus and cornified cells indicate phase I (also seen during pregnancy and pseudo-pregnancy); few leucocytes, many epithelial cells, early stages of cells with nucleus and cornified cells indicate phase II; and the lack of leucocytes plus many cornified cells indicate phase III, ie, oestrus. After mating, the vaginal smear is sperm-positive. During pregnancy, erythrocytes can also be seen in the vaginal smear from day 12 onwards and the vaginal opening is narrowed. During lactation a vaginal membrane develops which persists until weaning.

Copulatory behaviour patterns of females on the day of oestrus were described by Burley (1979). These included piloerection, present posture, darting and foot stamping, as well as an increase of female-initiated allogrooming and sniffing of the male's head and anogenital region. During oestrus, the male shows piloerection posture, presenting posture, intensive sniffing and chasing of the female before mounting the female, who responds with lordosis. Mounting occurs many times over a period of about 6h. Mating is accompanied by the male regularly foot stamping. Duration of a mount is about 2s. After mounting, both male and female lick their genitalia. A concealed vaginal plug develops in the upper part of the reproductive tract, but only remains in place for a day.

Implantation usually occurs 7–8 days after fertilisation. Pregnancy duration is between 24 and 28 days. However, if fertilisation occurred during post-partum oestrus, implantation of the blastocyst is retarded even further. According to Norris and Adams (1981a, 1981b), pregnancy duration is then increased by 1.9 days per neonate, if three or more pups of the previous litter are suckled. Pregnancy duration can increase to a maximum of 48 days. Pregnancy has a strong impact on maternal resources, especially if females are both pregnant and nurse the last litter. Females whose dams were both nursing while gestating them and were pregnant while suckling them are less fecund (smaller, more female-based litters) and show lower attachment to their mates (Clark *et al.* 2006). Pregnancy can be palpated from day 15 onwards, the teats are clearly visible from day 14. The female gains 10–30 g during pregnancy. Mating with unfertile males can lead to a pseudopregnancy of 13–23 days. Embryo-transfer has been described by Norris and Adams (1986).

Mean number of litters per reproductive lifespan in females is  $7.6 \pm 3.8$ , with a maximum of 17 (author's breeding colony), with litter size decreasing after the tenth litter. Life reproductive success is 33–48 young born per female (maximum 54).

### Nesting

The female builds the pup nest, but the male is also involved in nest building. Both males and females shred material (tissues, straw, hay, textiles) into small pieces, collect these in their mouth and carry bundles of them to their nest. If a nest box or shelter is available, gerbils also pad it out with nesting material. A nest is either globular or more frequently hemispherical, with a depression in the centre. Globular nests are constructed if the gerbils are kept at low ambient temperatures and if the female is caring for offspring. Nest-building serves both thermoregulatory and reproductive functions. One needs to be aware that the nest is located underground in wild gerbils, so depth underground adds additional insulation.

### Parturition

Parturition occurs usually during the night, its duration depends of the number of pups. The birth of one pup lasts 10–15 minutes; the whole parturition is somewhat longer than 1 h. The female eats placentae and stillbirths. The number of pups depends on the age and condition of the female, with very young and older females delivering smaller litters. The pups are altricial. Except for the first day post-partum the male is involved in pup care. Experienced males, either through prolonged residence with their own parents or through having raised their own young, are beneficial for the pups' development. Males are active in nest building, huddle over, clean and occasionally retrieve pups.

### The young

Basic developmental data are taken from Marston and Chang (1965), Norris (1987), Norris and Adams (1972, 1974, 1982) and Tumblebrook Farm (1979).

### Litter size and development

The litter size of wild gerbils averages 4.5. In laboratory gerbils, the litter size is 5.5, with a range of 1–12. Depending on whether the female is both pregnant with the next litter and suckling pups of the present one, inter-litter interval varies between 25 and 49 days. Mean inter-litter interval is 29–35 days (colony dependant). Neonatal mortality is around 20%, with most mortality in the first 5 days. Exceptionally large litters may show mortality up to 57%, and, likewise, single-pup litters may have high mortality (eg, 75%). Sex ratio is 1.03 at birth, but decreases to 1.0 at weaning age due to higher mortality in males (Field & Sibold 1999). Causes of pup mortality are lack of care, insufficient milk, suffocation, or failure of older pups to reach food or water due to poor cage layout.

Ear opening occurs between days 12 and 14, the first hair appears at 5–7 days, incisors erupt at 10–16 days, and the eyes open between days 16 and 20 (14 days earliest eye opening). Upon eye opening and eruption of the incisors, pups start to venture out of the nest box, digging and eating solid food. Birth weight is inversely correlated with litter size. Singletons might weigh up to 3.3 g, compared with about 2.6 g in pups from large litters (over 10 pups). Males are about 5% heavier than females, a sexual dimorphism that is increased to 10% at older ages. Adult weight is reached at the age of 3 months.

### Weaning age

Gerbil pups are artificially weaned at between 20 and 30 days, however, 21 days should be the earliest, and weaning at 28–35 days is recommended. The time between 3 and 4 weeks is critical, since the pups switch from milk to solid food only during this week and change to being completely homeothermic. Food and water should be placed within the cages from day 14 since such small pups cannot reach up to the food hopper and nipple of water bottle. Pups take their first solid food (vegetables or salad) from day 16, and dry pelleted food from day 18 onwards. Weaning weight should be at least 12–18 g, preferably 20 g, and pups should be checked for regular eating and lack of diarrhoea before separating them. Several aspects of behaviour suggest that an even later separation of pups and family would be advantageous: if gerbils are separated before the next litter of younger siblings is born, a significant increase of bar-gnawing is noted after the separation. Additionally, remaining with the family for the duration of the raising of another litter provides future breeding animals with relevant experience.

### Infanticide

Infanticide is very rare, but does occur in both males and females. It occurs spontaneously (Saltzman *et al.* 2006) or under poor husbandry conditions, for example if the female is undernourished during lactation. The author observed one female eating her 7-day-old pups after the animal care staff forgot to replenish the food. In contrast to house mice, infanticidal gerbil females do not first kill the pups, but might start to eat them from the tail region. If male gerbils are food-deprived, they might also become infanticidal (Elwood & Ostermeyer 1984).

## Feeding

### Water

Gerbils exhibit several adaptations to dry climate: they excrete relatively low amounts of urine (3–4 ml per day compared to 6 ml in the golden hamster, also an animal of arid habitats) and quite dry faecal pellets (McManus 1972a). They tolerate quite high salt concentrations (McManus 1972a). Mongolian gerbils are able to survive without drinking water or consuming green foodstuffs by the use of metabolic water, arising, for example via the oxidation of lipids (Wang *et al.* 2003). If provided with *ad libitum* water, gerbils consume 4–10 ml of water per day (McManus 1972a; Field & Sibold 1999). Experiments summarised by Thiessen and Yahr (1977) show that depending on the composition of the food (its fat content), water-deprived gerbils die after losing 30% of their body weight. Water deprivation also results in a halt of reproduction in breeding pairs. Pregnant and lactating females are especially susceptible to water under-supply. In the laboratory, with dry food pellets and low humidity, *ad libitum* water supply should be provided in any case. This is in accordance with recently revised European guidance (Council of Europe 2006): 'Uncontaminated drinking water should always be available to all animals.'

In general it is easier to provide water *ad libitum* via bottles or an automated drinking system than by regular supply with greens and vegetables. However, salad, dandelion leaves, cucumber, carrots, pumpkin (seeds and flesh), zucchini, fennel, etc are well liked by gerbils, as are fruit such as apples, pears, melon, etc. In contrast to the situation in the degu (*Octodon degus*), gerbils have not been found to be susceptible to type 2 diabetes (Besselmann & Hatt 2004), therefore sweet fruit and vegetables can be offered occasionally.

### Food

In the wild, gerbils are granivorous–herbivorous animals (Wang *et al.* 2003). Their diet consists of green parts of plants and seeds, for example of grasses, wormwood (*Artemisia* sp.), and various other, locally available plants with the occasional insect or larva as a supplement (Bannikov 1954; Naumov & Lobachev 1975; Scheibler *et al.* 2006b).

Gerbils hoard food extensively, both in the wild and in the laboratory (Naumov & Lobachev 1975; Agren *et al.* 1989b; Tsurim & Abramsky 2004). The author has seen laboratory gerbils stuffing food pellets in one corner of their cage, if loose food is available. In the wild, gerbils hoard up to 20 kg of food for winter (Naumov & Lobachev 1975), and pet gerbils sometimes hoard several kilograms of food despite the relatively constant temperatures of their surroundings. Gerbils have been used to analyse food-searching strategies and patch-choice theory in the laboratory (Forkman 1991, 1993a, 1993b). Food preferences are socially transferred in gerbils. Mothers pass on their food preferences to their pups (Valsecchi *et al.* 1996, 2002), but gerbils also learn food preferences from familiar or related conspecifics (Galef *et al.* 1998). Hunger also influences the acquisition of food preferences (Forkman 1995).

In the laboratory, gerbils can be fed standard mouse, rat or hamster breeding chow; however, the protein content needs to be 22% and fat content only 4% to prevent the development of obesity. This pellet diet can be supplemented with grains and seed mixtures. Gerbils can be easily trained for various laboratory routines by rewarding them with sunflower seeds or pumpkin seeds. These seeds have a very high fat content and should be used with restraint.

Food and water should be provided in a way that allows all animals, including pups, to access them. One way of presenting food is scatter it on the bedding. In the author's opinion, this has several advantages over presenting it only in the food hopper: it is accessible for all animals, it is hoardable, and the animals are occupied searching for food in the bedding. Since gerbils produce very few drops of urine, their bedding stays clean for a longer time than that of mice or rats, therefore food in the bedding will not be contaminated by urine so quickly. Gerbils eat about 18 times during the day at random times, therefore their stomachs contain a little food all the time (Kanarek *et al.* 1977). As a rule, food should be presented *ad libitum* and should not be time restricted.

## Laboratory procedures

### Handling

If carefully habituated, gerbils can be caught with cupped hands. An easy way to catch them is to use tubes since they will readily enter any tube provided. Usually they are caught at the base of their tail, with the body being immediately supported by the other hand. If gerbils are caught at the tip of their tail, they tend to struggle and kick vigorously, resulting in shedding of the skin of the tail (degloving). Gerbils can be restrained by a neck-grip, also securing them at the base of the tail. However, they often struggle very much when placed on their back. In small animal practice, a soft towel is often used to restrain adult gerbils. They are tightly wrapped in a towel from behind and will often remain still as long as some pressure, but not too much, is applied around their body (Figure 23.5). Gerbil pups can

**Figure 23.5** Gerbil restrained by wrapping the animal in a towel, a method often used in small animal practices.

**Figure 23.6** Gerbil habituated to coming forward in the laboratory cage, using positive reinforcement.

comfortably snuggle in a slightly closed fist. Gerbils can be habituated very well to handling procedures by offering them a treat if they come forward in the cage voluntarily and climb on a hand, and by rewarding them after replacing them in the cage and after procedures (Figure 23.6).

## Physiological monitoring

### Recording body temperatures

As noted earlier, gerbils have a body temperature of around 37.4–38.4°C. Body temperature can be measured by using a rectal probe, but this needs handling and manipulation, which itself could induce stress and temperature changes. For regular temperature readings, a subcutaneous temperature-sensitive passive transponder, injected (under isoflurane anaesthesia) between the shoulder blades, is recommended (Kort *et al.* 1998; Newsom *et al.* 2004). Infrared laser scanners can also be used to measure body surface temperature in slightly restrained animals. If gerbils are implanted with heart rate transmitters, core temperature can be measured (Weinandy 1995; Moons *et al.* 2007), but this needs major surgery.

### Collection of specimens

#### Blood

Haematological and clinical chemistry data are provided by Field and Sibold (1999 p. 10–11). Blood volume is 6.7% of

body weight or 66–78 ml/kg (van Zutphen *et al.* 2001). To be on the safe side, maximal blood volume to be collected should not be more than 10% of the purported maximal blood volume. The Swiss Laboratory Animal guidelines allow collection of a maximum of 1 ml in a gerbil weighing 80 g, or a maximum of 20% of the total blood volume within 2 weeks<sup>1</sup>. See also Joint Working Group on Refinement (JWGR) (1993) for general guidance on blood collection.

Blood collection routes have been summarised by Field and Sibold (1999). Blood can be collected from the lateral tail vein after warming the tail, either by placing it in warm water, by setting the animal under an infrared lamp or in a warmed chamber (30–35°C for 10–15 minutes) to allow for vasodilation. Another accepted method is the puncture of the saphenous vein (Hem *et al.* 1998). Small amounts of blood (0.1–0.2 ml) can also be attained by cutting the tip of the tail, a procedure that is usually only allowed once per animal in animal welfare guidelines. Retro-orbital sinus blood collection is also possible in gerbils, but it needs to be performed under anaesthesia, and, according to many animal welfare laws and guidelines, must be performed not more frequently than 2 weeks apart at the same eye. Unfortunately, puncture of the sublingual vein under inhalation anaesthesia has not been described in gerbils so far, despite its advantages over retro-orbital puncture in rats (safe, quick, improved healing) (Zeller *et al.* 1998). Cardiac puncture should be reserved for terminal blood collection and must only be performed under anaesthesia.

#### Urine

To collect urine, gerbils can be placed individually in metabolic cages. A much simpler method is to place filter paper in bedding-free cages. However, there is a danger of the gerbils shredding the paper within hours. Gerbils can also be placed in wire mesh bottom cages with a sheet of metal below to collect urine over 24 h (Fenske 1990, 1996; Waiblinger & König 2004). Handling can also be used to induce urination.

#### Faecal samples

Faecal samples can easily be collected, since they are dry and do not stick to the bedding. Gerbils produce about 15–20 dry pellets or 1.5–2.5 g faeces per day (author's own experience). Collecting these from the bedding is more tedious than using a metabolic cage, but probably less stressful for the animal, since it can be left in its own cage and bedding. Cortisol extraction from faeces has been done, however, Fenske (1996) found a dissociation of plasma and faecal/urinary cortisol after application of stressors (see above). However, faecal cortisol measurements might be used to assess long-term stressors.

#### Vaginal smears

To take vaginal smears, the same methods can be used as with mice: using a pasteur pipette with a rubber teat and irrigating the vagina with a small volume of sterile, warmed physiological saline. However, vaginal smears are not very well suited for determining oestrous state in gerbils.

<sup>1</sup><http://www.bvet.admin.ch/themen/tierschutz/00777/00778/index.html?lang=de>Richtlinie/Guideline No. 800.116-3.02>

### Milk

Collection of milk in gerbils has been described by Rassin *et al.* (1978). For the exact method of collecting milk from small rodents, see Feller and Boretos (1967) and Raffel and König (1999).

## Administration of medicines

### Dosing and injection procedures

Routine application procedures used for mice and rats can generally also be used for gerbils. Since gerbils should neither be held by their tails nor turned on their back, the procedure for intraperitoneal injection should be modified. The gerbil is placed on the wire top of a cage, where it will try to walk away. First the base of the tail is picked up with one hand, and the hindquarters of the animal lifted slightly off the grid. With the same hand, thumb and forefinger, the loose skin at the neck is picked up and the animal can be raised to an upright, vertical position (head up), at which time the injection can be made with the free hand or by an assistant. Intravenous injection in the femoral vein and the external jugular vein, both under anaesthesia, have been described since the lateral tail vein is not as easily accessible for injections in gerbils as in mice or rats due to their furry tail (Pérez-García *et al.* 2003; Kakol Palm & Hollaender 2007). Subcutaneous injections are usually given in the loose skin between the shoulder blades. In general 23–25 G needles are used. Details on dosing various common substances can be found in Field and Sibold (1999), pp. 73–75.

### Anaesthesia and analgesia

In commercial small animal veterinary practice, isoflurane inhalation anaesthesia via precision vaporiser is generally used as the method of choice for small mammals such as gerbils. It is used at 2–5% for induction, and 1.2–2.3% for maintenance. Recovery from isoflurane anaesthesia is usually very quick. Methoxyflurane has also been used in gerbils (Norris 1981). It is to be noted that these gaseous anaesthesia agents do not have analgesic properties, and therefore pre- and post-surgery analgesia must be used where appropriate. Field and Sibold (1999) present a list of commonly used, injectable anaesthetics and their combinations (p. 77). Some common intraperitoneally injectable anaesthetics for gerbils are: 50 mg/kg ketamine and 2 mg/kg clomazepam; 50 mg/kg ketamine and 2 mg/kg xylazine; or pentobarbital 60–80 mg/kg (duration 30–45 minutes). See also Flecknell (2009).

Post-operative pain should be relieved in gerbils using appropriate analgesia (this is required by most countries' animal welfare guidelines). A suitable analgesia regimen for gerbils might be 0.05–0.2 mg/kg buprenorphine sc or 0.003 mg/kg fentanyl sc (1:10 in NaCl; 1/3 of dose every 20 minutes) before surgery, and 5 mg/kg carprofen sc or 1 drop of meloxicam solution (5 mg meloxicam/ml) every 12–24 h after surgery, as required. Field and Sibold (1999) again list suitable analgesia agents for gerbils (p. 97), however, they centre on the opioids and do not give information about non-steroidal anti-inflammatory drugs (NSAIDs) such as

paracetamol or diclofenac. A list of suitable NSAIDs can be found in Flecknell (2007).

## Humane endpoints

If an animal shows signs of morbidity (disease or illness) for some days or is moribund (dying), then its condition should immediately be evaluated and a decision made as to treatment or euthanasia. In general, signs of morbidity are similar to those seen in hamsters and mice. Common signs, according to Field and Sibold (1999) include:

- hunched posture;
- ruffled fur;
- rapid weight loss (10–15% in a week);
- hypothermia or hyperthermia (depends on the experiment, ie, studies on infectious diseases differ from cancer studies);
- increased respiration rate;
- diarrhoea or constipation;
- changes in activity and behaviour;
- paralysis or other CNS signs.

For most of these signs, score sheets can be used. Body temperature can be measured non-invasively using subcutaneous, temperature-sensitive passive transponders (Kort *et al.* 1998; Toth 1997, 2000). Frequent monitoring for signs of morbidity is paramount if humane endpoints are to be applied.

## Euthanasia

Methods used for euthanasia must be painless, safe to apply and ensure a quick loss of consciousness. In the recommendations for euthanasia of experimental animals, the EU Commission working party suggests the following methods of euthanasia for rodents in general, not specifically for gerbils (Close *et al.* 1996, 1997), although national regulations may vary. See also Chapter 17.

### Physical methods

Physical methods suitable for gerbils are: stunning (only by well trained personnel), cervical dislocation or decapitation (only with specialised apparatus). If microwaves are used for euthanasia, only specialised apparatus adapted to the size of the animal and the species must be used to focus the irradiation exactly on the brain (Close *et al.* 1996, 1997).

### Chemical methods, injectable agents

Generally, if venepuncture and intravenous injection can be used, this route of administration (eg of appropriate barbiturate or other suitable agents) is recommended, since intraperitoneal injection is slower to act and might lead to irritation of the peritoneum. Other application routes for injectable anaesthetics should not be chosen except if the animal is fully anaesthetised, ie, no intracardiac injection of T61 (forbidden by law in Switzerland, for example, the EU working party also strongly discourages this application

route). Gerbils can be killed by an overdose of sodium pentobarbital, for example by intraperitoneal injection (>270 mg/kg, maximum 200 mg/ml injectable solution) (Field & Sibold, 1999). Three times the anaesthetic dose is recommended. T61 must be injected intravenously very slowly, and prior sedation might be required (for exact composition of T61 see Close *et al.* 1996).

#### Chemical methods, inhalational agents

If inhalation anaesthesia agents such as isoflurane, halothane or enflurane are used, the animals must be left in the chamber long enough for death to be ensured, and this must be confirmed, or the animals must subsequently be killed by another method that ensures their death, for example by decapitation or exsanguination. Methoxyflurane should not be used in gerbils. Animal welfare aspects of using carbon dioxide for euthanasia have widely been discussed; see Conlee *et al.* (2005) for a review, but also Leach *et al.* (2005). Carbon dioxide is aversive, and burrow-living rodents are reported to have a high tolerance for carbon dioxide. Both the prefilled-chamber and the gradual-influx methods have their disadvantages. If the gradual-influx method is used, the home cage of the animals should be covered with a tight-fitting lid. Carbon dioxide should be introduced from the top of the cage. Structures in the cage beneath the inlet (for example a nest box) help to distribute the gas equally through turbulence. Optimal flow rate is about 13 l/min for cages type III, 6 l/min for cages type II. Solid carbon dioxide (dry ice) should not be used, since carbon dioxide concentrations cannot be controlled and the animals must be prevented from touching the dry ice (Corbach 2006).

#### Euthanasia of neonates

Neonates cannot be killed by carbon dioxide, since they have a high tolerance for hypoxia. Neonates can be killed by decapitation (Close *et al.* 1997).

### Common welfare problems

#### Disease

##### Prophylaxis

In general, gerbils are remarkably healthy in captivity. The animals should be checked daily for their health status, and weighed at least once a week. Stressed animals are more susceptible to disease than unstressed ones. Positive reinforcement (training with treats) can be used to habituate gerbils to common handling and application procedures and reduce the impact of handling-induced stress (see Chapter 16).

##### Signs of disease

Diseased gerbils tend to show a reduction of activity, ruffled fur, hunched posture, diarrhoea and loss of body weight. Elderly animals tend to become emaciated (>3 years old) and to sink in at their flanks. Increased drinking might be indicative of either diabetes or renal failure.

#### Common diseases

Gerbils can contract Tyzzer's disease (*Bacillus piliformis*). Affected animals become apathetic and huddle in a hunched position in the corner of the cage with ruffled fur (Field & Sibold 1999). Sometimes diarrhoea can be seen. Since these animals do not feed, weight loss is quite severe, and the animals die within 1–3 days. Tyzzer's disease can be spread among animals by soiled bedding. If an outbreak occurs, affected animals, cages and rooms should be quarantined immediately. Tetracycline has been used to treat mice and might also be effective in gerbils. Oxytetracycline added to drinking water can be used, and dehydrated animals should be given rehydration therapy if they are not euthanased. Since *B. piliformis* is spore-forming, bodies, bedding, food and nesting material must be incinerated and cages, equipment and rooms thoroughly sterilised. Dihydrostreptomycin is toxic for gerbils and should therefore not be used (Field & Sibold 1999).

A much less severe condition is the red or sore nose disease sometimes observed in laboratory gerbils. The animals develop reddish sores (erythema) around the nose. Unpublished data of the author show that these sores were not caused by the animals digging in the substrate or by gnawing on the bars, since the occurrence and severity of the sore nose disease did not correlate with digging or bargaining frequency. Often, red nose disease is caused by a staphylococcal infection of the nose (*Staphylococcus aureus*) (Peckham *et al.* 1974). The author used odourless topical antiseptics creams or a systemic antibiotic treatment with good results in a non-SPF-colony (chloramphenicol 0.083 g/1100 ml water, or tetracycline 0.3 g/100 ml water for 14 days, as suggested by Field and Sibold (1999)). However, good hygiene should prevent the outbreak of this disease. As a rule, most gerbils recover from red nose disease, and only if the sores spread to larger areas of frontpaws and face, should animals be killed.

In aged animals, sebaceous gland carcinomas can occasionally be observed (Raflo & Diamond 1980; Matsuoka & Suzuki 1995; da Costa *et al.* 2007). Chronic interstitial nephritis is sometimes diagnosed in aged gerbils. Affected gerbils lose weight and exhibit polyuria and polydipsia (Johnson-Delaney 1998). Histopathological lesions of the ventral prostate have also been observed in aged gerbils (Campos *et al.* 2008).

Gerbils are prone to epileptic seizures and are used as a model to screen for antiepileptic drugs. Juveniles develop seizures at 2 months of age, by 10 months up to 80% of the animals can exhibit seizures of various degrees (Kaplan & Mizejes 1972; Loskota *et al.* 1974a; Kaplan 1975; Frey 1987; Cutler & Mackintosh 1989; Kupferberg 2001). For research not concerned with epilepsy, known seizure-eliciting stimuli such as handling stress, dangling by the tail, novelty, blasts of air or sudden noise should be avoided, as well as the use of seizure-prone strains of gerbils (Fujisawa *et al.* 2003). In the experience of the author, habituation to handling procedures reduces the incidence of epileptic seizures in gerbils, but this has not been analysed systematically so far. However, Jaworska *et al.* (2008, p. 539) mentioned having habituated gerbil pups to handling in order to reduce the frequency of seizures.

## Abnormal behaviour

Laboratory gerbils commonly develop two distinct, well recognised, abnormal behaviours: stereotypic digging and bar-gnawing (Figure 23.7). These behaviours are environmentally induced. Stereotypic digging is caused by the lack of an appropriate burrow structure, either self-dug or artificial. Provision with a dark nest box and access tube can significantly reduce the incidence of this behaviour (Wiedenmayer 1996, 1997a, 1997b, 1997c). Bar-gnawing possibly has social causes. Its development can be prevented if juvenile gerbils are not separated from their parents before the next litter is born, ie, if the juveniles are left with the parents for at least 5 weeks (Wiedenmayer 1997c; Waiblinger & König 2001, 2004; Waiblinger 2002, 2003). This might present some problems with standard laboratory routine.

Most animal welfare laws state that abnormal behaviour and stereotypies are a sign of suboptimal housing or husbandry, even a welfare problem, and should therefore be prevented. The method of choice is not the physical prevention of the performance of these behaviours, in gerbils for

example by denying them access to bars that might be chewed on, but the prevention of the ontogenetic development of stereotypies by removing the underlying causes of suboptimal housing or husbandry. Stereotypic behaviours in rodents originate from continuously thwarted motivations to escape or to search shelter (Würbel 2006), and therefore represent some sort of frustration and lack of control. There are strong indications that stereotypies result in CNS dysfunction (ie, recurrent perseveration and decreased dorsal striatal inhibitory behavioural control) (Garner 2006), thus making stereotypic behaviours fundamentally analogous to the repetitive behaviours associated with human pathologies such as schizophrenia and autism. Garner cautions against using such stereotyping rodents in behavioural tests in the laboratory since the underlying CNS dysfunctions might thwart their validity as animal models, at least if they are used in behavioural paradigms.

## Dedication

This chapter is dedicated to Rolf Gattermann whose premature death left a deep gap in the gerbil research community.

# 24 The Syrian hamster

David Whittaker

## Biological overview

### Taxonomy

Hamsters as a group can be described as stout-bodied, stubby-tailed, broad-headed, cheek-pouched, burrowing and nest building rodents. Some taxonomists (Nowak & Paradiso 1983) place hamsters in the family Muridae, whilst others (Corbet & Hill 1980; Honachi *et al.* 1982) retain them in the family of Cricetidae to which they were assigned in 1946 (Van Hoosier & McPherson 1987).

The most commonly used species in the laboratory is the Syrian hamster (*Mesocricetus auratus*), known also as the Golden Hamster. The Chinese (*Cricetus griseus*), Djungarian, or Russian (*Phodopus sungorus sungorus*), or Russian Dwarf and European hamsters (*Cricetus cricetus*) are less often used in research. For this reason, the remainder of the chapter relates to the Syrian hamster, unless otherwise indicated. A fuller account of the taxonomy of Cricetidae can be found in Van Hoosier and McPherson (1987) along with a tabulated classification scheme for 24 species in the family. Those using hamsters in research should be aware that accurate identification of the species used is essential for correct reproducibility of work and interpretation of results.

### Comparative anatomy and physiology

Species within the various hamster genera vary in body size. Hamsters in the genus *Cricetus* are the largest, *Mesocricetus* are medium sized whilst *Phodopus* are dwarf, mouse-like animals. Typically, adult Syrian hamsters reach weights of 150–180 g, Chinese hamsters 120–150 g and Djungarian 100–130 g. Larger European hamsters may reach 400–500 g.

Hamsters generally have shorter lifespans than rats and mice routinely used for long-term studies; Bernfeld *et al.* (1986) provide data from over 600 control F1 hybrid Syrian hamsters. There are also marked sex and strain differences, with males tending to live longer than females. Most reports of longevity record deaths from 1 year onwards with only 50% or less survival at 2 years. Hamsters rarely survive beyond 3 years, this age being more typically reached by Chinese rather than Syrian hamsters.

Adult females (Syrian) are larger than males, and Syrian hamsters have abundant, loose skin. Both sexes possess paired, bilateral scent or flank glands, consisting of sebaceous

glands, pigment cells and terminal hair. These glands are most prominent in the male, but are poorly developed in females.

The hamster's dental formula is:  $I_1^1C_0^0Pm_0^0M_3^3$ . They have only one set of teeth (monophyodont) and the cheek teeth are roughly quadrate and low crowned and (bunodont and brachyodont). Such teeth are characteristic of animals that have a diverse diet. The incisors are open-rooted while the molars are rooted. Primary eruption is regular. Some but not all genera possess buccal pouches extending dorso-laterally from the oral cavity on either side of the shoulder region. These structures are used experimentally as immunologically privileged sites. Hamster stomachs are divided into non-glandular and glandular segments separated by a muscular sphincter.

A detailed account of anatomy, physiology, haematology and clinical chemistry is available in Van Hoosier and McPherson (1987).

### Behaviour

Syrian hamsters are terrestrial, burrow-digging rodents. Their natural habitat is dry, rocky plains or lightly vegetated slopes. They build nests within their burrows. Although primarily grain eaters, they will also eat green plant shoots and roots, insects and fruit. In the wild, adults generally inhabit lone burrows (Van Hoosier & McPherson 1987).

Some species of hamsters hibernate under certain environmental conditions. Although this is of research interest it is not an important feature with respect to their husbandry in most laboratory situations. Hibernation can be induced in hamsters by a number of environmental stimuli including low temperature, short days, solitude, nesting material and adequate food stores. Aspects of behaviour which are of importance for their husbandry include their solitary nature, propensity to burrow and nest build and their nocturnal lifestyle. These are important factors in considering their housing and husbandry.

### Uses in the laboratory

Syrian hamsters have a number of unusual and unique features which make them particularly useful for certain experimental studies. The Syrian hamster has immuno-genetic

characteristics that underlie marked tolerance to homologous, heterologous and human tumours, parasites, viruses and bacteria. Moreover, the presence of reversible cheek pouches, which in the Syrian hamster appear to be immunologically privileged, allow tumour grafts from other species, including man, to grow freely and symmetrically without the need to induce immunosuppression.

The Syrian hamster has also been used for dental research as the form and occlusion of their molar teeth closely resemble those of humans and the induction of lesions is possible without fracturing of the teeth, as in rats. Other areas of use include teratology and the short gestation period is advantageous for inhalation studies. The Syrian hamster has been used in thermophysiology and circadian rhythm studies. Chijioke *et al.* (1990) described the use of the Syrian hamster oocyte in assessing human spermatozoal fertilising potential. They concluded it was a relatively precise method of quantifying the effects of various factors affecting human sperm function *in vivo*. Further detailed consideration of experimental biology in all hamster species can be found in Van Hoosier and McPherson (1987).

## Laboratory management and breeding

### General husbandry

#### Housing and caging

For routine purposes, cages and equipment designed for rats can be used for housing Syrian, Chinese and Djungarian hamsters. European hamsters require more space and stronger cages due to their size and aggressiveness towards each other. Table 24.1 sets out the space requirements for Syrian hamsters according to the revised Appendix A (adopted June 2007) of the Council of Europe Convention, ETS/123 (Council of Europe 2006) and the European Directive 86/609 (European Commission 2007). Table 24.2 sets out the space requirements for Syrian hamsters according to the US Guide for the Care and Use of Laboratory Animals published by the National Research Council (1996).

The differences between these guidelines illustrate the more general point that it is difficult to specify scientifically the minimal sizes of cages for maintenance. However the European guidelines took note of research indicating that hamsters were chronically stressed when housed in small enclosures, a condition likely to affect their welfare and the quality of science obtained from these animals (Kuhnen 1999a, 1999b).

While sufficient space is needed to allow appropriate enrichment and to give the animals some control over social interactions, other aspects of housing such as material of construction, floor type, provision of furniture and bedding, as well as appropriate social enrichment are equally important. Arnold and Estep (1994) explored the caging preferences of Syrian hamsters. Whilst their research showed that most Syrian hamsters preferred solid floors with bedding, they also demonstrated that previous housing conditions can affect cage preference and behaviour. Further information on environmental enrichment for Syrian hamsters can be found *Comfortable Quarters for Laboratory Animals* (Reinhardt & Reinhardt 2002) and see Chapter 10.

The Syrian hamster does not conform to the generalisation concerning other hamsters that males are more aggressive than females. Both sexes are highly aggressive, making group housing for welfare or experimental purposes problematic. Grell *et al.* (1974) investigated the influence of caging conditions and hormone treatments on fighting in male and female Syrian hamsters. They found that sex, hormonal state and caging condition interact in a complex manner. Arnold and Estep (1994) explored the effects of housing on social preference and behaviour in male Syrian hamsters. Their results showed that they spent more time in social proximity than out of proximity, especially if they had prior group-housing experience. In addition, singly housed animals showed more aggressive behaviour with conspecifics and lower weight gains than group-housed animals, which showed more evidence of wounding. They concluded that early housing experience can profoundly affect later social preference and behaviour.

In summary, solid-bottomed cages with bedding material are preferable and in general group housing may be preferable to individual caging so long as the groups are formed early in life and are stable and harmonious. Where this is not possible it is better to single house animals, either from the start of the study or, immediately upon arrival, if purchased from a commercial breeder. When group housing, there should be room for hiding or escaping from cage-mates.

#### Environmental conditions

Conditions suitable for maintaining rats and mice are also suitable for Syrian hamsters. Generally, seasonal variability in the Syrian hamster can be reduced by the provision of a constant temperature of 21–22°C and a minimum of 14h light. Such conditions will eliminate hibernation. Extraneous

**Table 24.1** Minimum enclosure dimensions and space allowances for Syrian Hamsters according to Appendix A of the Council of Europe Convention, ETS/123 (Council of Europe 2006) and the European Directive 86/609 (European Commission 2007). Reproduced with permission of FELASA.

Weight (g)	Floor area/animal (cm <sup>2</sup> )	Cage height (cm)
Less than 60	65	15
Up to 80	84	15
Up to 100	103	15
Over 100	123	15

\*Dimensions in Table 24.2 are to the nearest whole number as US measurements are in inches.

noise should be kept to a minimum, consideration being given to sources of ultrasound. Excessive deviance from the normal environmental parameters should always be avoided if at all possible, especially in breeding colonies when it may contribute to lowered breeding efficiency and maternal cannibalism.

### Identification and sexing

The marking of individual animals (other than by using microchips) should be avoided wherever possible as no completely satisfactory method has been developed. Ear punching can be performed as in other rodents and the ears of animals without dark pigmentation can be tattooed using a fine electric vibrating tattooing machine. Microchip implants have now become the preferred method for identifying many species of animals, including Syrian hamsters. Whilst they have the distinct advantage of being a reasonably permanent means of identification, microchip implants do have some disadvantages including cost, subcutaneous migration, chip failure etc. Although the author can find no specific reference to the use of microchips in hamsters, Ball *et al.* (1991) evaluated their use in rats over a 1 year implantation period and Mrozek *et al.* (1995) evaluated the method in rabbits, guinea pigs, woodchucks and amphibians. The author also has personal experience of successfully micro-chipping hamsters for long-term (2 year) studies.

The gender of mature Syrian, Chinese and Djungarian hamsters can be easily distinguished by the prominent testes of the male, even in pubescent animals, and the greater anogenital distance in the male (Figures 24.1 and 24.2). Sexing the European hamster however, presents some problems during the season when sexual activity ceases – usually October to February. It is difficult to tell the sexes apart at this time as the vulva of the female is closed and the testes of the male are drawn up into the abdominal cavity. At other times the criteria used for sexing other hamster species can be used.

### Transport

Transporting hamsters presents no special difficulties as long as plastic materials are used and no leading exposed edges are offered to the animals to chew. As an extra precaution when transporting European hamsters, a lining of fine wire mesh should be incorporated into the manufacture of the box. Boxes used for transporting other rodent species, made of plastic corrugated or sandwich construction with

**Figure 24.1** Male Syrian hamster.

**Figure 24.2** Female Syrian hamster.

plastic formed lids and incorporating filters over wire mesh panels of an adequate size, provide good insulation whilst being adequately ventilated.

Table 24.3 gives recommended stocking densities for Syrian hamsters in transit (Laboratory Animal Science Association (LASA) 2005). Optimum stocking densities are provided for non-filtered crates used during winter and for filtered crates travelling during the summer, representing the least and most demanding challenges to adequate ventilation respectively.

### Breeding

The influence of parity and litter size on weaning success and offspring sex ratio in Djungarian hamsters has been reported by Lerchl (1995). Table 24.4 presents breeding data for Syrian, Chinese and Djungarian hamsters. This section will concentrate on practical aspects of hamster breeding.

Sexual maturity of the Syrian hamster is reached by 42 days of age or earlier (see later in this section) and can be confirmed using the penile smear technique to look for the presence of sperm on the glans penis. Reproductive ability

at a very young age is marked in Syrian hamsters and it is not uncommon to find animals mating by 4 weeks of age. This can lead to husbandry problems with unplanned pregnancies occurring when litters are kept together post-weaning. Maximum reproductive capability is reached in Syrian hamsters by around 8–10 weeks of age for females and 10–12 weeks for males.

The oestrous cycle is regular, lasting 4 days. Two lateral pouches lined with cornified epithelial cells in the vagina of hamsters can make the vaginal cytology method of evaluating the phase of the cycle difficult. External indications of the cycle include the presence of a white, stringy, opaque discharge on the second day of the cycle followed by a waxy secretion on the third day. It is, therefore, possible to determine the day for mating by screening females for the stringy,

opaque discharge. This indicates that the female reached peak oestrus the day before and therefore she can be reliably mated on the third day after disappearance of the discharge. Large groups can be selected in this way with up to 90% conception rates.

Female hamsters are relatively aggressive in the presence of unfamiliar males and generally, unless sexually receptive, will not tolerate their presence. However, at peak oestrus the female Syrian hamster tolerates the male's presence and shows lordosis. Shortly afterwards copulation will take place, lasting around 30 minutes.

Using a breeding system in which females are selected in this way, one male can serve a harem of 12 females. This is a common method of breeding Syrian hamsters but is very labour intensive. The hamsters are mated soon after dark, when they are naturally most active. The female is placed in the same cage as the male and the pair observed to ensure mating occurs. Should fighting start, the pair must be immediately separated.

Monogamous pairing of hamsters at weaning is now considered the most satisfactory and labour-efficient method of breeding Syrian hamsters. Provided they are paired at this time they are normally compatible and produce very good results with weaning rates of around 1.4 young/female/week depending upon strain, with litter intervals of around 37 days. Djungarian and Chinese hamsters can also be bred successfully using the monogamous pairing system. In addition to being more efficient, monogamous pairing allows accurate record keeping and allows post-partum mating which can occur in Djungarian, Chinese and golden hamsters. It is however, unusual for conception to take place whilst the female is lactating.

Harem mating has been used for breeding Syrian hamsters but again is labour intensive and can be stressful for

**Table 24.3** Minimum floor area/animal (cm<sup>2</sup>) for Syrian hamsters during transport. Reproduced from LASA (2005) Guidance on the Transport of Laboratory Animals. Return to oestrus post partum	5–10 mins	Post-partum mating does occur	Post-partum mating does occur
No. of mammae	14–22	8	8

the animals. The usual procedure is to group one to four males with a large number of females and to separate out pregnant animals prior to parturition. Fighting will occur when the female is re-introduced into the harem.

Implantation of the fertilised ovum takes place 6 days post-coitus. It is important that at this time the animal is handled as little as possible. The Syrian hamster has a short gestation period (15.5 days) and the period is generally very regular, varying by only 2 or 3h. Pregnant females should be placed in clean cages with some form of nesting material and bedding approximately 2 days prior to parturition. Enough food should be made available in the cage to last the female 7–10 days so that there is minimal disturbance of the newborn litter. Any interference frequently results in cannibalism. Litter size normally increases with parity.

Newborn hamsters have closed eyes and ears, and are hairless but have teeth. Ears begin to open at 4 days, solids begin to be taken at 7–10 days and eyes open at 14–16 days of age. Water must be available to animals from 10 days of age. Hamsters are normally weaned around 21 days and the female re-mated. Figure 24.3 shows typical growth curves for the Syrian hamster.

The optimal reproductive life of a Syrian hamster is considered to be around 10 months and a significant reduction in reproductive capacity occurs from 1 year of age onwards. During her reproductive lifetime a female hamster will produce four to six litters.

It is commonly thought that cross-fostering is not possible, however Grainger and Plotkin (1987) investigated cross-fostering and maternal care in Syrian hamsters and concluded that it can be successfully undertaken at three different ages – soon after birth, at about 1 week of age and around 2 weeks of age. They found nest quality, survival and pup weights to correlate well. Cross-fostering could prove useful in disease control or eradication. However, the establishment of caesarean-derived, hand-reared hamster colonies has not yet been reported.

## Feeding

### Natural and laboratory diets

Hamsters are omnivorous and coprophagous and hoard food as a survival strategy in the wild. In the laboratory and intensive breeding situations complete diets of known formulation and quality are advised on both scientific and welfare grounds. Diets specifically formulated for rats and mice are adequate for the maintenance and breeding of hamsters (National Research Council 1978). Providing a good-quality, complete rodent diet is available, nutritional deficiencies are unlikely to occur. Vitamin E deficiency has been described by West and Mason (1958) and Keeler and Young (1979), but in both papers the deficiency was experimentally induced. More recently Mooij *et al.* (1992) described experimentally induced disturbed reproductive performance in extreme folic acid-deficient Syrian hamsters. Further information on hamster nutrition is available from Medical Research Council (1977) and National Research Council (1995).

### Water

A fresh, clean, *ad libitum* supply of water must be provided to hamsters either by means of water bottles or through automatic watering devices. The average daily consumption of water by an adult Syrian hamster is 10–20 ml depending upon the housing conditions, the type of feed and the hamster's physiological condition (eg, pregnancy, suckling).

## Laboratory procedures

### Handling

The Syrian hamster can have an unjustified reputation for being difficult to handle but this is usually due to poor or

Figure 24.3 Typical growth curves for Syrian hamsters.

intensive husbandry and breeding regimes. For routine handling the Syrian hamster can be picked up by a firm but gentle grasp across the back of the animal. Picking up by placing the thumb across the abdomen enables sexing to be carried out. Turning the animal over so that it lies in the palm of the hand, ventral side up, tends to inactivate most animals and has a quietening effect. This handling technique is illustrated in Figures 24.1 and 24.2. All species of hamsters can be picked up in a similar way but the use of cupped hands is preferred when minimal restraint is required.

For oral dosing, intraperitoneal injections and other manipulations most hamsters can be held by the dorsal skin ensuring that a firm grip is made at the scruff of the neck.

Hamsters can inflict serious bites, especially during the breeding season, so it is recommended that stout protective gloves are worn to handle the European hamster. However, animals may become tamer with frequent handling. When handling hamsters, it should be remembered that, under normal conditions, they spend long periods sleeping during the day when little activity will be seen. After diurnal handling they often appear aggressive towards their cage-mates and emit loud screeching noises and aggressive movements, disproportionate to the degree of interference. Information on the recognition and assessment of the signs of pain and distress in hamsters can be found in Wallace *et al.* (1990).

### Physiological monitoring

With care, a standard thermometer may be used to determine rectal temperature (37–38°C) but it is far more convenient to use an electronic, semi-rigid probe thermometer. In addition body temperature, motor activity and heart rate can all be monitored via telemetric devices.

### Blood sampling

There are no easily accessible, superficial veins in the hamster and therefore special care should be paid to the animal's welfare when collecting blood, which should be performed under general anaesthesia. Orbital venous sinus puncture, jugular access and cardiac puncture are recognised routes for blood sampling in the hamster. The circulating blood volume of the Syrian hamster is around 78 ml/kg body weight. Generally removal of no more than 10% of the circulating blood volume is advised at any one time. Further advice on the removal of blood from hamsters and other laboratory species can be found in a report by the Joint Working Group on Refinement (JWGR, 1993).

### Urine, faeces and expired gases

Standard glass, metal, or plastic metabolism cages can be used to separate urine from faeces, whereas only glass is recommended for the trapping of expired respiratory gases. The nesting of hamsters in feeders or other areas of metabolism cages should be avoided when possible. Cages that provide either access for liquid diets or closure of the access to the feeder may be used.

### Milk

A technique for collecting milk from mice has also been used for the collection of hamster milk, with only a minor modification to accommodate the longer nipple of the hamster. A plastic biopipette tip is placed over the nipple. Stimulants are not usually necessary to initiate milk flow. Experience shows that 0.1–0.2 ml total can be collected from two or three nipples on collections spaced a few hours apart. The use of approximately 1 USP unit of oxytocin, subcutaneously, will, however, increase milk flow if desired. No attempt has been made to collect milk more than 3 days after birth.

Various methods have been described for collecting saliva, bronchopulmonary lavage, ejaculate, vaginal mucus, urine, faeces, expired gases, milk and bile. More information on these techniques can be found in Van Hoosier and McPherson (1987).

### Administration of substances

#### Anaesthesia

Sources of information on anaesthesia in the Syrian hamster include Ferguson (1979), Green (1979), Flecknell and Mitchell (1984), Gaertner *et al.* (1987) and most recently Flecknell (2009). It must always be remembered that whichever anaesthetic regime is chosen, the dose required to achieve the appropriate depth of anaesthesia and the subsequent sleep time will vary between strains and species of hamsters and may also be affected by other environmental factors.

Table 24.5 Provides the recommended sedatives, tranquilisers and other pre-anaesthetic medication for use in the Syrian hamster. Table 24.6 gives the anaesthetic dose

**Table 24.5** Sedatives, tranquillisers and other pre-anaesthetic medication for use in the Syrian hamster. This article was published in Flecknell, P.A. (1996) *Laboratory Animal Anaesthesia*, 2nd edn, pp. 172–174, copyright Elsevier (1996). Reproduced with permission. Considerable variation in practice occurs between different strains.

Drug	Dose rate	Comments
Acepromazine	5 mg/kg ip	Light sedation
Atropine	0.04 mg/kg sc	Anticholinergic
Diazepam	5 mg/kg im, ip	Light sedation
Fentanyl/ fluanisone	0.5 ml/kg ip	Light–moderate sedation, moderate analgesia
Fentanyl/ droperidol	0.9 ml/kg im	Analgesia, unpredictable degree of sedation
Ketamine	100–200 mg/kg im	Deep sedation, mild analgesia
Medetomidine	0.1 mg/kg im, ip	Light–deep sedation, some analgesia
Midazolam	5 mg/kg im, ip	Mild–moderate sedation
Xylazine	5 mg/kg im	Light sedation, some analgesia

**Table 24.6** Anaesthetic dose rates in the Syrian hamster. This article was published in Flecknell, P.A. (1996) *Laboratory Animal Anaesthesia*, 2nd edn, pp.172–174, copyright Elsevier (1996). Reproduced with permission.

Drug	Dose rate (mg/kg)	Effect	Duration of anaesthesia (min)	Sleep-time (min)
Alphachloralose	80–100 mg/kg ip	Immobilisation	–	180–240
Alphaxalone/alphadolone	150 mg/kg ip	Immobilisation/anaesthesia	20–60	120–150
Fentanyl/fluanisone + diazepam	1 ml/kg im or ip + 5 mg/kg ip	Surgical anaesthesia	30–40	60–90
Fentanyl/fluanisone/midazolam	4.0 mg/kg ip*	Surgical anaesthesia	30–40	60–90
Ketamine/acepromazine	150 mg/kg + 5 mg/kg ip	Immobilisation/anaesthesia	45–120	75–180
Ketamine/diazepam	70 mg/kg + 2 mg/kg ip	Immobilisation/anaesthesia	30–45	90–120
Ketamine/medetomidine	100 mg/kg + 250 µg/kg ip	Surgical anaesthesia	30–60	60–120
Ketamine/xylazine	200 mg/kg + 10 mg/kg ip	Immobilisation/anaesthesia	30–60	90–150
Pentobarbital	50–90 mg/kg ip	Immobilisation/anaesthesia	30–60	120–180
Tiletamine/zolezepam	50–80 mg/kg ip	Immobilisation/anaesthesia	20–30	30–60
Tiletamine/zolezepam/xylazine	30 mg/kg + 10 mg/kg ip		30	40–60
Urethane	1000–2000 mg/kg	Surgical anaesthesia	360–480	non-recovery only

\*Dose in ml/kg of a mixture of 1 part fentanyl/fluanisone plus 2 parts water for injection, and 1 part midazolam (5 mg/ml initial concentration).

Duration of anaesthesia and sleep time (loss of righting reflex) are provided only as a general guide, since considerable between animal variation occurs. For recommended techniques see text.

rates in the Syrian hamster. Both tables are from Flecknell (1996).

### Other procedures and techniques

Haisley (1980) describes the following technique for cheek pouch examination in conscious golden hamsters and which does not require forceps. The hamster is held around the body with a thumb across its chest. The fifth finger of the opposite hand is placed near the caudal end of the cheek pouch. By pushing cranially, while pulling gently at the corner of the hamster's mouth with the thumb of the free hand, the cheek pouch can be completely everted. The tissue can be manipulated gently with either index finger, and the entire surface can be examined. If the tissue is too moist to be manipulated easily, the pouch can be dried with a swab. This technique has several advantages: the hamster need not be anaesthetised; they seldom bite, since in doing so, they bite their own cheek; forceps are not needed to evert the pouch thus minimising tissue damage. Additionally, animals can be examined rapidly and frequently since no restraining devices are needed.

Ransom (1984) describes the following method for intravenous injection of unanaesthetised Syrian hamsters. A 1 ml Monoject plastic syringe with a 25.4 mm 25G needle is filled with an appropriate solution for injection. Unanaesthetised animals are restrained by holding them by the skin of the neck and hindleg. A rubber band is then wrapped around either foreleg above the proximal joint. A small amount of 70% ethanol is applied to the lower foreleg where the cephalic vein on the ventral side is engaged by the rubber band tourniquet. The needle can be inserted easily into the vein at an approximately 10° angle to the vein, keeping the needle close to the surface of the skin after insertion through

the epidermis and subcutaneous layers into the vein. If a swelling occurs at the injection site during injection, then the injection is subcutaneous. After removal of the needle, pressure is applied to the injection site to minimise haematoma formation.

With practice, it should be possible to use this procedure to perform intravenous injections in hamsters with consistent success. Care should be exercised by the person restraining the hamster to ensure that injury does not occur. Ransom (1984) reports that two injections could be made in each animal using both forelegs, but once a vein was punctured a second injection was not attempted for 24 h. Volumes of 0.1–0.3 ml were readily tolerated by both male and female hamsters.

A method for measuring cardiovascular and renal function in unrestrained hamsters is detailed by Fox *et al.* (1993), while Ohwada (1993) describes a method for calculating the body surface area of Syrian hamsters.

### Euthanasia

Methods of euthanasia suitable for other small rodents can also be used for hamsters (specific methods can be found in Home Office (1997) and more extensive consideration of the various methods is given Close *et al.* (1996; 1997). See also Chapter 17. It is important to ensure that staff are competent to perform the procedure, especially when using physical methods. When using carbon dioxide, it is essential the animals are placed in a rising concentration of carbon dioxide and not a saturated atmosphere. Finally, whatever method is chosen, death must be confirmed via either severance of a major blood vessel, dislocation of the neck, or by observing rigor mortis before disposing of the carcass.

## Common welfare problems

### Diseases

Despite the fact that to date there has been no true caesarean derivation and hand-rearing of hamsters in order to establish true gnotobiotic or axenic stock, commercially sourced animals are typically of a high microbiological status. Antibiotic chemotherapy, prophylaxis and improved husbandry conditions have contributed significantly to this state of affairs. There are now several established health (microbiological) monitoring schemes published for hamsters and other laboratory species. One example of such a scheme is provided by Federation of European Laboratory Animal Science Associations (FELASA, 1994).

### Non-infectious diseases and welfare problems

Cannibalism is common especially when hamsters are stressed. Primiparous females are renowned for their tendency to eat their young. Injuries can vary from limb amputation to death (Griffin *et al.* 1989).

Nutritional and metabolic disorders include spontaneous haemorrhagic necrosis (SHN) of the central nervous system of foetal and newborn hamsters (Keeler & Young 1979). There is a strain-related variation in susceptibility to the disease which can be induced by feeding pregnant dams a diet deficient in vitamin E. The condition can be alleviated by supplementation of the diet with vitamin E.

Environmental, genetic and other disorders include bedding-associated dermatitis (Meshorer 1976), malocclusion and periodontal disease. Diabetes mellitus is a genetically recessive disorder of Chinese hamsters. Affected individuals display classic signs of the disease (Diani & Gerritsen 1987).

Non-neoplastic age-related diseases are primarily degenerative in nature and include arteriolar nephrosclerosis (hamster nephrosis), described by Slausen *et al.* (1978). Amyloidosis frequently occurs in older hamsters (Coe & Ross 1990). Atrial thrombosis is common in older hamsters in some colonies. Females are usually affected earlier than males. The syndrome is often associated with amyloidosis (McMartin & Dodds 1982) and changes also occur in coagulation and fibrinolytic parameters consistent with consumptive coagulopathy (Wechsler & Jones 1984).

Polycystic disease is characterised by multiple hepatic cysts and is occasionally seen in older hamsters at necropsy (Somvanshi *et al.* 1987). Hepatic cirrhosis is a spontaneous disorder occurring sporadically among hamsters, reaching an incidence of up to 20% in some colonies (Chesterman & Pomerance 1965). Brunnert and Altman (1991) describe the laboratory assessment of chronic hepatitis.

The incidence of neoplasms in hamsters is relatively rare but varies markedly between strains. The majority of tumours are benign and frequently arise from the endocrine system or alimentary tract. However, Brown *et al.* (1993) describe a chondroma of the foreleg in a Syrian hamster and Adaska and Carbone (1994) describe a spontaneous mesothelioma in a Syrian hamster. For extensive information on neoplasms in hamsters see Pour *et al.* (1976a, 1976b, 1976c,

1976d, 1979), Van Hoosier and Trentin (1979), Turusov and Mohr (1982), Bernfeld *et al.* (1986) and Barthold (1992).

### Viral infections

Whilst hamsters are susceptible to a number of viral infections, few are of practical importance. Lymphocytic choriomeningitis virus (LCMV), whilst an important zoonosis, should now be eradicated from most, if not all, commercially sourced animals. Hotchin *et al.* (1974) describe an outbreak in hospital personnel attributable to a research colony of Syrian hamsters and Skinner and Knight (1979) review the potential role of Syrian hamsters and other small mammals as a reservoir of LCMV.

Sendai virus causes clinical respiratory disease in hamsters and may reduce productivity in a breeding colony.

Coggin *et al.* (1978) reported natural horizontal transmission of lymphomas in Syrian hamsters but could find no evidence of hamster leukaemia virus. Barthold *et al.* (1987) provided evidence that a papovavirus is the probable aetiological agent of these lymphomas. However, they concluded that further study of the aetiology would be complicated due to the high degree of contagiousness, prolonged incubation period and complex epizootiology of the disease. Barthold (1992) presents a thorough review of hamster papovavirus biology.

### Bacterial infections

A wide variety of pathogenic or opportunistic bacterial infections may cause disease in hamsters if predisposing factors such as concurrent viral infection, stress, immunosuppression etc are present. Case reports are too numerous to mention but Amao *et al.* (1991) reports the isolation of *Corynebacterium kutscheri* from aging Syrian hamsters and Shoji-Darkye *et al.* (1991) describe the pathogenesis of cilia-associated respiratory (CAR) bacillus in Syrian hamsters.

The most common, complex and perplexing bacterial infection in hamsters is perhaps proliferative ileitis (transmissible ileal hyperplasia). This is the most commonly recognised disease in Syrian hamsters and usually results in high morbidity and high mortality. The term 'wet-tail' should not be used because this descriptive term includes virtually all the conditions that may cause diarrhoea. *Escherichia coli*, *Campylobacter* spp., *Cryptosporidium* and a new species of *Chlamydia* have all been implicated in the aetiology.

Other bacteria which may give rise to enteritis include *Salmonella* spp, *Clostridia piliformis* (Tyzzer's Disease) and *Clostridium difficile* (non-antibiotic-associated). Percy and Barthold (1993) provide an excellent overview of bacterial disease in hamsters together with further references.

### Parasitic infestations

Commercially sourced hamsters should for the most part be free of pathogenic parasites. Discovery of ectoparasites, nematodes and cestodes in purchased animals should trigger an investigation for alternative sources whilst intestinal protozoa are usually non-pathogenic.

Of the parasites capable of infesting hamsters those which have been reported most recently include: *Speleorodens clethrionomys* (nasal mite) (Bornstein & Iwarsson 1980), *Demodex aurati* (Skavlen & Peterson 1989), *Giardia* and *Trichomonas* (Moore 1990), *Syphacia obvelata* (Taylor 1992), *Giardia* and *Tritrichomonas* (Taylor *et al.* 1993) and *Spiroplasma* sp. (Kunstyr *et al.* 1993).

### Control and treatment of infections

Virus control is limited when caesarean re-derivation is not an option, however vaccination has been used against Sendai virus (Lindsey *et al.* 1991) and for some labile viruses, such as Sendai, strict quarantine and 'fire-break' techniques may be successful (Lindsey *et al.* 1991).

For a general review on the use of antibiotics to treat bacterial disease the reader is referred to Morris (1995).

La Regina *et al.* (1980) compared three antibiotics (tetracycline hydrochloride, dimetridazole and neomycin) in the treatment of proliferative ileitis. They found tetracycline hydrochloride to be the most effective whilst dimetridazole was less effective and neomycin had no effect. McNeil *et al.* (1986) reported similar success when treating wet-tail in a closed hamster colony. Isolates from affected animals included *E. coli*, *Clostridium perfringens* and *Bacteroides*. They found all three isolates were sensitive to oxytetracycline which was subsequently successfully used to treat and control the outbreak. Boss *et al.* (1994) report the successful use of oral vancomycin for the treatment of *Clostridium difficile* enteritis in Syrian hamsters while Srivastava (1988) demonstrated it was possible to eliminate the endogenous microbial flora from conventionally raised hamsters using a two-step administration of antibiotics.

Taylor (1992) describes the elimination of pinworms (*Syphacia obvelata*) using a combination of piperazine hydrate and thiabendazole.

# 25 The husbandry and welfare of non-traditional laboratory rodents

Chris Sherwin

## Introduction

In this chapter, the physiology, behaviour, lifestyles and senses and communication of some rodent species not traditionally used in the laboratory are discussed and at the end of each section suggestions derived from these considerations are given to promote best welfare practice for these animals.

The order Rodentia is probably the most diverse taxonomic group among mammals, containing the largest number of species. Worldwide, there are approximately 2277 species of rodents, representing 42% of all mammal species (Wilson & Reeder 2005). New species continue to be discovered (eg, Werner *et al.* 2006) including, during the writing of this chapter, a giant rat from Papua New Guinea which is five times the size of a typical laboratory rat. Rodents are found around the world except in Antarctica, and in a very wide range of habitats except for the oceans and some oceanic islands. Table 25.1 presents a classification of the Rodentia adapted from Wilson and Reeder (2005), and which is regularly updated<sup>1</sup>.

## Non-traditional laboratory rodent species

The range of rodent species used in laboratories is steadily increasing as our understanding of their diversity increases and our quest for knowledge continues. Examples of these include: the Arctic porcupine (*Erethizon dorsatum*) (Folk *et al.* 2006), beaver (*Castor* spp.) (McKean 1982), capybara (*Hydrochoerus hydrochaeris*) (Labruna *et al.* 2004), chinchilla (*Chinchilla laniger*) (Burgstahler *et al.* 2008; Hamernik *et al.* 2008; Shera *et al.* 2008), collard lemming (*Dicrostonyx torquatus*) (Weil *et al.* 2006), coypu or nutria (*Myocaster coypus*) (McKean 1982; Marounek *et al.* 2005), grey squirrel (*Sciurus carolinensis*) (Van Hooser *et al.* 2005), ground squirrel (*Spermophilus* spp.) (Zhao *et al.* 2004; Mateo 2008), naked mole-rat (*Heterocephalus glaber*) (Towett *et al.* 2006; Park *et al.* 2003, 2008), southern flying squirrel (*Glaucomys volans*) (Gibbs *et al.* 2007) and zockor (*Myospalax* spp.) (Wei *et al.* 2006).

Non-traditional rodent species are increasingly being used in the following fields of research: models for human

or other animal disease and other applied studies; fundamental studies; conservation research; and pest control. However, the use of less frequently used species in research requires specialist knowledge to ensure high standards of welfare.

It might be thought, due to the similar appearance of many rodents, that they have similar requirements in terms of housing and husbandry. Although some of their requirements may be similar, all species have species-specific physiology, behaviour, lifestyles and senses, which must be understood if we are to provide adequate welfare in the laboratory. It is clearly impossible to give a comprehensive review of the welfare considerations of the entire Rodentia in this single chapter, but this chapter provides a 'flavour' of the great diversity of the non-traditional laboratory rodents, and serves to highlight the need for specialist knowledge in their care. The consideration of rodent requirements taking into account their ecology, behaviour, anatomy and physiology should also help to shed light on the welfare considerations of both non-traditional and more commonly used laboratory rodents.

## Physiology

### Anatomy

Despite their ecological diversity, all rodents share the characteristic that their dentition is highly specialised for gnawing. It is this specialisation which gives rodents their name (from the Latin, *rodere*, to gnaw and *dens*, *dentis*, tooth). All rodents have a single pair of upper and a single pair of lower incisors, followed by a gap (diastema), and then one or more molars or premolars. Rodent incisors grow continuously and must be kept worn down by gnawing. Their anterior and lateral surfaces are covered with enamel, but the posterior surface is exposed dentine. During gnawing, the incisors grind against each other, wearing away the softer dentine leaving the enamel edge as the blade of a chisel (Hurst 1999). This 'self-sharpening' system is very effective and is one of the keys to the enormous success of rodents (Myers 2000). The diastema of the upper jaw is longer than that of the lower jaw, which allows rodents to engage their gnawing incisors while their chewing teeth (molars and premolars) are not being used. The reverse is also true;

<sup>1</sup><http://museum.utep.edu/mammalogy/>

**Table 25.1** Classification of the order Rodentia (after Wilson & Reeder 2005).

Suborder	Superfamily	Family	Species	Common name
Sciuromorpha		Aplodontiidae	1	Mountain beaver, boomer or sewellel
		Sciuridae	278	Tree squirrels, flying squirrels, ground squirrels, sousliks, chipmunks, marmots, prairie dogs, woodchuck
		Gliridae	28	Dormice
		Geomyidae	40	Pocket gophers
Castorimorpha		Castoridae	2	Beavers
		Heteromyidae	60	Pocket mice, kangaroo rats, kangaroo mice
Myomorpha	Dipodoidea	Dipodoidea	6	Jumping mice and jerboas
		Muroidea	61	Malagasy rats and mice, climbing mice, African rock mice, swamp mice, pouched rats, white-tailed rat
		Cricetidae	681	Hamsters, voles, lemmings, New World rats and mice
		Muridae	730	Mice, rats, gerbils
		Platacanthomyidae	2	Spiny dormice, Chinese pygmy dormice
		Spalacidae	36	Blind mole-rats, bamboo rats, root rats, zokors
		Calomyscidae	8	Mouse-like hamsters
Anomaluromorpha		Anomaluridae	7	Scaly-tailed squirrels
		Pedetidae	2	Springhare
Hystricomorpha		Ctenodactylidae	5	Gundis
		Bathyergidae	16	African mole-rats, blesmols
		Hystricidae	11	Old World porcupines
		Petromuridae	1	Dassie rat
		Ctenomyidae	60	Tuco-tucos
		Echimyidae	90	Spiny rats
		Thryonomyidae	2	Cane rats
		Erethizontidae	16	New World porcupines
		Chinchillidae	7	Chinchillas, viscachas
		Dinomyidae	1	Pacarana
		Caviidae	18	Cavies, guinea pig, mara or Patagonian hare, capybara
		Dasyproctidae	13	Agoutis, acouchis
		Cuniculidae	2	Paca
		Octodontidae	13	Degus or octodonts
		Abrocomidae	10	Chinchilla rats
	Myocastoridae	1	Coypu, nutria	
	Capromyidae	20	Hutias	
	Heptaxodontidae	4	Giant hutia	

rodents can use their chewing teeth (also called cheek teeth) while their incisors are disengaged. No rodent has more than one incisor in each quadrant, and no rodent has canines. The entire skull structure of rodents is designed to accommodate the separate use of the different types of teeth. Rodent skulls have long snouts; the articulation of the lower jaw with the skull is orientated front-to-back rather than sideways as in other mammals; the jaw muscles (masseter complex) are extended well forward into the snout; and the number of cheek teeth is less than in most other mammals – all features unique to rodents. They have well developed muscles that move the lower jaw (pterygoid), and a long glenoid fossa which gives them the ability to move the lower jaw forward and backward. Gnawing is an essential behaviour for rodents and they should be provided with opportunities to gnaw when housed in the laboratory. Malocclusion can occur if suitable hard food and/or non-toxic chewing materials such as cardboard, hay, branches or other wood

materials are not provided. Overgrowth of teeth can be a particular problem for long-lived species (Hurst 1999).

### Morphology

The overall morphology of most rodents is relatively similar. Rodents tend to be small; very few weigh more than 1 kg and most weigh less than 100 g. The tiny African pygmy mouse *Mus minutoides* is only 6 cm in length and 7 g in weight. At the other extreme, the capybara can be 130 cm in length and weigh up to 66 kg (Macdonald 1984), and the extinct *Phoberomys pattersoni* is believed to have weighed 700 kg. Most rodents have short compact bodies with short legs. Some groups (jerboas Dipodidae, gerbils Gerbillinae, springhare *Pedetes capensis*) have long rear legs and feet that allow them to hop over large distances of the deserts they inhabit (the springhare can bound over 2 m). Other grass-

land rodents have no need for jumping and subsequently have evolved similarly sized, short front and rear limbs. The beaver, capybara, coypu and earless water rat (*Crossomys moncktoni*) have webbed, or partly webbed, feet for their aquatic lifestyle. Some rodents, particularly nocturnal species, have large eyes (dormice, hamsters) while others which have adopted a subterranean lifestyle have very small eyes, which are sometimes covered with a layer of skin making them functionally blind (blind mole-rats). Similarly, ear morphology varies amongst the rodents from being relatively large (mice, rats, springhare) to absent or invisible (blind mole-rats, earless water rat) and may have specialist structures such as a well developed cartilaginous flap (tragus) that prevents sand or soil from entering the ear during digging.

Rodents, being mammals, all possess hair, however, even this characteristic shows some remarkable adaptations. Most wild rodents are covered over their entire body with brown or grey agouti-type coloration, in which the coat might show light and dark bands for camouflage, whilst desert rodents have a more sandy appearance. The albino appearance of laboratory rodents is an artificially selected character as these mutations would be heavily selected against in the wild. Research with degus (*Octodon degus*) indicates that ultraviolet visible patterns on their coat might have a role in communication (Chavez *et al.* 2003). Some rodents are nearly completely naked (naked mole-rat), whereas others (chinchillas, beavers) have thick luxuriant coats making thermoregulation an important welfare consideration for these species when used in the laboratory – cooling may be necessary at higher ambient temperatures than for many other rodent species. Conversely, nude or less hirsute species may need to be housed in warmer than usual ambient temperatures, or at least provided with nesting materials for those species that build nests to create a suitable microclimate.

Perhaps the most varied characteristic of the rodents is their tail. Some rodents have long, nude or sparsely haired tails (mice, rats) or long, hairy tails (gerbils) which they use for balancing whilst standing running or climbing. Some species have a long prehensile tail (European harvest mouse (*Micromys minutus*)), which they use during climbing. The tail of arboreal squirrels is also used as a counterbalance and for signalling, perhaps being enhanced by its bushiness. It has been suggested that Californian ground squirrels add an infrared component from their tails when tail-flagging at infrared sensitive predatory snakes (Rundus *et al.* 2007). Some groups such as cavies (Caviidae) and hamsters (Cricetinae) have vestigial tails or no visible tail at all, whereas others, such as the beavers, have highly developed, flat muscular tails used for propulsion during swimming. Knowledge of the tail can be important for appropriate handling in the laboratory. Mice and some other small rodents are routinely picked up by the tail, however, this should not be done with gerbils and degus as the skin may tear off.

## Diet

Nearly all rodents feed on plants, seeds in particular. Some species are omnivorous whereas others are exclusively her-

bivorous, eg, beavers, voles (Microtinae) and lemmings (Hurst 1999). Other species are highly specialised, eating, for example, only a few species of invertebrates or fungi. Some species eat fish (beavers) and some squirrels are known to eat passerine birds such as cardinals and blue jays. It has been reported that the diet of the grasshopper mouse (*Onychomys leucogaster*) is 89% animal matter (insects, scorpions, small mice) and only 11% plant matter – captive individuals are apparently especially fond of raw liver and newborn mice (Davis & Schmidley 1997). In the laboratory a suitable diet in terms of both quantity and quality must be provided. Care should be taken to avoid generalist assumptions – apparently similar species may have very different requirements for specialist diets, which must be considered before introducing the species into the laboratory.

## Habitat

As might be expected from the numerous Rodentia species, they inhabit highly diverse habitats. Some are terrestrial (cotton rats (*Sigmodon* spp.), jerboas, kangaroo rats (*Dipodomys* spp.)) while others are fossorial and dig out extensive underground burrow systems (ground squirrels, mole-rats, marmots (*Marmota* spp.)). Others are largely arboreal (tree squirrels, New World porcupines (*Sphiggurus* spp.) or have become volant, (ie, they have a loose fold of furred skin (patagium) which connects the front and hindlimbs from the wrists to the ankle that allows them to glide between trees (flying squirrels)). A few have even adopted an aquatic lifestyle (beavers, capybara, coypu, water rats (*Hydromys* spp.)). Rodents are often opportunistic in their choice of habitat, but others can be highly specialist. One of the most remarkable artificially created habitats in the animal kingdom is constructed by a rodent; beavers construct their homes, or lodges, out of sticks, twigs and mud in artificial ponds they create by building dams which can be substantial structures. Clearly it would be impossible to provide or simulate many of these habitats in the laboratory, but the basic behaviours of the animals in these environments, such as burrowing, gliding, swimming, etc must be considered when designing enclosures for them. In some instances it might be possible to provide surrogate habitats, eg, pre-fabricated tunnel systems for burrowing species, small ponds or water baths for aquatic species, or construct enclosures to suit the animal's behaviour, eg, long narrow enclosures for gliding species.

## Social organisation

Some rodents are highly social animals living in families (African brush-tailed porcupine *Atherurus africanus*, beavers), large groups (mice, rats), or in highly complex social systems in extensive colonies (marmots, prairie dogs (*Cynomys ludovicianus*)). The naked mole-rat and the Damaraland mole-rat (*Cryptomys damarensis*) are the only mammals currently known to be eusocial (living somewhat like termites and ants in a colony with castes) (Scantlebury *et al.* 2006). The naked mole-rat lives in subterranean colonies that commonly contain around 80 but sometimes up to 300 individu-

als. Reproduction is monopolised by a single dominant 'queen' and one or two males, whereas the remainder of the colony act as 'workers', maintaining the burrow system, or 'soldiers' defending the colony against foreign mole-rats or predators (Holmes *et al.* 2007). The females of the subterranean rodents, the tuco-tucos (Ctenomyidae) and degus, frequently share one burrow and nurse one another's young. Solitary ways of life are associated with species living in arid grasslands and desert areas (jerboas, marmots, Plains pocket gopher (*Geomys bursarius*), Syrian hamster *Mesocricetus auratus*, crested porcupines (*Hystrix* spp.)). Clearly, the social organisation of any species used in the laboratory needs to be considered to maintain good welfare. Unless there is evidence to the contrary, the animals should be housed as near as possible to their natural groupings, eg, individual or group housing, large or small groups, single- or mixed-sex groups.

### Chronobiology

Most rodents are nocturnal or crepuscular, although some are strictly diurnal (eg, ground squirrels, tree squirrels). Some species are flexible in this regard and regulate their 24h activity around human activity (guinea pigs, coypu (Meyer *et al.* 2005)). Most rodent species are active throughout the year, but others, notably ground squirrels, may hibernate for several months (Zhao *et al.* 2004). There is a growing acceptance that gathering data from animals in the laboratory during times when they would normally be asleep is often not best practice for scientific validity or animal welfare. For example, in behavioural studies of nocturnal mice or rats, red lights are often used to allow data collection from the animals during the dark phase (their active period) without disturbing the animals. Such considerations should be extended to the chronobiology of other species brought into the laboratory.

### Senses and communication

The senses of the typical laboratory rodents have been studied widely and there have been several reviews of how the laboratory environment can (adversely) affect animal welfare in this regard (eg, Olsson *et al.* 2003; Sherwin 2002, 2004). There have also been studies on the senses of non-traditional laboratory rodent species. These are discussed here, along with the welfare implications.

#### Pain

Rodent species are widely represented in studies of pain. All the typical laboratory species have been used: rats (eg, Dobner 2006; Vissers *et al.* 2006), mice (eg, Dobner 2006; Delporte *et al.* 2007; Marabese *et al.* 2007), gerbils (Vissers *et al.* 2006) and guinea pigs (Fox *et al.* 2003). Less well studied species used in this field include degus (Pelissier *et al.* 1989) and naked mole-rats. Rather bizarrely, the skin of African naked mole-rats lacks a key neurotransmitter called substance P that is responsible in mammals for sending burning

pain signals to the central nervous system. When these animals are exposed to acid or capsaicin, it has been reported that they behave as if they feel little or no pain to these substances (Park *et al.* 2003, 2008).

#### Olfaction

Humans are unusual compared to other mammals because a much smaller proportion of our genome is devoted to olfaction and our vomeronasal organ is vestigial or non-existent (Burn 2008). It is therefore easy for us to underappreciate the role that olfaction has in other species. Rodents use a variety of specialised scent glands, together with urine, faeces and vaginal secretions for olfactory communication. There is considerable diversity between the species, and between the sexes, in the location of scent glands and in their secretions, but urine is a particularly rich source of odour used by many species (Hurst 1999).

A considerable amount has been written about olfaction in the typical laboratory rodents (eg, Lonstein & Gammie 2002; Novotny 2003; Brennan & Keverne 2004; Lai *et al.* 2005; Bargmann 2006; Maras & Petrulis 2008) and some of the behavioural functions of olfaction are now understood in great detail (Humphries *et al.* 1999; Beynon & Hurst 2003; Hurst & Beynon 2004). From such studies, several welfare issues relating to olfaction in typical laboratory rodents are now recognised, eg, cleaning cages to minimise social disruption and reducing the potential for exposure to the odour of predators (please see species chapters for further information). Considerably less research has been published on the atypical laboratory rodent species, but there are reports on olfaction in beavers (Rosell 2002; Rosell & Sanda 2006; Rosell & Thomsen 2006), chinchillas (Oikawa *et al.* 1994), flying squirrels (Pyare & Longland 2001; Borgo *et al.* 2006), lemmings (Huck & Banks 1984), mole-rats (Menziez *et al.* 1992; Zuri *et al.* 1998; Smith *et al.* 2007), tuco-tucos (Fanjul *et al.* 2003; Zenuto *et al.* 2004) and voles (Marchlewska-Koj *et al.* 2003; Wolff 2004). The blind mole-rat (*Spalax ehrenbergi*), uses its latrines in territory marking (Zuri *et al.* 1997). As with laboratory mice, removal of these markings during cleaning might have welfare implications by reducing the familiarity of the environment, and causing social disruption if dominance status is conveyed by these markings. Further research should reveal the role of olfaction in these animals, and help determine the optimum balance between cleaning whilst allowing the marks to achieve their effect.

#### Hearing (mechanoreception)

Many desert rodents communicate by drumming their feet on the ground to create mechanical vibrations. This is an important means of communication and occurs in a wide variety of contexts including individual-spacing, resource competition and predator defence. Foot-drumming is widespread and includes kangaroo rats from North America, and gerbils from Africa and Asia (Randall 2001; Shier & Randall 2007). All these rodents have specially adapted ears for reception of the low-frequency vibrations transmitted via

both the air and seismically through the ground. A similar behaviour using head-drumming is performed by blind mole-rats (Rado *et al.* 1987). These animals possess poor auditory sensitivity, which is limited to low-frequency sounds. They detect low-frequency seismic waves using their paws, and can accurately determine the direction of the vibratory source (Kimchi *et al.* 2005). Some burrowing mole-rat species, eg, *Cryptomys hottentotus* (Muller *et al.* 1992), *Spalax ehrenbergi* and *Fukomys anselli* (Burda 2006) have ears adapted to the lower range frequencies transmitted through the ground, and have much reduced sensitivity to the higher frequencies that surface-dwelling species can hear. The welfare implications of low-frequency mechanoreceptivity have yet to be researched, but it seems likely that sources of low frequency air or seismic waves in the laboratory (eg, construction work, lifts, cages or racks being moved or knocked, items being dropped) might interfere with this sensory modality or could possibly lead to sensory overload, indicating that they should be avoided. In addition, if the animals are to be permitted to perform natural behaviours, it might be necessary to provide them with the opportunity to build tunnel systems for them to communicate effectively.

### Ultrasound

Typical laboratory rodents can hear over a broad spectrum of frequencies and can hear well above the frequency of human hearing sensitivity (ultrasound). Both audible and ultrasonic calls are used by rodents in a variety of situations. Ultrasound is used in sexual communication and by pups when they have fallen out of the nest (eg, Clough 1982; Ehret 2005; Wöhr & Schwarting 2008). It has even been reported that rats and shrews use ultrasound for echolocation (Kaltwasser & Schnitzler 1981; Forsman & Malmquist 1988). Some non-traditional laboratory rodents are also sensitive to ultrasound or emit these frequencies (voles, Rabon *et al.* 2001; ground squirrels, Wilson & Hare 2004; mice, Kalcounis-Rueppell *et al.* 2006; bank voles, Szentgyorgyi *et al.* 2008), although this has been considerably less well researched. Several items of common laboratory equipment such as pressure hoses, running taps, computer monitors or oscilloscopes emit ultrasound, some at very high sound pressures (Sales *et al.* 1999). These are silent to humans, but could have considerable effects on rodents and on experimental data obtained from them. Laboratory-generated ultrasound could conceivably interfere with communication between animals, cause distress or perhaps even sensory damage if severe enough. The use of bat detectors, which register ultrasonic frequencies, to detect this problem could help to improve the rodents' welfare.

### Magnetoreception

It has been claimed that mole-rats (Marhold *et al.* 1997; Kimchi *et al.* 2004), Siberian hamsters (Deutschlander *et al.* 2003) and laboratory mice (Muheim *et al.* 2006) have the capacity to detect magnetic fields. Deutschlander *et al.* (2003) suggest that studies on other rodents might have incorrectly

indicated that they do not possess this capability, raising the possibility that magnetoreception might be more widespread than is generally thought. Our understanding of this capability in rodents is currently limited, but sources of magnetism in the laboratory (eg, computer monitors, many items of electrical equipment) could conceivably interfere with magnetoreception.

### Vision

Many rodents are nocturnal and therefore have a retina dominated by rods and which contains only a small proportion of cones. Even in these species, the cones comprise two spectral types and thus, contrary to popular belief, provide dichromatic colour vision, the most common form of mammalian colour vision (Jacobs 1993). There have been many studies on the vision of non-traditional laboratory rodents and there is considerable diversity in its physiology and function (eg, Cooper *et al.* 1993; Cernuda-Cernuda *et al.* 2002; Peichl 2005; Bobu *et al.* 2008; Lluch *et al.* 2008; Ortiz *et al.* 2008), presumably due to the diversity in lifestyles and habitats. For example, flying squirrels from both Siberia and North America no longer have colour vision, most probably as a result of switching from diurnality to a nocturnal lifestyle (Carvalho *et al.* 2006). However, the subterranean cururo (*Spalocopus cyanus*), is reported to have dichromatic colour vision with an unusually high proportion of cones in the retina, indicating adaptation to sporadic phases of diurnal surface activity, rather than to the lightless subterranean environment (Peichl *et al.* 2005). Most squirrel species are diurnal with cone-dominated retinas, similar to the primate fovea, and have excellent dichromatic colour vision that is mediated by green and blue cones (Heimel *et al.* 2005; Van Hooser & Nelson 2006). In traditional laboratory rodents, retinal functional development and visual acuity can be improved by environmental enrichment (Prusky *et al.* 2000; Landi *et al.* 2007); presumably, the same could be true of non-traditional laboratory species, indicating that enrichment should be provided to ensure appropriate development of their visual systems.

Perhaps unexpectedly, some subterranean rodents usually considered as 'blind' do respond to light (Wegner *et al.* 2006) and possess different visual capabilities and adaptations (Nemec *et al.* 2007), even if they live in apparently similar optic environments (Burda 2006). African mole-rats possess relatively well developed functional visual subsystems involved in photoperiodicity and used for form and brightness discrimination, but severely reduced subsystems involved in coordination of visuomotor reflexes, indicating the retention of only basic visual capabilities. This residual vision may enable subterranean mole-rats to find breaches in the burrows that let in light, enabling them to reseal such entry points and prevent entry of predators (Nemec *et al.* 2008). Naked mole-rats' eyes are markedly reduced in size, and generally these rodents move about with their eyes closed, suggesting they do not rely on vision. Nevertheless, they have retained most of the well characterised mammalian cell types found in the eye, although their eye's structural organisation is considerably less regular than that in more sighted mammals. The naked mole-rat reportedly

cannot perceive images but can detect amorphous light (Hetling *et al.* 2005). Similarly, although the blind mole-rat has subcutaneous eyes and atrophied structures involved with image formation, the non-image-forming visual pathways involved in photoperiod perception are well developed (Xiao *et al.* 2006). The visual capabilities of non-traditional laboratory rodents should be considered by, for example, providing dim shelters or refuges for those species, which might be particularly sensitive to (strong) light. In addition, it should be remembered that even in species shown to be functionally blind, light and dark phases might be required for the animal to express behavioural and physiological periodicity.

There is growing acceptance that to gain valid data and to improve animal welfare, many studies on animals should be conducted during the animal's active phase rather than when the animal is inactive. This can pose a visibility problem for those working with nocturnal species. Dim red light is sometimes used to observe nocturnal behaviour in typical laboratory rodents because it is on the upper limit of the frequencies visible as colour to them (Jacobs *et al.* 2001) and they are thought to be insensitive to this light. However, rats' rod cells are stimulated by similar wavelengths to human rod cells, including red light (Akula *et al.* 2003). As an alternative to red light, sodium lamps, which emit very narrow peaks of yellow-orange (589 and 589.6 nm) light, can be used (McLennan & Taylor-Jeffs 2004). Not only is it more visible to humans than red light, but also there were no significant long-term differences between the activity levels of mice when illuminated by this lamp or in darkness. However, if studies unequivocally require rodents to behave as if in total darkness, infrared light should be used. The lighting considerations, given above, also apply for studies using nocturnal non-traditional laboratory rodents.

### Ultraviolet vision

Ultraviolet (UV) vision seems to be absent in most mammalian species (Honkavaara *et al.* 2002) although several typical and non-traditional laboratory rodent species are capable of UV vision. These include rats (Akula *et al.* 2003; Jacobs *et al.* 1991, 2001), mice (Jacobs *et al.* 1991, 2004; Szel *et al.* 1992), gerbils (Jacobs *et al.* 1991; Jacobs & Deegan 1994), hamsters (Calderone & Jacobs 1999), gophers (Jacobs *et al.* 1991) and degus (Chavez *et al.* 2003). Within the Sciurognathi (squirrels, chipmunks, beavers and many types of mice), the shortwave-sensitive visual pigments are ultraviolet-sensitive amongst the largely nocturnal murine species, whereas violet-sensitive pigments are thought to be present in diurnal ground and tree squirrels (Carvalho *et al.* 2006). The distribution of the UV-sensitive cones on the retina differs between rodent species. In rats, the cones are scattered over the entire retina, whereas in mice, the middle-wave sensitive cones occur exclusively in the dorsal half of the retina and most of the shortwave UV-sensitive cones occur in the ventral half (Szel *et al.* 1992). The function of this difference is not yet known. The functions of UV vision in rodents are not yet well understood, but include urine-mark visibility (eg, degus, Chavez *et al.* 2003; voles, Koivula *et al.* 1999; mice, Desjardins *et al.* 1973), social communication (degus, Chavez

*et al.* 2003) and improved twilight ultraviolet vision (rats, Robitaille & Bovet 1976).

The human-visible spectrum is 400–700 nm; the human cornea strongly absorbs in the far UV, below 310 nm, and the lens has major absorption (high density) in the near UV and to a lesser extent in the visible (van de Kraats & van Norren 2007; Barber *et al.* 2006). This implies normal adult humans are visually insensitive to UV. As a consequence, artificial lights, including those used widely in laboratories, emit little or no UV. Our lack of knowledge about how rodents use UV sensitivity makes it difficult to say precisely how this lack of UV wavelengths is likely to affect the welfare of UV sensitive rodents, but potentially, it could impair communication and/or distort vision.

### Acuity and depth perception

Compared to humans, laboratory rodents, especially albinos, generally have much poorer visual acuity (Creel *et al.* 1970; Prusky *et al.* 2002) and depth perception (O'Sullivan & Spear 1964; Routtenberg & Glickman 1964). It has been estimated that the visual acuity of laboratory rats<sup>2</sup> and gerbils is approximately twice that of mice, but 10 times less than that of humans (Artal *et al.* 1998; Prusky *et al.* 2002). Rats have an enormous depth of focus. Depth of focus is the range of distances at which an object is in equivalent focus for an unaccommodated eye. In humans, the depth of focus is from 2.3 m to infinity. In rats, the depth of focus is from 7 cm to infinity (Powers & Green 1978; Green *et al.* 1980). A gerbil's pupil is positioned vertically in the eye. This is consistent for animals that live in desert or open steppe environments. Having vertical pupils gives the gerbil greater depth perception in the horizontal plain. This enables them to see predators both on the ground and in the air. Visual acuity in African mole-rats is thought to be low (ranging between 0.3 and 0.5 cycles/degree) (Nemec *et al.* 2008). Visual acuity should be considered during handling where a person or hand approaching the animal might very suddenly come into focus, thereby evoking a flight reaction or perhaps aggression.

### Summary information for some non-traditional laboratory rodents

Tables 25.2–25.4 provide summary information for seven rodent species that have been used in the laboratory and are likely to be used in the future. The information in these tables is derived from various sources, some of which are websites that have not been peer-reviewed and independent verification has been impossible. These are not necessarily scientific reports but might include information from zoos, breeding societies, or even pet owners. These tables are meant only as an introductory guide for those considering research on the species, and researchers are strongly encouraged to seek the most recent and reliable sources of information available to them (eg, Alderton & Tanner 1999; Nowak 1999; Richardson 2003; Macdonald 2006; Begall *et al.* 2007).

<sup>2</sup>Simulated at <http://www.ratbehavior.org/RatCam.htm>

**Table 25.2** Basic biology of some non-traditional laboratory rodents.

Common and scientific name	Adult weight/size	Lifespan	Sociality	Mating
Beaver Genus: <i>Castor</i>	15–35 kg Beavers continue to grow throughout life	Usually 6–7 years One female lived 21 years	Lives as families Three generations may occupy a single lodge	Monogamous
Naked mole-rat <i>Heterocephalus glaber</i>	30–35 g Queen is larger – up to 80g	28 years Queen 13–18 years	Eusocial Groups of 75–80, but up to 300	Polyandry and male monogamy Single queen mates with harem of 1–3 males
Capybara ‘water pig’ <i>Hydrochaeris hydrochaeris</i>	Average of 40 kg but up to 66 kg. Largest living rodent	10 years in captivity	Mainly herds of 10–40. Single dominant male High incidence of infanticide in captivity	
Coypu (Nutria) ‘mouse-beaver’ <i>Myocastor coypus</i>	Up to 16 kg	12 years in captivity	Single dominant male Groups of approx. 11	Polygynous Induced ovulation
Degu <i>Octodon degu</i> Bite leaves an eight-sided mark	200–300 g	4–6 years in captivity	Highly social Groups of 2–5 females and 1–2 males	Harems, but also reported that degus pair for life Induced ovulation
Fat sand rat <i>Psammomys obesus</i>	14–19 cm Tail up to 15 cm		Solitary Communal nest	
Chinchilla <i>Chinchillidae</i>	600–800 g 35 cm long	15–20 years	Colony Can be kept as same-sex groups but might fight	Breed any time of the year

**Table 25.3** Lifestyles of some non-traditional laboratory rodents.

Common and scientific name	Activity	Habitat	Diet	Home range or territory
Beaver Genus: <i>Castor</i>	Mainly nocturnal	Semi-aquatic Builds lodges in ponds or burrows in banks	Herbivorous (one report of opportunistically eating salmon)	Approx. 1 km of waterway
Naked mole-rat <i>Heterocephalus glaber</i>	Nocturnal	Solely subterranean Digs burrows with teeth 25% of an individual’s muscle mass is involved in jaw closure	Radicivores May eat dead pups	Tunnel system can be 4 km in length, 20 football fields in area
Capybara ‘water pig’ <i>Hydrochaeris hydrochaeris</i>	Naturally diurnal, but nocturnal in disturbed areas	Semi-aquatic Builds burrows in banks May cover itself in mud to protect from sunburn	Herbivorous/ graminivorous Coprphagous	10–200 ha
Coypu (Nutria) ‘mouse-beaver’ <i>Myocastor coypus</i>	Nocturnal or crepuscular	Semi-aquatic Digs short burrows May also build floating nests of reeds and other aquatic plants	Herbivorous Reports of eating fish, earthworms, and bivalve molluscs	
Degu <i>Octodon degu</i> Bite leaves an eight-sided mark	Crepuscular in summer, diurnal in winter Diurnal in captivity	Semi-fossorial Digs burrows with teeth and front feet	Herbivorous	0.04–0.71 ha
Fat sand rat <i>Psammomys obesus</i>	Mainly diurnal	Semi-fossorial Complex burrow system	Largely herbivorous, occasional insects	75–190 m tunnel system
Chinchilla <i>Chinchillidae</i>	Crepuscular Nocturnal	Burrows or crevices in rocks Dustbathes regularly	Largely herbivorous, occasional insects	

**Table 25.4** Scientific uses of some non-traditional laboratory rodents.

Common and scientific name	Uses in science
Beaver Genus: <i>Castor</i>	Diving physiology
Naked mole-rat <i>Heterocephalus glaber</i>	Unique metabolism Magnetoreception Nociception Only known mammals to be poikilothermic No sweat glands Does not produce the neurotransmitter substance P
Capybara 'water pig' <i>Hydrochaeris hydrochaeris</i>	Diving physiology
Coypu (Nutria) 'mouse-beaver' <i>Myocastor coypus</i>	Diving physiology
Degu <i>Octodon degu</i>	Prone to diabetes Cannot produce vitamin C
Bite leaves an eight-sided mark	Chronobiology
Fat sand rat <i>Psammomys obesus</i>	Prone to obesity and diabetes Highly efficient kidneys
Chinchilla <i>Chinchillidae</i>	Hearing Digestion

# 26 Voles

Jonathan J. Cooper

## Origins

Voles belong to the sub-family Arvicolinae (comprising voles, lemmings and muskrats) within the family Cricetidae of the Rodentia. It is thought that the Cricetids originated in the Eurasia during the mid-Miocene epoch, from ancestors that resemble modern squirrels. The voles themselves arose during the Pliocene epoch, and rapidly diversified during the Pleistocene. There are now about 70 species to be found in grassland, open forest and tundra. Voles are Palearctic and Nearctic in distribution being found in Europe, Asia, Northern Africa and North America. The most numerous genus in terms of species is the Microtidae, which includes the field vole (*Microtus agrestis*), one of the most common mammals of north-west Europe and the prairie vole (*Microtus ochrogaster*) of North America (Musser & Carleton 2005). Other genera include *Avicola*, the water voles, and *Myodes* (formally *Clethrionomys*) including the red-backed voles, such as the bank vole (*Myodes glareolus*).

## Biological overview

### General biology

Voles are often confused with mice. Voles have been classified as Muridae (rats, mice and their relatives) (MacDonald 2001) and some species are locally described as mice. For example, the meadow vole (*Microtus pennsylvanicus*) of North America is often called the field or meadow mouse. Compared with mice, voles tend to have a stouter body, a shorter hairy tail, a rounder head with a blunt snout, and smaller ears and eyes. They tend to be grey-brown to reddish brown in colour often with paler grey or silvery fur on the underside. Whilst some species such as water voles can be considerably larger, most vole species maintained under laboratory conditions are about the size of mice. For example, adult field or short-tailed voles have a body approximately 90–110 mm long and weigh between 20 and 40 g, whilst bank voles are between 80 and 120 mm long, weighing between 15 g and 40 g.

A distinguishing feature of voles is their molars which, unlike those of many rodents, are rootless and continue to grow during their entire life. Superficially many vole species appear similar, but their teeth can be used both to identify modern and ancestral species. For this reason, they can be

useful to archaeologists for dating strata, in a method referred to as the 'vole clock'. The technique is based on extraction of vole teeth from substrates. Most vole species can be identified by the structure and patterns of wear on their cheek or molar teeth, and distribution of ancestral species can be used to date sediments (Jernvall *et al.* 2000). Voles are largely herbivorous and their teeth structure allows them to chew large quantities of abrasive grasses. The diet of the field vole, a largely grassland species, consists for the most part of green leaves and stems of grass, herbs, sedges and bark, whilst the bank vole, which is associated with woodland habitats, has a more varied diet of grass, flowers, fruits, seeds, leaves, roots, fungi, moss, insects and worms (Flowerdew *et al.* 1985; Harris & Yalden 2008).

## Reproduction

In the wild, many vole species have a high population turnover, with few individuals surviving from one year to the next (Chitty 1952, 1996). They have a large number of natural enemies, including most carnivores, such as foxes, cats, weasels and stoats, birds of prey and owls. Average lifespan is in the order of 3–6 months and it is rare for wild voles to live for longer than 12 months, though laboratory colonies can include individuals over 18 months of age (Cooper *et al.* 1996). Voles are more active at night than during the daytime, though daytime activity can still be noticeable in the wild and the laboratory setting. Voles do not hibernate, and will continue to be active beneath lying snow. They are capable of rapid population growth in favourable conditions, and exhibit large cyclic fluctuations in population density similar to those of the closely related lemmings (Chitty 1996). Voles breed from early spring until early autumn, and their gonads are generally in a much less active state in the late autumn and winter, when they are not usually fertile. In the wild, voles do not normally have an oestrous cycle, though this can be induced under laboratory conditions by housing females in close visual contact with adult males. Ovulation in voles is normally caused by stimuli provided by mating and occurs 6–12 h later. There are normally two components of the mating process, one causing ovulation and another causing corpora lutea to become functional (Clarke 1985). Gestation lasts 16–28 days depending on species.

Vole infants or pups are altricial being born blind, hairless and heavily dependent on maternal care. Nestling voles use

ultrasonic vocalisations to communicate with their mother. These signals include distress calls, which change with the developmental stage, and with ambient and body temperature (Blake 1992). Maturation is rapid with many species weaning pups within 3 weeks of age. Voles reach sexual maturity soon afterwards. For example, male field voles are sexually mature by the age of 6–7 weeks, whilst females are sexually mature by 4 weeks of age (Spears & Clarke 1987). Female field voles have, however, been known to have perforate vaginas, and to be capable of conceiving at the age of 18 days (Chitty 1952). On weaning, most vole species are solitary and do not form stable reproductive pairs. Males are promiscuous or polygamous and court females for as long as is necessary to successfully mate. There is no paternal care of the young, whereas females are highly protective of their pups.

The prairie vole is a notable exception with regard to reproduction. These voles naturally live in multigenerational family groups with a single breeding pair. The offspring remain sexually suppressed so long as they remain within their natal group, and sexual maturity in the females (rather than developing with age as with other voles) depends on exposure to chemical cues in the urine of an unrelated male. Within 24 h of this cue, repeated mating can occur and following this they form a long-lasting relationship in which they tend to be monogamous, and the males share in the raising of pups (Insel 1997; Roberts *et al.* 1998).

## Sources of supply

If it is not possible to obtain breeding stock from an established laboratory colony, a new colony can be started with voles caught from the wild, though it may take about 3 months for the wild-caught animals to begin producing litters. Voles can be easily caught in their natural habitats, using 'Longworth' traps (Gurnell & Flowerdew 1982). Traps should be baited with cereals such as rolled oats or whole wheat grain, and fresh, succulent, vegetable matter such as discs of carrot. A bedding material such as hay should be provided in the trap's nest box. It is advisable to cover the traps with foliage, or if that is sparse, with a small amount of hay, to give insulation against extremes of climate. Such traps will also catch shrews which soon die unless reasonable precautions are taken. Blowfly (*Calliphora*) puparia are adequate for overnight survival of shrews, or a small hole can be made in the trap which allows escape of shrews but not the larger rodents. Such precautions are not only in the interest of animal welfare but are a legal requirement in many countries (Little & Gurnell 1989). As with any other forms of live trapping, permission should be sought from landowners, and it is advisable to liaise with local ecology or naturalist groups.

## Uses in the laboratory

Whilst not as common a laboratory animal as mice and rats, voles have been housed under laboratory conditions for a number of purposes, including studies of reproductive biology, disease and behavioural biology. Voles have been

used in the laboratory to investigate problems bearing on their population ecology, for example their bioenergetics as well as various aspects of their reproductive biology (Leslie & Ranson 1940; Clarke 1985). There is also considerable interest in the ecto- and endoparasites of voles (eg, Kaplan *et al.* 1980; Randolph 1995). Voles have been intensively studied since they appear to be the reservoir hosts of cowpox virus (Crouch *et al.* 1995; Burthe *et al.* 2008). The occurrence in *M. agrestis* of very large sex chromosomes has encouraged their use in studies upon heterochromatin (Kalscheuer *et al.* 1996). Voles have also been employed in the hope that they would prove useful for detecting the accumulation in herbivores of toxic minerals in herbage (Beardsley *et al.* 1978). Voles have been used to investigate rodent communication and have been used as a model to investigate the control of behaviour (Fentress 1968). Bank voles have been used in the investigation of the causes and effects of stereotypic behaviour in captive animals (Ödberg 1987).

Prairie voles and meadow voles have been used to investigate genetic and hormonal factors involved in sexual fidelity. Male prairie voles show some variation in tendency to monogamy. Extra-pair copulations can occur and the likelihood of engaging in such behaviour has been related to genetic and physiological factors (Ophir *et al.* 2008). Those males most likely to be monogamous and engage in paternal care have longer strings of repetitions of microsatellite DNA (Hammock & Young 2005). Microsatellite DNA from prairie voles has been inserted into the genome of meadow voles and found to reduce promiscuity and increase pair-bonding behaviour in males (Lim *et al.* 2004). Similarly the hormonal control of sexual fidelity involving vasopressin, oxytocin and dopamine has been investigated by manipulating their levels in male prairie voles (Cushing *et al.* 2001; Young *et al.* 2005). Finally, prairie voles have been promoted as a model for anxiety and depression (Kim & Kirkpatrick 1996; Grippo 2009) as socially isolating adult females leads to elevated corticosteroid concentrations, prolonged sensitivity to stress-inducing challenges, and affects their performance in tests of negative affective state.

## Laboratory management and breeding

The bulk of this section will concentrate on laboratory management of the short-tailed field vole (*Microtus agrestis*) and the bank vole (*Myodes glareolus*). The chapter will cover their basic biology, care and management in laboratory conditions, as well as application of laboratory procedures to these species. The chapter will illustrate issues that arise from the captive rearing of rodent species which have not been intentionally selected for laboratory conditions.

### Housing, environmental provisions, hygiene

#### Physical environment

As with other laboratory rodents it is important that voles be housed in controlled, secure, protected environments, with reliable access to food, water, shelter and/or nesting materials, where risks of infection are minimised and avoiding extremes of climatic variation. Vole rooms should be

designed to provide suitable enclosures for the animals, ease of management and safety for the researchers. A well designed room should minimise disturbing noises, and be able to maintain constant temperature and humidity. A temperature of 20°C and relative humidity of about 60%, with 15–20 changes of warm air per hour is an adequate atmosphere for a vole colony. A photoperiod of 16h light per day is appropriate for a breeding colony. Providing access to natural daylight is appropriate so long as room temperature can be controlled to avoid hot spots within the room. To reduce noise, bins for food, sawdust and rubbish should be made of heavy-duty plastic.

The colony room should be large enough to allow cages to be placed along one wall and sufficient space for basic husbandry procedures such as washing cages or sexing pups. A room of about 4.5m length, 3.0m width and 2.5m height should be adequate for colonies of 100 cages. This would provide sufficient space for a bench along one wall with sinks and the cages on shelving along the opposite wall, or fitted into racks mounted on castors. If the vole colony is housed in windowless rooms, then artificial lighting can be provided. For example, in a room laid out as above, a central 180cm long 75W fluorescent tube connected to a time switch, gives a light intensity of 105–735 lux at the front of cages in the absence of natural daylight. This light level seems adequate for basic husbandry procedures without flooding the cages with light, though it would be advisable to cover the top cages on a rack from direct lighting.

### Housing

Voles can be housed in plastic, opaque polypropylene, or transparent polycarbonate cages designed for mice or rats. Litter can be coarse sawdust prepared commercially for use in rodent laboratory colonies or similar absorbent material. Nesting material should be provided to allow nesting behaviour. This is particularly important for pregnant or lactating females which construct spherical nests 5–10cm in diameter in which litters are born and reared. However, all voles will build nests and provision of nesting material or other opportunities for sheltering considerably reduces the incidence of stereotypic behaviour in bank voles (Ödberg 1987; Cooper *et al.* 1996). Meadow hay makes a good nesting material, but is not suitable for systems requiring high hygiene and can evoke allergic responses in some people. In these situations, shredded paper or commercially produced rodent nesting material (eg, nestlets) may be an adequate substitute. A nest can last for a number of weeks, particularly if it is kept at the end of a cage away from the water bottle spout and can be transferred with the voles during cage cleaning.

### Social grouping

It is possible to group house voles in single-sex groups following weaning, though groups should be monitored for signs of aggression (Clarke 1956; Sorensen & Randrup 1986). This is most prevalent in groups of unfamiliar males, though can arise in males housed together from weaning. Singly housed animals can be kept in standard cages such as those measuring 33cm × 15cm × 13cm (l × w × h). Unless there

has been significant spoilage of bedding (eg, from flooding) these can be cleaned once per week. Cages run the risk of flooding as voles are prone to rapidly emptying water bottles (possibly in association with stereotypic licking and/or locomotion) and for this reason cages should be inspected at least once every 24h. Lactating females or breeding pairs benefit from housing in larger cages (eg, 48cm × 15cm × 13cm), which again only need to be cleaned once per week unless significant spoilage has occurred. For bank voles, more frequent cleaning appears to be disturbing and may contribute to poor reproduction and infanticide. Wild-caught voles should be handled and their cages cleaned less frequently at least in the first months of introduction to the colony.

### Food and water

Where problems of bulk and supply make the precise replication of wild diet impracticable for a laboratory colony, standard laboratory rodent diets can be used to meet the voles' nutritional requirements. Field voles should be given 8% or more protein in their diet, as a reduction to 4% has been shown to retard growth and sexual development (Spears & Clarke 1987). This can be provided by feeding whole oats, meadow hay, carrots and a few pellets of a rat and mouse laboratory diet. These supplies should be replenished every week or when cages are cleaned out. Field voles can be fed primarily a commercial pelleted standard rat and mouse breeding and grower diet *ad libitum*, though once per week a handful of commercial hamster food or toasted wheatgerm, should be added to each cage. Although bank voles naturally eat a more varied diet than field voles, they can also be maintained on simple diets such as whole oats augmented by pellets of rat and mouse breeding diet. Bank voles will sample from a wide range of food items and this basic diet should be supplemented by hamster mix including nuts and seeds such as rolled corn, barley, peanuts and sunflower seeds. Fresh forage can be also given to voles including chopped apples, pears and carrots, as well as meadow hay.

Water can be supplied in standard laboratory drinking bottles and should be checked daily. In addition to regular replacement with fresh tap water, water bottles and spouts should be cleaned regularly to avoid growth of algae. Voles are particularly susceptible to water shortage and total deprivation of water for 48h will cause death. Daily water consumption is about 10ml/24h in both bank and field voles, so conventional water bottles should be adequate for many days. However, field vole colonies commonly water bottle siphon (Sorensen & Randrup 1986) and this behaviour is also known in other vole species (Kruckenburg *et al.* 1973). This involves the rapid emptying of water bottles, and repeated emptying of water can flood the cage and spoil litter. Voles showing this behaviour often develop the hunched posture associated with illness. This behaviour has also been termed polydipsia though evidence of over-consumption of water is sparse. Changing the drinker spout to a design less likely to allow siphoning may solve this problem, though animals that engage in this behaviour are often culled once they show overt signs of illness.

## Identification and sexing

Toe clipping as a method of identification of animals is no longer either acceptable or necessary in voles as microchips can be used where individual identification is desirable. However, unless individuals need to be identified from groups then a cage card system, supported by a computer database, would be adequate for keeping records for breeding colonies and for identifying individually caged animals. Each cage should carry, in a metal holder, a card bearing the cage number and giving details of animals' identification, birth date and parents of the animals. Breeding records should be monitored to ensure that breeding stock comprise females and males descended from mothers of high fertility. Care should be taken to ensure paper cards are kept out of reach of the cage's inmates as voles have a tendency to chew these records.

The sexes can be distinguished by the greater ano-genital distance of males (about 10 mm) compared to that of females (about 5 mm). Sexually mature males have testes bulging in the perineal region to form the typical rodent scrotum. The penis is immediately anterior to the scrotum. The vaginal opening of sexually mature females has the clitoris at its anterior border. The ano-genital distance is very much smaller in newborn and sucking young of either sex, but with practice can be used to distinguish males from females. Newborn and sucking females can also be recognised by rudimentary nipples which are slightly better developed than in males. In prepubertal animals or those whose sexual development has been retarded by exposure to natural or artificial winter photoperiods, overlap in the frequency distribution of the ano-genital distance of the two sexes can cause difficulties in sexing. However, slight pressure on the lower abdomen may cause testes to descend more fully into the perineal region: they can be seen through the skin or will cause slight bulging. Females that are not yet perforate often have a small scale of skin marking the future vaginal opening.

## Reproduction and breeding

If wild-caught voles are to be used to found a colony (and any local or national legal and ethical permits required for this have been obtained) they should be caught during the breeding season, though even in these situations females may take several months to produce their first laboratory conceived litter. Animals brought from the wild to create a colony should be disturbed as little as possible and, provided cages are not damp through leakage of a water bottle or are otherwise unsavoury, the cage should be cleaned infrequently. Quiet conditions in the animal room probably shorten the acclimatisation time.

Voles do not have long life expectancies, and long-term studies of their biology can be more efficiently conducted by establishing a breeding colony, than through recruitment from wild populations. A common breeding system is to house pairs permanently together until there is evidence that a pairing is not regularly producing litters or reliably rearing young: in these circumstances partners of different pairs can be swapped around. At the first and any subsequent pairing, the male can be introduced to the cage already

occupied by the female. Recruitment for breeding should be reviewed once a month and animals should be removed from the breeding colony once they reach 12 months old, since by about that age fertility of females has declined. Colony records, which provide some idea of the likely fertility of stock animals, are a good guide for the recruitment of new females and males for the breeding colony.

The male and female of a pair should not be closely related and, in the field vole, it is advisable to select females and males with short upper (as well as lower) incisors. From time to time, animals of either sex may develop overgrown upper incisors. This causes difficulties in feeding, and these animals can become trapped when gnawing the wire mesh of cages. If animals with overgrown incisors are inadvertently recruited to the breeding colony or a long-term experiment, the upper incisors can be quickly clipped to a proper length with sharp fine scissors, without anaesthesia. The absence of any reflex response by voles has been taken to indicate this treatment does not cause distress, although independent measures of discomfort or pain have not been taken.

A long photoperiod consistent with natural breeding season (eg, 16L:8D for field voles) is necessary for rapid sexual development and maximum efficiency of breeding colonies of voles (Clarke 1985; Spears & Clarke 1987). Under these conditions, male field voles have spermatozoa in the testes, epididymides and vasa deferentia by the age of 42–49 days. Sexually mature males have well developed patches of sebaceous tissue on their hindquarters. These are secondary sexual characters which in laboratory stock frequently became bare, pink areas 20 × 15 mm, with folding of the skin, producing abundant sebaceous secretion giving off a musty odour and making the adjacent fur greasy. Females will develop perforate vaginas and be fertile by 28 days of age under a 16L:8D light regime, though some can be fertile by as little as 18 days of age. In an established colony, females should be recruited to breeding stock from 2 months of age, and males from about 2.5 months of age (see also Chapter 13).

Voles from laboratory colonies are generally heavier than animals from natural populations. For example by the age of 24 weeks both male and female field voles are considerably heavier than comparable wild animals, where mean maximum body weight during the breeding season has been recorded as 30 g for males and 26 g for females (Chitty 1952). The males most suitable for recruitment for breeding weigh 30–40 g and have somewhat spare bodies without much subcutaneous fat. In sexually mature males the penis is well developed, about 3 mm long within its prepuce, and the testes produce paired bulges in the perineal region, so forming a typical rodent scrotum. The scrotum may develop dark pigmentation in animals which have been sexually mature for several months, but this is not a prerequisite condition for the fertile state. Suitable sexually mature females have a perforate vagina which in the oestrous state is pink, gaping and slightly rugose. A vaginal smear made up of cornified epithelial cells is a good indication that the animal is fertile. Amongst virgin female field voles with these vaginal characteristics, those weighing from 25–35 g are usually more fertile than lighter or heavier animals. Females with abundant subcutaneous and abdominal fat

(apparent from their 'feel' and conformation) tend to be less fertile than those with a more spare body.

When a sexually mature female, even one with an oestrous vaginal smear, is paired with a sexually mature male, the interaction of the animals may at first resemble that between a dominant and a subordinate male. The male may pursue the female, attempting to mount her and, at the outset, the female will often turn on the male, squeaking vigorously and lunging defensively at him. This seeming antagonism may be part of courtship behaviour. After a period ranging from a minute or two to half an hour, the squabbling interactions usually end, and copulations commence. The male usually mounts the female a number of times within a minute or two. After each mounting the female often runs ahead of the male and stops: the male follows and mounts again. Bouts of repeated leading by the female and mounting by the male are usually separated from each other by an interval of 5–15 minutes, during which the animals appear not to respond to each other (Clarke, unpublished observations).

Following copulation, a white or cream-coloured vaginal plug, formed from the male's ejaculate, can be found in the vagina, though not invariably: whether this is because it has fallen out before the female is examined, or because it has not formed, is not known. Sperm are detectable in vaginal smears for a few hours after copulation. The likelihood that a female has become pregnant or pseudopregnant can be fairly reliably gauged from the vaginal smear: the oestrous smear made up of cornified epithelial cells changes 24–48 h after mating to one consisting almost exclusively of many leucocytes, and by day 5 or day 6 after copulation there are very few cells of any sort. Pregnancy can also be reliably gauged by a gain in body weight of 2–4 g in pregnant females which occurs at about the 10th day of pregnancy, so weighing breeding females once per week (for example during cage cleaning) can avoid the need to conduct vaginal smears. Blastocysts implant 90–96 h post-coitus and pregnancy lasts 20–21 days. Pregnancy will be blocked if a female is exposed to an unfamiliar male 48–72 h after mating with a stud male. Females have a post-partum oestrus, and implantation of the resulting blastocysts is only slightly delayed by the concurrent sucking by the young.

Females in the later stages of pregnancy should be checked daily for young. By full term, pregnant female field voles may weigh between 35 and 50 g. As females are fertile post-partum and throughout lactation, and since males are normally permanently present in breeding cages, many females produce litters at 20–23-day intervals for much of their breeding lives. Disturbance during cage cleaning, or handling of litters on the day of birth and twice a week thereafter has not been found to have an adverse effect on the survival of young. However, should researchers wish to minimise disturbance then nests can be visually inspected for young with minimal disturbance using soft plastic tweezers.

Bank voles also have a breeding season lasting generally from early spring (March) until early autumn (September) so a photoperiod of 16L:8D is suitable to maintain a breeding colony. Spermatogenesis takes 31 days in males which are sexually mature. The reproductive physiology of females is, in its essentials, like that of the field vole. The general

pattern of sexual behaviour in bank voles is similar to that of field voles and has been described by Christiansen and Døving (1976) and Milligan (1979). Ovulation is induced by mating and occurs 6–14 h thereafter. There is no oestrous cycle of the sort occurring in the laboratory mouse but, as in the field vole, cycles of change in the vaginal smear lasting 4–10 days, accompanied by ovulations, can occur through the remote influence of males. Compared with field voles, a smaller proportion of bank voles are likely to be in oestrus at any one time, though oestrus can be rapidly induced by nearby males. Multiple sets of corpora lutea occur in females from the wild, in young laboratory bred animals kept permanently with one male, in females mated with a succession of males at 2-day intervals, as well as through the remote influence of males. Young perforate, virgin females are less fertile than older perforate virgin animals, and bank voles take longer, generally, than field voles to become pregnant for the first time. This has been attributed to the need to have the reproductive tract primed by ovarian hormones, or the failure of corpora lutea at first mating to become functional. Implantation of blastocysts in non-lactating females occurs 105–107 h after coitus (Clarke 1985).

Pregnancy lasts 18–19 days in primigravida bank voles and a high proportion of females will be in oestrus and fertile immediately post partum, the proportion declining a day or two later and rising after the young are weaned. Permanently paired voles produce a steady stream of litters, but because implantation of blastocysts arising from post-partum mating of lactating females is delayed, their pregnancies last from 19–22 days. Although voles can deliver litters of five to six pups, smaller litter sizes (mean of 3.5 pups) are more commonly reported (Clarke 1985).

### Parturition, rearing and weaning

Young are born in the nest during the day or night. Occasionally litters of permanently mated pairs are found dead and damaged. When pups are found dead or damaged it is often not clear if the pups have been attacked whilst alive, or if they have died from neglect or poor cage conditions and subsequently been eaten by the adults. Changing the pairing or removing the male before parturition can reduce this problem, but can also cause some loss of breeding efficiency since re-introduction or introduction of another male to the lactating female's cage can in itself cause the death of her young. An unpaired lactating female vole usually vigorously attacks any male added to her cage, and, in the following mayhem, young are often neglected, damaged or killed by the adults. Increasing the cage size, providing a more natural diet and nest materials (use of meadow hay) and reducing the frequency of cage cleaning may also be effective in reducing pup mortality. Randrup *et al.* (1988) reported that in bank vole colonies with little cover or nesting material, high pup mortality was associated with mothers repeatedly moving pups around the cage. Again, providing ample, suitable nesting material may reduce this problem.

Newborn vole pups are bright pink in colour, have sealed eyelids and limited capacity for movement, though development is rapid in the subsequent days and weeks (Spears &

Clarke 1987). At 2 days of age the head and back change from bright pink to grey. By about 4 days the young are able to crawl, and at 7 or 8 days they show uncoordinated walking. At this stage the coat is made up of smooth, very fine hair, brown above, light cream beneath, and the eyes have opened. When the young are 12–13 days old walking becomes coordinated as in an adult. It is possible to foster sucking young by choosing a female with a small litter of about the same age as the young to be fostered. Sucking young are quite hardy and if they are found in a cold, wet, moribund state, may revive if placed with their mother, or a suitable foster mother, in a clean, dry cage with adequate nesting material. Field voles are weaned by about 14 days, although they can be kept in the parental cage until 16 days, after which there is a small risk of juvenile females becoming fertile. At this age they have fine grey juvenile fur. From about 21 days the coarser adult coat develops on the head and then spreads down the body. It is grey with yellow-brown or reddish brown tips and black guard hairs on the upper side, and on the underside cream to pale grey.

Bank voles are born in essentially the same state as the young of field voles, and the pelage goes through the same stages as in field voles, though the hair colour is a richer brown. Because sucking bank voles develop a little more slowly than field voles, they are removed from the parental cage at the age of 18 rather than 16 days.

Following weaning, males and females should be housed separately to avoid unwanted pregnancies. Adult females, which have been living separately, can be put together in a cage without the risk of stressful interactions, but if sexually mature males from different cages are put together they will fight vigorously, with consequent severe wounding. Even those which have been living together since weaning can start fighting when they become sexually mature.

## Laboratory procedures

### Transport and handling

Clear national guidelines covering transport of laboratory and other animals can be found elsewhere (eg, for UK see Laboratory Animal Science Association (LASA) 2005). This section will provide some practical advice to support these guidelines. As with other species, voles should be transported in escape-proof containers that protect the animals from unfavourable environmental conditions, ensuring they arrive alive and well at their destination. In general, voles can be transported in a similar fashion to laboratory mice. Containers should be made of rigid plastic, or similar escape-proof materials such as metal. Adequate bedding (for warmth and the absorption or containment of urine and faeces), food and a source of water must be provided, and for long journeys the container should have an inspection flap. Voles from the wild can be transported for short periods (say up to 3h) in the 'Longworth' traps in which they had been caught. Traps should always be well stocked with oats, fresh carrot and meadow hay.

For transport over long distances and lasting some hours, by road in a supervised vehicle, or by air freight, a purpose-

built carrier can be used. A good practical example could consist of 12 metal boxes, each 15 cm × 9 cm × 8 cm lightly welded together to give container of overall dimensions of about 45 cm × 36 cm, with a wire mesh lid (4 mm square mesh). A more convenient, though less portable solution would be to use conventional cages for short distances only. In all cases, each compartment should be provided with a little sawdust and some non-absorbent cotton wool, oats and fresh carrot. In order to eliminate aggressive encounters, only one animal should be housed in each compartment, except if the animals were intended for a breeding colony, where one female and one male can travel together satisfactorily. It is said that voles are less stressed if the familiar bedding from their cage in the animal room is transferred to transport boxes, rather than if they are furnished with fresh material. If animals are to be sent abroad, a health certificate (from the relevant government department) for the animals will be needed, and the rules regulating importation into the destination country will need to be observed.

Voles are easily picked up by the loose skin of the neck. They should be quite decisively and firmly grasped, and, retaining the grip, can be cradled upside down in the palm of the hand for examination (Figure 26.1). A struggling animal, in these circumstances, can often be calmed momentarily by blowing on its nose. Under laboratory housing, bank voles are more 'lively' than field voles, even after many generations of laboratory breeding. This can make bank voles more challenging to handle. For experienced personnel, bites are very rare. Rodents can carry serious infectious diseases and careful precautions should be taken to avoid bites. As a variety of infectious and parasitic diseases can be

carried by field and bank voles, careful hygiene procedures should be followed.

## Physiological monitoring

### Blood samples

Some people report that (in a warm room and with practice) up to 200 µl of blood can be obtained by snipping no more than 1 mm from the tip of the tail. An analgesic or anaesthetic should be given when this method is used. Blood samples can be taken easily from the external jugular vein under alphaxalone/alphadolone anaesthesia using a 0.5 mm × 16 mm needle attached to a 1 ml plastic syringe. Clotting of blood in the syringe can be prevented by wetting the inside of the syringe with a solution of heparin (1000 U/ml, made up in 0.9% saline), shaking out fluid remaining in the nozzle. To facilitate blood collection, an incision should first be made in the neck, then fat overlying the external jugular parted, and the hypodermic needle inserted into the vein by passing it under the delicate pectoral muscle. This muscle, by its tension, serves to reduce bleeding which, with practice in delicate manipulations, becomes virtually non-existent. Nevertheless, the neck incision should be sutured, following sampling.

Terminal samples can be obtained from the heart under isoflurane anaesthesia, using an 0.8 mm × 16 mm needle, and a 1 or 2 ml syringe. It is much easier to take such samples if the manipulations are carried out while observing the site with an operating or a dissecting microscope. The needle is inserted in the midline, directly behind the sternum, at an angle of about 30° to the horizontal. It is possible routinely to get 0.75–1.25 ml of blood from field voles in this way. Taking terminal blood samples requires that an overdose of anaesthetic is given at the end of the procedure.

Valuable general information and principles about collection of blood samples is provided by Joint Working Group on Refinement (JWGR) (1993) and by the NC3Rs at their blood sampling microsite<sup>1</sup>.

### Vaginal smears

These can be easily taken using a small platinum wire loop (c.1.0 mm diameter) fixed into a glass or metal rod. After flaming the loop to remove debris, it can be used to transfer a drop of physiological saline onto a clean microscope slide, again dipped in saline and then carefully inserted into the vagina. The loop is then dabbed in the drop of saline on the slide. Cells from the vagina are thus transferred to the slide which can be immediately examined as a wet, unstained preparation with the simplest of monocular microscopes (total magnification ×60). Smears comprise: nucleated epithelial cells; or cornified epithelial cells; or leucocytes; or a mixture of two or all three cell types. Air-dried smears can be stained, for example, with 0.04% aqueous toluidine blue, and made into permanent preparations.

## Administration of medicines

### Anaesthesia

Alphaxalone mixed with alphadolone acetate (such as Saffan: Glaxovet Ltd, Uxbridge) is a good anaesthetic for simple surgery of field voles and bank voles (gonadectomy, vasectomy, manipulating the uterus, intravenous administration of drugs). A dose of 0.1 ml Saffan per 10 g body weight is appropriate, administered intraperitoneally. This dosage seems quite reliable with voles weighing between 20 and 30 g, though the relationship between body weight and anaesthetic dose seems more variable with larger animals. Isoflurane, administered through a mask as a vapour from a small anaesthetic machine, has been found to be a very safe anaesthetic for voles. Sodium pentobarbital, at a concentration of 72 mg/kg, has also been used (the dose for a 25 g field vole is about 0.03 ml). However this is a less safe method and success depends on the state of the animal: stressed animals can die quickly, and very active or excited animals may need a slightly higher dose (a further 0.01 ml). In simple surgical procedures, field and bank voles need be anaesthetised and immobile for no more than about half an hour. It is important to keep animals warm as they recover from anaesthesia, for example by nestling them within a cage in clean, non-absorbent cotton wool and beneath a warming light bulb. Flecknell (2009) provides general information and principles relevant to rodent anaesthesia.

### Dosing and injecting

Subcutaneous injections are easily given under the skin of the neck or back. It is helpful to shave the site, or part the fur by blowing, in order more easily to guide the needle subcutaneously, to see the bleb at the injection site or to detect any leakage. Light anaesthesia makes the procedure less stressful for lively voles and the experimenter. The skin of the back or neck is held between index finger and thumb, the needle of the syringe inserted low down between finger and thumb through the fold of skin, and checked by touch and visually for correct positioning. Volumes of up to 0.2 ml can be injected in this fashion.

Intraperitoneal injections can be given by first grasping the vole by the loose skin of the back with the index finger and thumb which can then be rotated so that the animal, with its belly uppermost, is supported by the palm. The needle should be inserted a couple of millimetres at an angle of about 45°, then the angle changed so that the needle is nearly parallel to the surface of the belly, and finally the needle should be pushed a little forward before discharging the fluid. Intravenous injections can be made into the external jugular vein, accessed as described above for taking a blood sample. The neck incision should be sutured following surgery. See JWGR (2001) for detailed information about administration of substances.

### Euthanasia

It is possible for trained personnel to cull sick individuals in emergencies using dislocation of the neck by instantaneous

<sup>1</sup><http://www.nc3rs.org.uk/bloodsamplingmicrosite/page.asp?id=313>

sharp pressure using the index finger and thumb, though researchers and technicians may prefer euthanasia by injection or inhalation for aesthetic reasons. If inhalation is to be used the same guidelines and advice apply to voles as to similar sized mice. High concentration of carbon dioxide within a chamber connected to a carbon dioxide cylinder causes rapid loss of consciousness followed by death in voles, though it is not known how aversive they find the short exposures to this potentially noxious gas. In other rodents, euthanasia using a rising concentration of warmed hydrated carbon dioxide has been recommended as this appears to render animals unconscious before they experience highly noxious concentrations of carbon dioxide. More recent work, however has suggested that some rodents can detect carbon dioxide and find it aversive even at these low concentrations. As voles are an uncommon laboratory species no systematic research has been conducted into their perception of euthanasia agents and if small numbers of animals are to be killed, then an overdose of an injectable anaesthetic agent as a humane means of killing should be considered. Finally, if surplus stock need to be disposed of, and if local regulations permit, then it may be worthwhile considering releasing them back into the wild. However, this introduces a number of welfare and ethical issues, in particular whether captive-reared voles will be equipped with the skills required to forage and avoid predation, and also the potential disturbance to resident voles. For these reasons the matter would need to be carefully researched and it is likely also that there would be a need for careful screening for infectious diseases which might affect released animals or those with which they may come in contact. To date, no studies have tracked survival of laboratory-reared voles, following release into the wild, or their impact on resident populations.

## Common welfare problems

### Health, disease and zoonosis
